Testes

Bradley D. Anawalt, MD and Glenn D. Braunstein, MD

ACTH	Adrenocorticotropic hormone	**IVF**	*In vitro* fertilization
cAMP	Cyclic adenosine monophosphate	**LH**	Luteinizing hormone
DHEA	Dehydroepiandrosterone	**mRNA**	Messenger ribonucleic acid
DHT	Dihydrotestosterone	**PDE5**	Type 5 phosphodiesterase
FSH	Follicle-stimulating hormone	**PRL**	Prolactin
GnRH	Gonadotropin-releasing hormone	**SHBG**	Sex hormone–binding globulin
hCG	Human chorionic gonadotropin	**TGFβ**	Transforming growth factor β
ICSI	Intracytoplasmic sperm injection		

The testes contain two major components that are structurally separate and serve different functions. The **Leydig cells**, or **interstitial cells**, produce sex steroid hormones and comprise one of the two major endocrine cells of the testes. The primary secretory product of Leydig cells, testosterone, is responsible either directly or indirectly for embryonic differentiation along male lines of the external and internal genitalia, male secondary sexual development at puberty, and maintenance of libido and potency in the adult male. The Leydig cells make 4 to 6 mg of testosterone daily. The **seminiferous tubules** comprise the bulk of the testes and are responsible for the production of approximately 30 million spermatozoa per day during male reproductive life (puberty to death). The Sertoli cells, the nurse cells of the seminiferous tubules, are the other major endocrine cells, and they produce inhibin B, anti-Müllerian hormone (AMH) and products important for regulating spermatogenesis.

The two testicular components are interrelated, and both require an intact hypothalamic-pituitary axis for initiation and maintenance of their function. In addition, accessory genital structures (including the epidydimi) are required for the functional maturation and transport of spermatozoa. Thus, disorders of the testes, hypothalamus, pituitary, or accessory structures may result in abnormalities of androgen or gamete production, infertility, or a combination of these problems.

ANATOMY AND STRUCTURE-FUNCTION RELATIONSHIPS (FIGURE 12–1)

TESTES

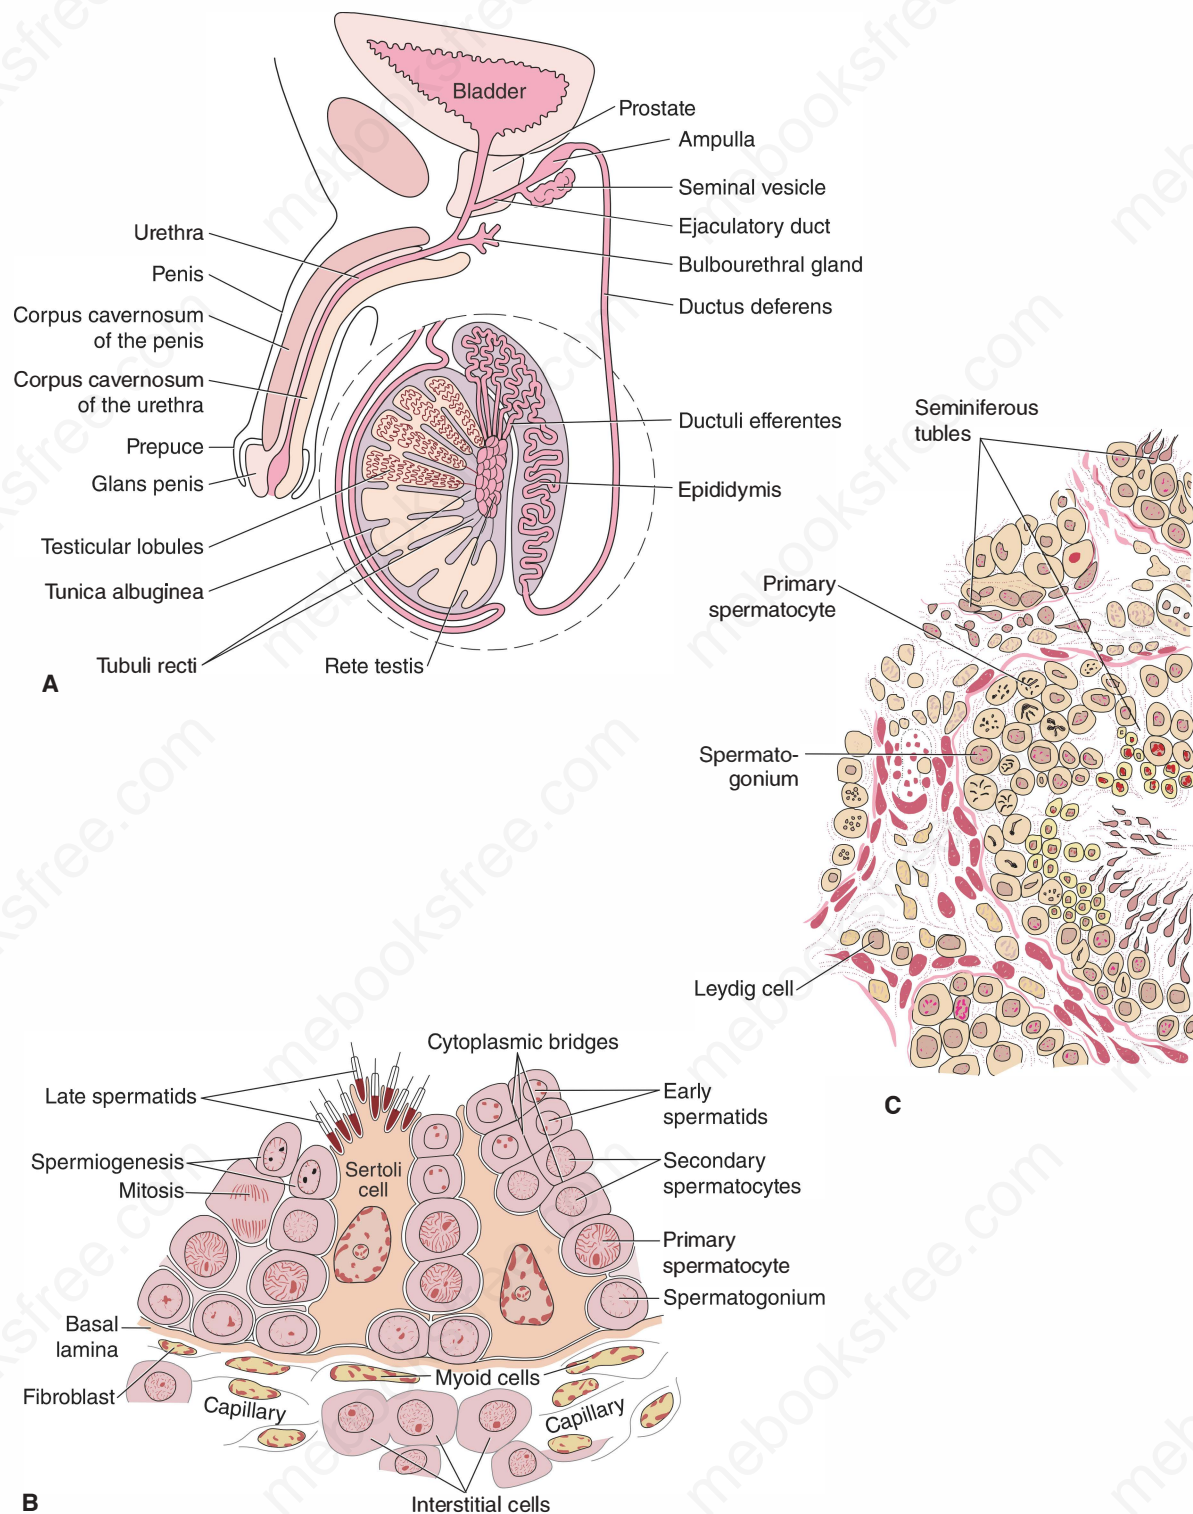
The adult testis is a prolate spheroid with a normal volume that ranges from 15 to 30 cc. The mean volume is about 20 cc. The average length measures 3.5 to 5.5 cm, and the average width is 2.0 to 3.0 cm. The testes are located within the scrotum, which not only serves as a protective envelope but also helps to maintain the testicular temperature approximately 2°C below the body core temperature. Three layers of membranes—visceral tunica vaginalis, tunica albuginea, and tunica vascular—comprise the testicular capsule. Extensions of the tunica albuginea into the testicle as fibrous septa result in the formation of approximately 250 to 300 pyramidal lobules, each of which contains coiled seminiferous tubules. Within each testis there are over 400 meters of seminiferous tubules, and these structures account for about half of the testicular mass. The approximately 200 million androgen-producing Leydig cells, as well as the blood and lymphatic vessels, nerves, and fibroblasts, are interspersed between the seminiferous tubules.


FIGURE 12–1 Male genital system. **A.** The testis and the epididymis are in different scales from the other parts of the reproductive system. Observe the communication between the testicular lobules. **B.** Structural organization of the human seminiferous tubule and interstitial tissue. This figure does not show the lymphatic vessels frequently found in the connective tissue. (**A** and **B** reproduced with permission from Junqueira LC, Carneiro J, Kelley RO. *Basic Histology*. 9th ed. New York: McGraw-Hill Education; 1999.) **C.** Section of human testis. (**C** reproduced with permission from Ganong WF. *Review of Medical Physiology*. 20th ed. New York: McGraw-Hill Education; 2001.)

The blood supply to the testes is derived chiefly from the testicular arteries that are branches of the internal spermatic arteries. After traversing a complicated capillary network, blood enters multiple testicular veins that form an anastomotic network, the lamniform plexus. The lamniform plexuses coalesce to form the internal spermatic veins. The right spermatic vein drains directly into the vena cava; the left enters the renal vein.

The seminiferous tubules in the adult average 165 μm in diameter and are composed of Sertoli cells and germinal cells. The Sertoli cells line the basement membrane and form tight junctions with other Sertoli cells. These tight junctions prevent the passage of proteins from the interstitial space into the lumens of the seminiferous tubules, thus establishing a *blood–testis barrier*. Through extension of cytoplasmic processes, the Sertoli cells surround developing germ cells and provide an environment essential for germ cell differentiation. In addition, Sertoli cells regulate the movement of differentiating germ cells from the base of the tubule toward the lumen and the release of mature sperm into the seminiferous tubular lumen. Sertoli cells also actively phagocytose damaged germ cells and residual bodies that are portions of the germ cell cytoplasm not used in the formation of spermatozoa. Sertoli cells secrete androgen-binding protein, a molecule with high affinity for androgens, into the seminiferous tubular lumen. This protein helps to provide a high concentration of testosterone to the developing germinal cells during the process of spermatogenesis; intratesticular testosterone concentrations are 60 to 100 fold higher than circulating concentrations. Finally, Sertoli cells secrete inhibin B, a protein that is an important regulator of pituitary follicle-stimulating hormone (FSH) secretion.

More than a dozen different types of germ cells have been described in males. Broadly, they can be classified as spermatogonia, primary spermatocytes, secondary spermatocytes, spermatids, and spermatozoa. Spermatogenesis occurs in an orderly fashion, with the spermatocytes being derived from the spermatogonia via mitotic division. Through meiotic (or reduction) division, the spermatids are formed; they contain a haploid number of chromosomes (23). The interval from the beginning of spermatogenesis to release of mature spermatozoa into the tubular lumen is 74 (±4) days. Although there is little variation in the duration of the spermatogenic cycle, a cross-section of a seminiferous tubule demonstrates several stages of germ cell development.

ACCESSORY STRUCTURES

The seminiferous tubules empty into a highly convoluted anastomotic network of ducts called the **rete testis**. Spermatozoa are then transported through efferent ductules into a single duct, the epididymis, by testicular fluid pressure, ciliary motion, and contraction of the efferent ductules. During the 12 to 21 days required for transit from the seminiferous tubular lumen through the epididymis, spermatozoa undergo morphologic and functional changes essential to confer on the gametes the capacity for fertilizing an ovum. The epididymis also serves as a reservoir for sperm. Spermatozoa stored in the epididymis enter the vas deferens, a

muscular duct 35 to 50 cm long that propels its contents by peristaltic motion into the ejaculatory duct.

In addition to the spermatozoa and the secretory products of the testes, retia testis, and epididymi, the ejaculatory ducts receive fluid from the seminal vesicles. These paired structures, 4.5 to 5.5 cm long, are composed of alveolar glands, connective tissue, and muscle. They are the source of seminal plasma fructose, which provides nourishment to the spermatozoa. In addition, the seminal vesicles secrete seminogelin I, phosphorylcholine, ergothioneine, flavins, prostaglandins, and antioxidants, including superoxide dismutase, catalase, and ascorbic acid. About 60% of the total volume of seminal fluid is derived from the seminal vesicles.

The ejaculatory ducts terminate in the prostatic urethra. There additional fluid (~20% of total volume) is added by the prostate, a tubuloalveolar gland with a fibromuscular stroma that weighs about 20 g and measures 4 cm × 2 cm × 3 cm. The constituents of the prostate fluid include spermine, citric acid, cholesterol, phospholipids, fibrinolysin, fibrinogenase, zinc, acid phosphatase, and prostate-specific antigen, a 34-kDa kallikrein-like serine protease. Fluid is also added to the seminal plasma by the bulbourethral (Cowper) glands and urethral (Littre) glands during its transit through the penile urethra.

PHYSIOLOGY OF THE MALE REPRODUCTIVE SYSTEM

GONADAL STEROIDS (FIGURE 12–2)

The three steroids of primary importance in male reproductive function are testosterone, dihydrotestosterone (DHT), and estradiol. From a quantitative standpoint, the most important androgen is testosterone. Testicular Leydig cells produce over 95% of circulating testosterone. In addition to testosterone, the testes secrete small amounts of the potent androgen DHT and the weak androgens dehydroepiandrosterone (DHEA) and androstenedione. The Leydig cells also secrete small quantities of estradiol, estrone, pregnenolone, progesterone, 17α-hydroxypregnenolone, and 17α-hydroxyprogesterone. The steps in testicular androgen biosynthesis are illustrated in Figure 12–2.

DHT and estradiol are also produced by target tissue conversion of testicular and adrenal-secreted androgen and estrogen precursors. Thus, about 80% of the circulating concentration of these two steroids is derived from peripheral conversion. Table 12–1 summarizes the approximate contributions of the testes, adrenals, and peripheral tissues to the circulating levels of several sex steroid hormones in men.

In the blood, androgens and estrogens exist in either a free (unbound) state or as bound to serum proteins. Although about 38% of testosterone is weakly bound to albumin, the major binding protein is *sex hormone–binding globulin* (SHBG), a high affinity, low capacity binding protein that binds 60% of the testosterone. This glycosylated dimeric protein is homologous to the androgen-binding protein secreted by the Sertoli cells. SHBG is synthesized in the liver, with the gene located on the short arm of chromosome 17.
FIGURE 12–2 Pathways for testicular androgen and estrogen biosynthesis. Heavy arrows indicate major pathways. Circled numbers represent enzymes as follows: ①, CYP11A1 (20,22-desmolase; P450scc); ②, 3β-hydroxysteroid dehydrogenase and Δ^5,Δ^4-isomerase II (3βHSDII); ③, CYP17 (17α-hydroxylase; P450c17); ④, CYP17 (17,20-lyase; P450c17); ⑤, 17α-HSD3 (17α-hydroxysteroid dehydrogenase 3; 17-ketoreductase); ⑥, 5α-reductase; ⑦, CYP19 (aromatase). StAR, steroidogenic acute regulatory protein. (See also Figures 9–4, 13–4, and 14–13.)

Certain drugs (including estrogen, tamoxifen, many anti-epileptic drugs, exogenous thyroid hormone) and diseases (including untreated hyperthyroidism) increase serum SHBG concentrations while exogenous androgen, glucocorticoid, or growth hormone therapy and untreated hypothyroidism, obesity, and hyperinsulinemic states decrease serum SHBG concentrations.

About 2% of the circulating testosterone is not bound to serum proteins. According to the free testosterone hypothesis, unbound or "free" testosterone is the bioactive hormone. According to this hypothesis, testosterone is avidly bound to SHBG and is not available to tissues. Testosterone is weakly bound to albumin, and it

may dissociate rapidly from testosterone to enter target tissues. Testosterone bound to albumin is often described as "weakly bound" testosterone and is considered to be bioavailable to target tissues. The sum of unbound, free testosterone plus weakly bound testosterone is often called "bioavailable testosterone." There is relatively little human data to support the free testosterone hypothesis, but it remains the most prevalent theory to explain the effects of circulating testosterone.

Testosterone is converted to DHT and estrogen within specific androgen target tissues. Most circulating testosterone is converted primarily by the liver into various metabolites such as

TABLE 12–1 Relative contributions (approximate percentages) of the testes, adrenals, and peripheral tissues to circulating levels of sex steroids in normal men.

Hormone	Testicular Secretion	Adrenal Secretion	Peripheral Conversion of Precursors
Testosterone	95	<1	<5
Dihydrotestosterone	<20	<1	80
Estradiol	<20	<1	80
Estrone	<2	<1	98
DHEA sulfate	<10	90	—

androsterone and etiocholanolone, which, after conjugation with glucuronic or sulfuric acid, are excreted in the urine as 17-ketosteroids. However, it should be noted that only 20% to 30% of the urinary 17-ketosteroids are derived from testosterone metabolism. The majority of the 17-ketosteroids are formed from the metabolism of adrenal steroids. Therefore, 17-ketosteroid determinations do not reliably reflect testicular steroid secretion.

Testosterone leaves the circulation and rapidly traverses the cell membrane (Figure 12–3). In most androgen target tissues, including the male urogenital tract, testosterone is enzymatically converted to the more potent androgen DHT by the microsomal isoenzyme 5α-reductase-2, which has a pH optimum of 5.5. In the skin, another isoenzyme, 5α-reductase-1 which has a pH optimum near 8.0, converts testosterone to DHT. 5α-reductase-1

FIGURE 12–3 Mechanisms of androgen action (DHT, dihydrotestosterone; mRNA, messenger RNA; Rc, inactive receptor; Rn, activated nuclear receptor; T, testosterone).

activity contributes to male pattern baldness. This enzyme is not found in the urogenital tract.

DHT and testosterone bind to the same specific intracellular receptor protein (R_c in Figure 12–3) that is distinct from both androgen-binding protein and SHBG. The genes that encode for the androgen receptor are located on the X chromosome. The androgen receptor is a member of the steroid-thyroid hormone nuclear receptor superfamily. It is synthesized in the cytoplasm, and it is associated with several heat shock proteins and immunophilin chaperones that modulate receptor structure. When testosterone or DHT binds to the androgen receptor, the androgen–androgen receptor complex dissociates from the heat shock and chaperone proteins, and conformational changes take place that allow it to form a homodimer with another androgen–androgen receptor molecule and to be translocated into the nucleus through binding to transporter proteins, importins (R_n in Figure 12–3). In the nucleus, the androgen–androgen receptor complex binds to androgen response elements in DNA and interacts with protein coactivators to initiate transcriptional activity. Thus, the classic pathway of androgen action results from changes in protein synthesis, a process that takes hours to days. In addition to this classical genomic pathway, androgens may exhibit a rapid effect (seconds to minutes) through nonclassical signaling pathways via cell surface actions that alter traditional secondary messengers such as calcium, cyclic AMP, and others.

A variety of biologic effects of androgens have been defined in humans. As discussed in Chapter 14, they are essential for appropriate differentiation of the internal and external male genital system during fetal development. During puberty, androgen-mediated growth of the scrotum, epididymis, vas deferens, seminal vesicles, prostate, and penis occurs. The normal development of these organs requires androgens. Androgens stimulate skeletal muscle growth and growth of the larynx, which results in deepening of the voice, and of the epiphyseal cartilaginous plates, which results in the pubertal growth spurt. Both ambisexual (pubic and axillary) hair growth and sexual (beard, mustache, chest, abdomen, and back) hair growth are stimulated, as is sebaceous gland activity. Other effects include stimulation of erythropoiesis and social and behavioral changes.

CONTROL OF TESTICULAR FUNCTION

Hypothalamic-Pituitary-Leydig Cell Axis (Figure 12–4)

The hypothalamus synthesizes gonadotropin-releasing hormone (GnRH), a decapeptide, and secretes it in pulses every 30 to 120 minutes into the hypothalamohypophyseal portal blood. After reaching the anterior pituitary, GnRH binds to the receptors on gonadotrophs and stimulates the pulsatile release of luteinizing hormone (LH) and, to a lesser extent, FSH into the general circulation. LH binds specific membrane receptors on Leydig cells. The LH receptor is a G protein–coupled receptor containing seven transmembrane domains with a serine- and threonine-rich cytoplasmic region containing a phosphorylation site and a 350 to 400
FIGURE 12–4 Hypothalamic-pituitary-testicular axis (ABP, androgen-binding protein; DHT, dihydrotestosterone; E$_2$, estradiol; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; T, testosterone; +, positive influence; –, negative influence).

amino acid extracellular hormone-binding domain. The binding of LH to its receptor leads to activation of adenylyl cyclase and generation of cAMP and other messengers. It also stimulates the synthesis of steroidogenic acute regulatory (StAR) protein. StAR enhances the transfer of cholesterol into the inner mitochondrial membrane of Leydig cells, leading to increased synthesis and secretion of sex steroid hormones.

The hypothalamus and the pituitary have androgen and estrogen receptors. Experimentally, pure androgens such as DHT reduce LH pulse frequency, whereas estradiol reduces LH pulse amplitude. However, the major inhibitory effect of androgen on the pituitary hypothalamus is mediated by estradiol that is derived by local aromatization of testosterone. Leydig cells also secrete small quantities of cytokines and other peptides that are important for paracrine regulation of testicular function.

Hypothalamic-Pituitary-Seminiferous Tubular Axis (See Figure 12–4)

After stimulation by GnRH, the gonadotrophs secrete FSH into the systemic circulation. This glycoprotein hormone binds to specific receptors in the Sertoli cells and stimulates the production of inhibin B and several other factors including insulin-like growth factor-I, transferrin, and Müllerian duct inhibitory factor. FSH is necessary for quantitatively and qualitatively normal spermatogenesis. Its effects on spermatogenesis include maintenance of very high intratesticular testosterone concentrations by stimulation of Sertoli cell production of androgen-binding protein.

Although two forms of inhibin have been identified, inhibin B is the physiologically form in men. This 32-kDa protein, which is composed of an alpha and a beta subunit, selectively inhibits FSH release from the pituitary without affecting LH release. FSH directly stimulates the Sertoli cells to secrete inhibin B. Serum inhibin B concentrations reflect Sertoli cell number and sperm production and, therefore, correlate with testicular size. There is a reciprocal relationship between serum inhibin B and FSH concentrations: inhibin B levels are lower and FSH concentrations are higher in conditions associated with lower levels of spermatogenesis. Inhibin B is the most important physiologic regulator of pituitary FSH secretion, and, together with circulating sex steroids, provides negative feedback on FSH secretion.

Activin and transforming growth factor β (TGFβ), inhibin B-related proteins have been identified in human testes. These factors can selectively stimulate pituitary FSH secretion *in vitro*, but their role in the physiologic regulation of FSH secretion in men is unknown. It is more likely that these proteins have a local paracrine effect in the human testis.

EVALUATION OF MALE GONADAL FUNCTION

CLINICAL EVALUATION

Clinical Presentation

The clinical presentation of patients with deficient testosterone production or action depends on the age at onset of hypogonadism. Androgen deficiency during the second to third months of fetal development results in varying degrees of ambiguity of the genitalia and male pseudohermaphroditism. If the deficiency develops during the third trimester, defects in testicular descent leading to cryptorchidism as well as micropenis may occur. These topics are also discussed in Chapter 14.

Postnatal prepubertal androgen deficiency leads to poor secondary sexual development and eunuchoidal skeletal proportions. The penis fails to enlarge, the testes remain small (≤2 cc), and the scrotum does not develop the marked rugae characteristic of puberty. The voice remains high-pitched, and the muscle mass does not develop fully, resulting in less than normal strength and endurance. The lack of appropriate stimulation of sexual hair growth results in sparse axillary and pubic hair (which receive some stimulation from adrenal androgens) and absent or very sparse facial, chest, upper abdominal, and back hair. Although the androgen-mediated pubertal growth spurt fails to take place, the epiphyseal plates of the long bones continue to grow under the
FIGURE 12–5   **A.** Hypogonadal habitus. Note absence of body and facial hair as well as feminine body distribution. **B.** Hypogonadal facies. Note absence of facial hair and fine wrinkles around the corners of the eyes and lips.

influence of insulin-like growth factor-I and other growth factors. Thus, the long bones of the upper and lower extremities grow out of proportion to the axial skeleton. Healthy white men have an average upper segment (crown to pubis) to lower segment (pubis to floor) ratio of greater than one, whereas prepubertal hypogonadism results in a ratio of less than one. Similarly, the ratio of total arm span to total height averages 0.96 in white men. Because of the relatively greater growth in the upper extremities, the arm span of eunuchoidal individuals exceeds height by 5 cm or more.

If testosterone deficiency develops after puberty, the patient may complain of decreased libido, erectile dysfunction, and low energy. Patients with mild androgen deficiency or recent onset of androgen deficiency do not typically present with decreased facial or body hair growth. Although adult androgen levels must be achieved to *stimulate* male sexual hair growth, relatively low levels of androgens are required to *maintain* sexual hair growth. After years of hypogonadism, the growth of facial hair may diminish, and the frequency of shaving may decrease (Figure 12–5). In addition, fine wrinkles may appear in the corners of the mouth and eyes.

Genital Examination

Adequate assessment of the genitalia is essential in the evaluation of male gonadal disorders. The examination should be performed in a warm room in order to relax the dartos muscle of the scrotum. If necessary, a warm towel may be applied to the scrotum for a few minutes to further relax the dartos and allow a retracted testis to

drop into the scrotal sac. The penis should be examined for the presence of hypospadias, epispadias, and chordee (abnormal angulation of the penis due to a fibrotic plaque) that might interfere with erectile function and fertility. If clinically indicated, the fully stretched dorsal penile length should be measured in the flaccid state from the pubopenile skin junction to the tip of the glans. The normal range in adults is 12 to 16 cm (10th and 90th percentiles, respectively).

Accurate measurement of testicular volumes is important. Historically, careful measurement with calipers of the longitudinal and transverse axes of the testes could be used to estimate testicular volume (V) with the formula for a prolate spheroid: $V = 0.52 \times \text{length} \times \text{width}^2$. However, this method is uncomfortable for the patient and is subject to significant variability. A Prader orchidometer is a more reproducibly accurate method. The Prader orchidometer consists of a series of plastic ellipsoids ranging in volume from 1 to 35 mL. Each testis is compared with the appropriate ellipsoid. The epididymis should not be included in the volume estimation. Adults normally have a testicular volume more than or equal to 15 mL by this method. Prader orchidometry correlates well with volume determined by ultrasound although the volumes measured by ultrasound are consistently smaller. A normal testicular volume measured by ultrasound is more than 10 mL.

Because about the majority of human testicular volume (>80%) is composed of seminiferous tubules, low testicular volumes correlate with decreased spermatogenesis due to lack of tubular development (a prepubertal disorder) or regression of tubular size (a postpubertal disorder). The consistency of the testes

should be noted. Small, firm testes are characteristic of hyalinization or fibrosis, a finding suggestive of Klinefelter syndrome. Men with postpubertal testicular atrophy may have soft testes of low-normal or normal volumes.

The epididymis and vas deferens should also be examined. Acute epididymitis is characterized by marked epididymal tenderness. A firm or enlarged epididymis suggests chronic epididymitis. The normal vas deferens feels like a small firm cord or string in the larger, spongy spermatic cord. The absence of one or both vasa deferens in an infertile man is highly suggestive of cystic fibrosis; congenital absence of the vas(a) deferens may be the only manifestation of cystic fibrosis. In an infertile man, examination for a large varicocele is important. The patient should be examined in the upright position while performing the Valsalva maneuver. About 85% of varicoceles are located on the left side, and 15% are bilateral.

LABORATORY TESTS OF TESTICULAR FUNCTION

Serum Testosterone Measurement

In normal healthy young and old men, serum testosterone concentrations peak in the early morning and decline to a nadir in late afternoon and night. The normal range for testosterone is based on measurements done on early morning samples from men with normal reproductive function. A normal serum testosterone concentration measured on an afternoon or evening serum sample virtually excludes male hypogonadism.

Because reliable total testosterone assays are generally widely available and inexpensive, the Endocrine Society guidelines and most experts advocate measurement of total testosterone as the initial serum testosterone test. A total testosterone concentration that is clearly in the normal range (>400 ng/dL) generally excludes hypogonadism when measured using a reliable total testosterone assay with a lower limit of normal of 275 to 300 ng/dL.

When the clinician suspects that the patient might have an abnormality in SHBG concentrations (eg, patients with diabetes mellitus, obesity, or hepatopathy and patients taking corticosteroids, anti-epileptics or age ≥65), many experts would recommend measurement of serum free testosterone by an accurate method. Men with Klinefelter syndrome may have relatively high serum estradiol concentrations that will raise SHBG concentrations. For men with suspected Klinefelter syndrome, it is prudent to measure a free testosterone concentration, even if the serum total testosterone concentration is well within the normal range. For many endocrinologists, the conditions that affect serum SHBG concentrations (Table 12–2) are so common that measurement of serum free testosterone might be useful in the majority of their patients. Measurement of serum free testosterone concentrations by an accurate method is also useful in men with borderline low or low-normal serum total concentrations.

The most commonly available total testosterone assays are immunoassays. These assays are convenient and inexpensive. They are generally reliable although the clinician must confirm whether

TABLE 12–2 Conditions commonly associated with altered serum SHBG concentrations.

Lower SHBG	Higher SHBG
Obesity	Hepatopathy
Corticosteroids	Anti-epileptics
Hypothyroidism	Hyperthyroidism
Androgens	Estrogens

an appropriate cohort was used to establish the normal range. The normal range should be determined using early morning blood samples from 60 to 100 healthy young men—ideally with proven fertility. Laboratories often use the normal range supplied by the manufacturer or establish a normal range on an inappropriate convenience sample such as those from blood donors. Immunoassays tend to be less accurate and reliable in samples with very low or very high serum total testosterone concentrations. The most reliable methods are specific immunoassays following extraction of serum or gas chromatography or liquid chromatography-tandem mass spectroscopy. Such assays require expensive equipment, but they are becoming more common and offer significant advantages over traditional immunoassays.

When clinically indicated or for a patient with borderline low or low-normal serum total testosterone concentration, free testosterone concentration should be determined. The gold standard method for measurement of free testosterone is equilibrium dialysis, but this method is expensive, slow, and not widely available. Serum free testosterone concentrations can be calculated based on the measurement of total testosterone, SHBG, and albumin concentrations. There are several validated formulae for the calculation of free testosterone concentrations. There is some controversy about which method is the best, but several of the formulae provide results that correlate highly with values measured by equilibrium dialysis. Platform serum free testosterone assays that use an analog methodology are inaccurate and significantly underestimate true serum free testosterone concentrations. These assays are still widely available, but they should not be used.

At least as important as the choice of the testosterone assay is to understand the principles of when to test and how to interpret the test results. Any acute systemic or flare of chronic illness may significantly suppress the gonadal axis resulting in a low serum total and free testosterone concentrations. Laboratory assessment for male hypogonadism should occur when a man is not acutely ill. In addition, there is significant variation in day-to-day serum testosterone concentrations (10%-20%). Before making the diagnosis of male hypogonadism, serum testosterone concentrations must be demonstrated to be low on at least two occasions on blood samples obtained in the early morning. In addition, measurement of serum testosterone during the fasting state reduces the variability and results in higher serum testosterone concentrations. Therefore, measurement of testosterone on an early morning blood sample obtained after 6 to 8 hours of fasting may be useful in many men with equivocal testosterone concentrations.

Serum Estradiol Measurement

Serum estradiol concentrations are at or below the lower limit of sensitivity for most commercial immunoassays. It is rarely necessary or useful to measure serum estradiol concentrations in men. However, when clinically indicated, a clinician may send a serum sample to a specialty laboratory that uses liquid chromatography-tandem mass spectroscopy to measure serum estradiol concentrations.

Gonadotropin and Prolactin Measurements

LH and, to a lesser extent, FSH are released in pulsatile fashion throughout the day. In addition, there is a diurnal variation with higher levels in the morning than in the evening. In general, serum FSH and LH concentrations should be measured simultaneously on a single serum sample obtained between 7 and 10 AM. As a strategy to address the variability of serum testosterone, FSH and LH concentrations, some experts recommend obtaining at least three blood samples at 20- to 40-minute intervals, and measuring testosterone, FSH, LH concentrations in a single pooled specimen. In practice, pooled samples are seldom necessary.

The concentrations of gonadotropins measured in one laboratory are generally not directly comparable to those measured in another because of differences in assays, reference preparations, cohorts used to establish normal ranges, and other factors. The lower limit of normal for an accurate assay should be less than 1.0 IU/L. The upper limit of normal serum FSH is 7 IU/L in men of confirmed normal reproductive and gonadal function; laboratories that report a higher normal range for FSH are likely not using men of normal reproductive capacity to establish the normal range.

The primary use of basal FSH and LH concentrations is to distinguish between primary (hypergonadotropic) hypogonadism (both gonadotropins are elevated), and secondary (hypogonadotropic) hypogonadism, in which the gonadotropins are low or inappropriately normal in the presence of decreased androgen production. In primary hypogonadism, serum FSH concentrations are always higher than LH concentrations because the decreased negative feedback from inhibin B and sex steroids has greater effects on FSH secretion than the decreased negative feedback of sex steroids on LH secretion. In secondary hypogonadism, the pituitary may secrete gonadotropins that are immunoreactive, but not bioactive, thus resulting in inappropriately normal serum gonadotropin concentrations.

Elevations of serum prolactin (PRL) inhibit the normal release of pituitary gonadotropins (shown by a reduced LH pulse frequency), probably through an effect on the hypothalamus.

Serum PRL measurements should be performed in any patient with hypogonadotropic hypogonadism. Serum PRL concentrations are generally stable throughout the day; therefore, measurement of this hormone in a single sample is usually sufficient. However, the patient should abstain from eating for 3 hours before the blood sample is obtained, because a protein meal may acutely stimulate the release of PRL from the pituitary.

TABLE 12–3 Typical normal ranges for sex steroids, gonadotropins, and prolactin in normal men.*

Hormone	Ranges
Testosterone, total	280-900 ng/dL (10.0-31.3 nmol/L)
Testosterone, free	50-210 pg/mL (173-729 pmol/L)
Dihydrotestosterone	27-75 ng/dL (0.9-2.6 nmol/L)
Androstenedione	50-250 ng/dL (1.7-8.5 nmol/L)
Estradiol	10-50 pg/mL (3.67-18.35 pmol/L)
Estrone	15-65 pg/mL (55.5-240 pmol/L)
FSH	1.0-7.0 mIU/mL (1.0-7.0 IU/L)
LH	1.0-7.0 mIU/mL (1.0-7.0 IU/L)
Prolactin	5-18 ng/mL (218-780 nmol/L)

*Normal ranges will vary modestly based on assay techniques. The normal range should be determined in a group of ≥60 healthy young men with proven normal reproductive function.

Table 12–3 shows the typical normal ranges for serum concentrations of sex steroid hormones, gonadotropins and prolactin in normal healthy men.

In men less than or equal to 50 years old with secondary hypogonadism, iron overload due to hemochromatosis should also be excluded. An iron saturation or ferritin measurement in a single serum sample is usually adequate. In men greater than 50 years old, it is very rare to present with isolated hypogonadotropic hypogonadism as the sole manifestation of hemochromatosis. In men greater than 50 years old, measurement of iron saturation or ferritin is not necessary unless there is clinical suspicion of an iron overload syndrome.

SPECIAL TESTS

Semen Analysis

Seminal fluid analysis is the most important test in the evaluation of male infertility. With some exceptions, a normal semen analysis excludes significant gonadal dysfunction. However, a single abnormal semen analysis is not a sufficient basis for a diagnosis of disturbance of testicular function, because marked variations in several of the parameters may be seen in normal individuals: at least three semen samples should be examined over a 2- to 3-month interval in order to evaluate this facet of male gonadal function. As noted earlier, approximately 3 months are required for completion of the spermatogenic cycle and movement of the mature spermatozoa through the ductal system. Therefore, when an abnormal semen sample is produced, one must question the patient about prior fever, trauma, drug exposure, and other factors that may temporarily impair spermatogenesis.

The semen should be collected by masturbation after 2 to 7 days of ejaculatory abstinence and examined within 1 hour after collection. Normal semen has a volume of more than 2 to 4 mL, with 15×10^6 or more sperms per milliliter. Over half of the spermatozoa should exhibit progressive motility, and 30% or more should have normal morphology.

Chorionic Gonadotropin Stimulation Test

Human chorionic gonadotropin (hCG) is a glycoprotein hormone with biologic actions similar to those of LH. Following an injection of hCG, this hormone binds to the LH receptors on the Leydig cells and stimulates the synthesis and secretion of testicular steroids. Administration of hCG may be useful to confirm the presence of testicular tissue in the evaluation of cryptorchidism in prepubertal boys. There are a number of published protocols, but one protocol is to administer of 1500 IU hCG twice weekly for 3 weeks. Anorchic boys have no significant increase of serum testosterone following administration of hCG whereas serum testosterone concentrations increase into the normal adult male range in boys with cryptorchidism.

Testicular Biopsy

Testicular biopsy is primarily indicated as a diagnostic study for infertile men with normal-sized testes and azoospermia in order to distinguish between spermatogenic failure and ductal obstruction. Although germinal aplasia, hypoplasia, maturation arrest, and other abnormalities of spermatogenesis may be diagnosed by examination of testicular tissue in oligospermic males, knowledge of the type of defect does not alter therapy. Therefore, testicular biopsy is not usually indicated for evaluation of mild to moderate oligospermia. For treatment of male infertility, testicular biopsies are also done to perform testicular sperm extraction for possible intracytoplasmic sperm injection (ICSI) into ova.

Evaluation for Male Hypogonadism

The prevalence of male hypogonadism is not high enough to justify screening. Even in older men, where the prevalence increases with age, the prevalence appears to be less than 5%. Case finding of hypogonadism should be based on symptoms such as decreased libido and sexual function and signs such as osteoporosis, unexplained anemia, and weakness. Testing for male hypogonadism should be performed when the man is at baseline health and not during acute systemic illness or flares of chronic illness. The initial testing would ideally be done on serum obtained between 7 AM and 10 AM. Initial testing consists of measurement of total testosterone using an accurate assay with a normal range of approximately 300 to 900 ng/dL. The authors advocate for simultaneous measurement of FSH and LH on the initial sample because the results can be helpful for interpreting the serum testosterone concentration, particularly when the testosterone concentration is in the low-normal range. Assessment of free serum testosterone concentration is useful in men with borderline low to low-normal serum concentrations. Low serum testosterone concentrations must be confirmed with at least one additional measurement from an early morning blood sample (after the patient has fasted for at least 6 hours).

Serum gonadotropin concentrations are useful to determine the etiology of male hypogonadism and to determine additional diagnostic evaluation. Elevated gonadotropin concentrations indicate primary hypogonadism due to testicular dysfunction. Serum karyotyping is useful to diagnose Klinefelter syndrome although this diagnosis may often be made clinically in males over age 16

with very small testes and biochemical evidence of primary hypogonadism. Men with symptoms and signs of hypogonadism, unequivocally low serum testosterone concentrations and inappropriately normal or low serum gonadotropins have secondary hypogonadism due to hypothalamic or pituitary disease. Common causes of secondary hypogonadism include Cushing syndrome, hyperprolactinemia, and sellar tumors or infiltrative disease. In younger men, iron overload syndromes such hereditary hemochromatosis should also be considered. For men with secondary hypogonadism, evaluation for Cushing syndrome consists of review of prescription and over-the-counter medications and supplements, querying for common symptoms of hypercortisolism (weakness, easy bruisability) and physical examination. All men with secondary hypogonadism should have a serum prolactin. Although some experts recommend sella imaging in the evaluation of secondary hypogonadism only in those men with hyperprolactinemia, the authors recommend sella imaging in all men less than or equal to age 50 (even in those with normoprolactinemia) to exclude a pituitary tumor or mass. Imaging by computed tomography is sufficient to exclude a large sellar mass that could cause gonadotropin deficiency. Magnetic resonance imaging is more commonly ordered, but it is more expensive and will commonly detect pituitary microadenomas that are not the cause of secondary hypogonadism. The yield of sella imaging is very low in men greater than age 50, and the authors recommend sella imaging for men greater than age 50 only for those who have new onset of headaches, visual complaints, signs of cranial neuropathy, serum testosterone less than or equal to 150 ng/dL, low serum FSH and LH concentrations or hyperprolactinemia. Even minor hyperprolactinemia is an indication for sellar imaging in all men with secondary hypogonadism. Figure 12–6 outlines an approach to the diagnosis of male hypogonadism.

DRUGS USED FOR TESTOSTERONE REPLACEMENT THERAPY IN MALE HYPOGONADISM

ANDROGENS

A variety of drugs are available for the treatment of androgen deficiency.

Oral Androgens

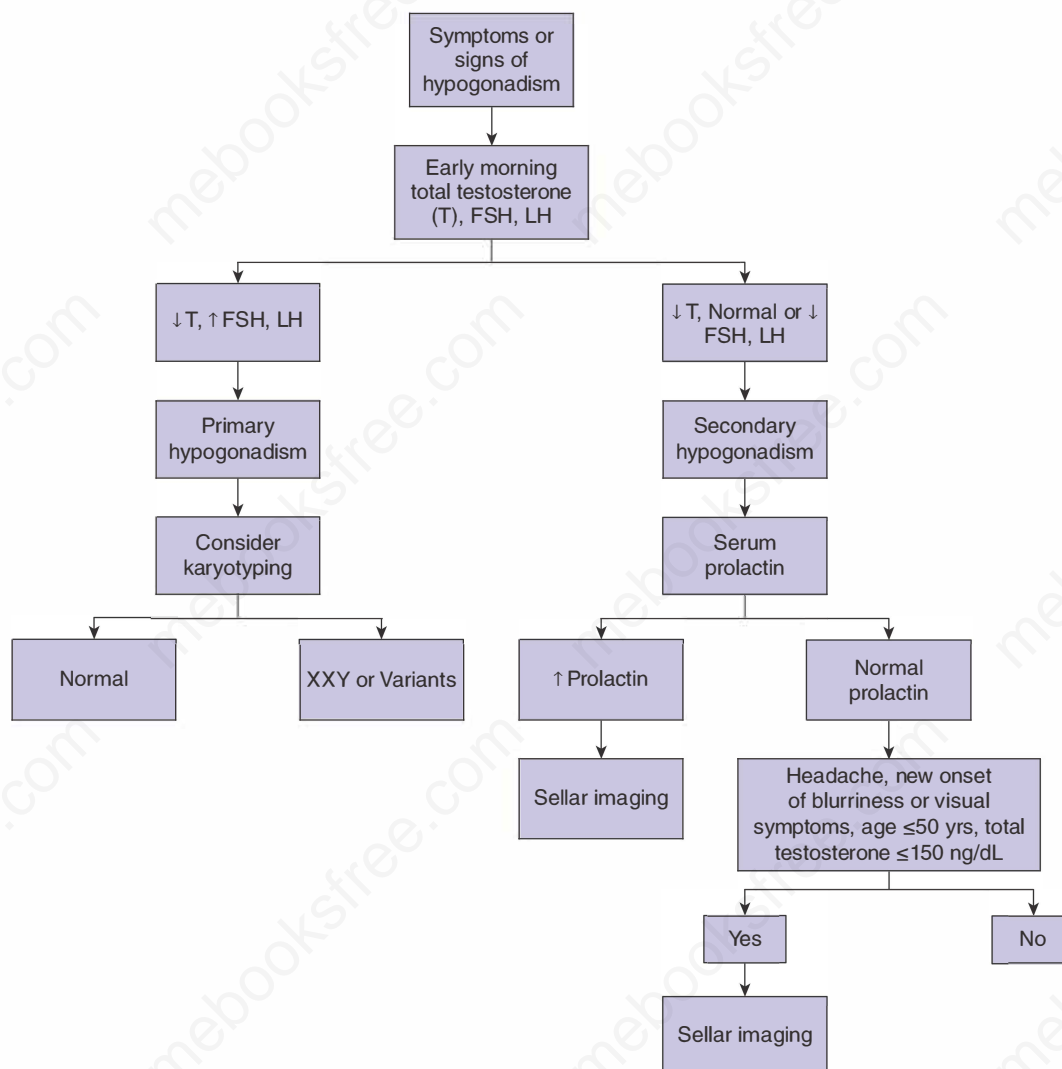
Alkylated forms of testosterone, such as methyltestosterone, oxymetholone, and fluoxymesterone can be taken orally, but are associated with hepatopathy and have erratic absorption and decreased effectiveness compared to the intramuscular preparations. Oral testosterone undecanoate has been safely prescribed in many countries for decades, but it has a very short half-life and requires administration two to three times daily. It is not available in the United States. Buccal testosterone tablets have been approved for use in the United States. These tablets are designed


FIGURE 12–6   Algorithm for evaluation of clinical hypogonadism.

to adhere to the gum or inner cheek. This formulation is rarely used because it requires twice daily usage, and some men (5%-10%) experience significant gingival irritation. Novel formulations of oral testosterone and other androgens are under development for treatment of male hypogonadism.

Injectable Testosterone Esters

There are four injectable (intramuscular) testosterone esters that are used clinically: testosterone propionate, enanthate, cypionate, and undecanoate. Testosterone propionate is a short-acting androgen. Its main use is for hypogonadal men with severe bladder outlet obstructive symptoms due to prostate hyperplasia. Obstructive symptoms due to benign prostatic hypertrophy following therapy with testosterone propionate usually resolve rapidly because of its short duration of action. However, because testosterone therapy seldom causes significant worsening of bladder outlet obstruction symptoms, testosterone propionate is very rarely used.

Testosterone enanthate or cypionate have similar pharmacokinetics. The usual dosage of these esters is 75 to 100 mg every week or 150 to 200 mg every 2 weeks. Patients (or relatives) can be taught to self-administer testosterone enanthate and cypionate, and these injectable testosterone esters remain the least expensive, commonly used formulation of testosterone replacement therapy. A long-acting intramuscular formulation of testosterone undecanoate has been approved recently by the Food and Drug Administration (FDA) for use in the United States. The formulation (Aveed) that is available in the United States is administered 750 mg every 10 weeks; some men may need injections every 8 weeks. Clinicians who prescribe Aveed must undergo special training (FDA-approved "Risk evaluation and mitigation strategy"). The FDA has required this training because of the concern of pulmonary oil embolism (from the oily vehicle), a very rare event that usually manifests as cough and transient dyspnea. All Aveed injections must be administered by a healthcare professional in a clinical setting. Outside of the United States, the formulation (Nebido) is dosed 1000 mg every 6 weeks for two dosages followed by 1000 mg every 12 weeks. Injectable testosterone undecanoate has become the most commonly prescribed form of testosterone replacement therapy in many countries outside of

the United States, but it is used much less commonly in the United States because of the inconvenience of clinic visits for administration and expense.

Implantable Testosterone Pellets

Testosterone pellets may be implanted subcutaneously every 3 to 6 months. However, this therapy has not enjoyed much popularity in the United States because it requires a minor office procedure and there is a small risk of extrusion. In addition, the development of injectable testosterone undecanoate has provided a more convenient, long-acting option.

Transdermal Testosterone Therapy

Transdermal delivery of testosterone by patch or gel is the most commonly prescribed testosterone replacement in the United States. Testosterone patches have been intermittently available recently, but a generic testosterone patch is expected to be available in the next few years. There are several different testosterone gels available that are applied daily to (depending on the formulation) the back, flanks, axillae, or thighs. The dosing varies based on the formulation, but the usual starting dosage of testosterone gels is intended to provide 5 to 6 mg of testosterone daily. It is important that the sites of gel application be covered when in close physical contact with children and be cleansed with soap and water prior to heterosexual sexual intercourse in order to avoid the transdermal transfer of the testosterone to children or female partners.

GONADOTROPIN THERAPY

Injectable Human Chorionic Gonadotropin

hCG may be injected subcutaneously or intramuscularly two to three times weekly to induce endogenous testosterone production in men with secondary hypogonadism. Injectable hCG induces aromatization of testosterone to estrogen and is associated with a higher incidence of gynecomastia than other treatments for testosterone deficiency. Because of the need for relatively frequent injections and the higher incidence of gynecomastia with injectable long-term hCG usage, hCG therapy is reserved for treatment of infertility in men with secondary hypogonadism and low levels of spermatogenesis.

Recombinant Human Luteinizing Hormone (rhLH)

Because rhLH is much more expensive than hCG, it has not been used commonly in men.

Side Effects of Testosterone Replacement Therapy

The most common side effects of testosterone replacement therapy are erythrocytosis in older men and acne in younger men. In younger men, significant erythrocytosis seldom occurs whereas

acne rarely occurs in older men. Testosterone induces erythropoiesis by stimulating erythropoietin production and by suppressing hepcidin, an important regulator of iron transport. Testosterone therapy may precipitate male pattern balding in men who are predisposed to that condition, but it reflects normal physiology and is not a true side effect. Transient, tender gynecomastia occurs in a small percentage of men, but it generally resolves within a few weeks of continued treatment. Testosterone therapy tends to suppress serum high density lipoprotein cholesterol concentrations. The effect is more pronounced in younger men with baseline high serum HDL concentrations and with administration of oral alkylated testosterone derivatives. There is no other consistent effect of androgens on serum lipid concentrations.

In older men, testosterone replacement therapy may increase serum prostate specific antigen concentrations, but the effect is usually modest (~0.5-0.6 ng/mL). The 2010 Endocrine Society guidelines recommend that men who experience an increase serum PSA of greater than 1.4 ng/mL in 12 months should be evaluated by a urologist for the possibility of prostate cancer. Androgen therapy currently is contraindicated in patients with prostatic carcinoma, but some clinicians are prescribing testosterone replacement to symptomatic, hypogonadal men with untreated low-grade, localized prostate cancer or intermediate grade, localized prostate cancer that has been successfully treated.

Occasionally, testosterone replacement therapy induces clinically significant sodium and water retention in susceptible individuals. There is significant controversy about whether testosterone replacement therapy is beneficial, neutral or harmful for cardiovascular health.

Another rare side effect of testosterone is worsening or unmasking of underlying sleep apnea. In men who develop erythrocytosis while on modest dosages of testosterone, evaluation for sleep apnea should be done. Although high dosages of synthetic androgenic, anabolic steroids may cause abnormal or aggressive behavior, there is little evidence that physiological testosterone replacement therapy induces aggressive behavior. Hypogonadal men report feeling "irritable," a symptom that improves with testosterone replacement therapy. Some hypogonadal men report feeling more "assertive" while on testosterone replacement therapy.

Monitoring of testosterone replacement therapy includes periodic assessment of hematocrit or serum hemoglobin concentrations in all men. In men treated with transdermal testosterone therapy or men on long-acting intramuscular testosterone undecanoate, it is prudent to check serum testosterone concentrations episodically to assess for adequacy of dosage. For transdermal testosterone, the optimal timing might be 8 to 12 hours after application of the transdermal product, but it is not clear that timing of the blood sample is clinically significant. For intramuscular testosterone undecanoate, a trough serum testosterone should be measured during the week before the next injection. For men using injectable testosterone cypionate or enanthate, routine measurement of serum testosterone is not necessary or useful because of the pharmacokinetics of these intramuscular testosterone esters. With typical dosages of these formulations, testosterone concentrations are supraphysiological at 24 to 72 hours after injection and then fall steadily to the lower limit of normal

by 2 to 3 weeks after the injection. In some men who request higher than usual dosages of injectable testosterone cypionate or enanthate, it is useful to measure serum testosterone concentrations at the mid-interval between injections (when concentrations should be below the upper third of the normal range).

For any formulation of testosterone therapy, the goal is maintenance of serum testosterone concentrations in the normal range, relief of symptoms and signs of hypogonadism and avoidance of adverse effects such as erythrocytosis. Attempting to adjust the dosage of testosterone to the middle of the normal range is not possible because of the variability of testosterone concentrations with any of the currently available therapies. Even with transdermal testosterone formulations that provide the most constant daily testosterone concentrations, targeting a goal testosterone concentration around the middle of the normal range is not feasible. Unfortunately, assessment of serum gonadotropins cannot be used to determine the dosage of testosterone therapy.

For all men on testosterone therapy, the dosage of testosterone should be decreased if erythrocytosis occurs. If erythrocytosis occurs at a low dosage of testosterone, evaluation of sleep apnea should be considered. For all men on testosterone therapy, increasing the dosage of testosterone may be considered if symptoms of hypogonadism have not resolved and erythrocytosis is not present.

It is controversial whether to follow serum prostate specific antigen concentrations in older men using testosterone therapy. There is conflicting evidence about the effects of exogenous testosterone on prostate cancer, and there is also evidence that screening for prostate cancer causes significant harm (from emotional stress) and cost (from procedures including transrectal ultrasound and prostate biopsies) without improving overall mortality. It is the authors' practice to discuss these controversies with older men and to offer them the option of prostate cancer screening with periodic measurements of serum prostate specific antigen.

CLINICAL MALE GONADAL DISORDERS

Hypogonadism may be subdivided into three general categories (Table 12–4). A thorough discussion of the hypothalamic-pituitary disorders that cause hypogonadism is presented in Chapters 4 and 13. The defects in androgen biosynthesis and androgen action are described in Chapter 14. The following section focuses on primary gonadal dysfunction.

SYNDROMES ASSOCIATED WITH PRIMARY GONADAL DYSFUNCTION

Primary hypogonadism is characterized by deficient production of testosterone or its metabolites (estradiol and DHT) and/or defects in spermatogenesis. It has been estimated that 10% to 15% of adult men have isolated defects in spermatogenesis with preservation of Leydig cell function and normal circulating testosterone concentrations. Although there is some controversy about the prevalence of combined hypogonadism with deficient spermatogenesis and

TABLE 12–4 Classification of causes of male hypogonadism.

Hypothalamic-Pituitary Disorders
Panhypopituitarism
Isolated LH and FSH deficiency
  Prepubertal (testes ≤2 cc)
    Congenital
      With hyposmia or anosmia, colobomas, synkinesia (Kallmann syndrome)
      With complex neurologic syndromes
        Prader-Willi syndrome
        CHARGE syndrome
        Laurence-Moon-Bardet-Biedl syndrome
        Cerebellar ataxia syndrome
    Acquired
      Tumor (craniopharyngioma, pituitary adenoma)
      Cushing syndrome
      Hyperporlactinemia
      Severe iron overload syndromes
  Postpubertal (testes >2 cc)
    Congenital with partial LH and FSH deficiency
    Acquired
      Tumor (pituitary adenoma; rarely parasellar tumor)
      Cushing syndrome
      Hyperprolactinemia
      Iron overload syndromes
      Medications (opioids)
      Sleep apnea

Primary Testiscular Abnormalities
Klinefelter syndrome (XXY)
Other chromosomal defects (XX male, XY/XXY, XX/XXY, XXXY, XXXXY)
Bilateral anorchia (vanishing testes syndrome)
Leydig cell aplasia
Cryptorchidism
Noonan syndrome
Myotonic dystrophy
Defects in androgen biosynthesis

Defects in Androgen Action
Complete androgen insensitivity (testicular feminization)
Incomplete androgen insensitivity

testosterone secretion, it is much less common. The best estimates are that 2% to 4% of middle-aged and older men and 0.5% to 1.0% of younger men have combined hypogonadism.

CAUSES OF PRIMARY HYPOGONADISM PRESENTING IN CHILDHOOD

KLINEFELTER SYNDROME (XXY SEMINIFEROUS TUBULE DYSGENESIS)

Klinefelter syndrome is the most common genetic cause of male hypogonadism, occurring in one of 600 male births. An extra X chromosome is present in about 0.2% of male conceptions and

0.1% to 0.2% of live-born males. Sex chromosome surveys have demonstrated that up to 2.5% of boys and young men with congenital cognitive impairment have an extra X chromosome. Patients with an XXY genotype often have classic Klinefelter syndrome; those with an XXXY, XXXXY, or XXYY genotype or with XXY/chromosomal mosaicism may have milder, variant forms of the syndrome.

Etiology and Pathophysiology

The XXY genotype is usually due to meiotic nondisjunction during parental gametogenesis that results in an egg with two X chromosomes or a sperm with an X and a Y chromosome. After fertilization, nondisjunction during mitotic division results in mosaicism.

Infants and young boys with Klinefelter syndrome may present with micropenis, but there are commonly no physical stigmata of Klinefelter syndrome until puberty. As serum and testicular gonadotropin concentrations increase at the usual age of puberty, the seminiferous tubules do not enlarge, but instead undergo fibrosis and hyalinization that results in small, firm testes. Obliteration of the seminiferous tubules results in azoospermia.

In addition to dysgenesis of the seminiferous tubules, the Leydig cells are functionally abnormal. Basal Leydig cell testosterone production rate is reduced, and Leydig cells fail to stimulate normally with endogenous LH or exogenous hCG.

The clinical manifestations of androgen deficiency vary considerably from patient to patient with Klinefelter syndrome and are related to the degree of diminished testosterone production and sometimes to alterations in the androgen receptor. Some untreated boys in their late teens and adult men with Klinefelter syndrome have virtually no secondary sexual developmental changes, but others are indistinguishable from healthy individuals. Based on data from the Danish national registry, we know that only 25% of men with Klinefelter syndrome are correctly diagnosed. Although many of the missed diagnoses are due to failure to recognize Klinefelter syndrome, the high percentage of missed diagnoses is due to minimally abnormal phenotype of many men with Klinefelter syndrome.

Klinefelter syndrome is characterized by a compensatory rise in serum FSH and LH concentrations. The elevated LH concentrations stimulate aromatization of testosterone and testosterone precursor, resulting in increased production of estradiol and estradiol precursors. The relatively high estradiol:testosterone ratio causes variable degrees of gynecomastia in patients with Klinefelter syndrome. The elevated serum estradiol concentrations stimulate the liver to produce more SHBG, resulting in a disproportionately greater decrease in free or unbound testosterone compared to total testosterone. Some men with Klinefelter syndrome have normal total serum testosterone concentrations, but low free serum testosterone concentrations.

In addition to symptoms and signs of male hypogonadism, boys and men with Klinefelter syndrome have an increased prevalence of cognitive impairment. The pathogenesis of the cognitive abnormality is unknown, but it is likely that testosterone deficiency is not the sole cause.

Testicular Pathology

Most of the seminiferous tubules are fibrotic and hyalinized although Sertoli cells and spermatogonia are occasionally present. The tunica propria lack elastic fibers, and the Leydig cells are arranged in clumps and appear hyperplastic although the total mass is normal.

Clinical Features

A. Symptoms and signs   There are usually no symptoms before puberty except poor school performance in some affected individuals. Intellectual impairment is noted in many patients with Klinefelter syndrome, but the true proportion with subnormal intelligence is not known. Deficits in language and higher intellectual functions, such as concept formation and problem solving, have been noted. Poor social skills also are common.

Puberty may be delayed but rarely more than 1 to 2 years. During puberty, the penis and scrotum undergo varying degrees of development, with some individuals appearing normal. Most patients with classic Klinefelter syndrome (80%) have diminished facial and torso hair growth. The major complaint is persistent gynecomastia in the majority of patients. Teenage boys and men are often embarrassed by incomplete genital development. Other symptoms include decreased libido (compared to peers) and infertility. The testes are classically small (<4 mL each in volume) and very firm. Bone mineral density may be dramatically reduced and osteoporotic fractures are more common in patients with long-standing, untreated androgen deficiency.

Patients with Klinefelter syndrome have abnormal skeletal proportions that are similar to, but not identical, to eunuchoidal proportions. Growth of the legs is relatively greater than that of the trunk and arms; therefore, pubis-to-floor height (which represents appendicular bone growth) is greater than crown-to-pubis height (which predominantly represents axial bone growth), and arm span is less than total height (Figure 12–7). Thus, the abnormal skeletal proportions are not solely the result of androgen deficiency (which results in arm span greater than height).

Several clinical and genotypic variants of Klinefelter syndrome have been described. In addition to small testes with seminiferous tubular hyalinization, azoospermia, deficient secondary sexual development, and elevated gonadotropins, patients with three or more X chromosomes uniformly have severe cognitive impairment.

Skeletal deformities such as radioulnar synostosis, flexion deformities of the elbows, and clinodactyly are more commonly seen in Klinefelter syndrome. Patients with sex chromosome mosaicism (XX/XXY) typically manifest a mild phenotype. These patients may have normal testicular size and may be fertile if their testes contain the XY genotype.

Klinefelter syndrome is associated with a shortened overall life expectancy (by a few years) and a small absolute increased risk of autoimmune disease, diabetes mellitus, chronic pulmonary disease (emphysema, chronic bronchitis), extragonadal germ cell tumors, deep venous thrombosis and other medical diseases and comorbidities. There is a significantly increased relative lifetime risk of breast cancer, but the absolute lifetime risk remains very low.

FIGURE 12–7 Klinefelter syndrome in a 20-year-old man. Note relatively increased lower/upper body segment ratio, gynecomastia, small penis, and sparse body hair with a female pubic hair pattern.

B. Laboratory findings Serum testosterone is typically low or low normal, and serum FSH and LH concentrations are elevated with FSH concentrations always more elevated than LH concentrations. Men with classic Klinefelter syndrome are azoospermic although some men with mosaic Klinefelter syndrome have variable degrees of oligozoospermia. Buccal smear analysis for examination of Barr bodies is not commonly done because this test is not sensitive enough. Serum karyotyping reveals multiple X chromosomes, but even a normal serum karyotype does not definitively exclude Klinefelter syndrome.

Differential Diagnosis

Klinefelter syndrome should be distinguished from other causes of hypogonadism. The finding of small, firm testes and elevated serum gonadotropin concentrations is virtually pathognomonic of Klinefelter syndrome. Other causes of primary hypogonadism with testosterone deficiency include mumps orchitis (particularly postpubertal mumps orchitis), severe pelvic trauma, testicular ischemia and orchidectomy. These other causes of primary hypogonadism are usually obvious by history.

Treatment

A. Medical treatment Teenage boys and men with Klinefelter syndrome with low or low-normal serum testosterone concentrations should be treated with testosterone replacement. There is some controversy about the timing of initiation of testosterone therapy in men with Klinefelter syndrome and normal serum testosterone concentrations. Teenage boys should be treated with low

dosages of testosterone to allow for some degree of virilization but to avoid stunting adult height due to sex steroid-induced premature closure of bony epiphyses. Testosterone enanthate or cypionate, 50 to 100 mg intramuscularly, monthly or low dosage testosterone gel to deliver 2 to 3 mg of testosterone daily is sufficient to virilize teenage boys. The authors prefer monitored administration of intramuscular testosterone enanthate or cypionate in teenage boys because this therapy is less expensive and ensures adherence. The dosage of testosterone replacement should be increased to adult dosages when growth has ceased or by age 18.

B. Surgical treatment If gynecomastia presents a significant cosmetic problem, reduction mammoplasty may be performed. Mammoplasty should be delayed until after androgen therapy has been optimized (in order to prevent recurrent gynecomastia after surgery). A surgeon who is experienced at the procedure should be consulted in order to optimize cosmetic results.

CRYPTORCHIDISM

Cryptorchidism is unilateral or bilateral absence of the testes from the scrotum because of failure of normal testicular descent from the genital ridge through the external inguinal ring. Between 1% and 8% of full-term and 20% to 25% of premature male infants have cryptorchidism. In most cases of cryptorchidism noted at birth, spontaneous testicular descent occurs during the first year of life, reducing the incidence to 0.2% to 0.8% at 1 year of age. Unilateral cryptorchidism is five to ten times more common than bilateral cryptorchidism.

Almost 50% of cryptorchid testes are located at the external inguinal ring or in a high scrotal position; about 20% lie within the inguinal canal between the internal and external inguinal rings; about 10% are intra-abdominal; and about 25% are ectopic (ie, located away from the normal pathway of descent from the abdominal cavity to the scrotum). Most ectopic testes are found in a superficial inguinal pouch above the external inguinal ring.

Etiology and Pathophysiology

Testicular descent usually occurs between the 12th week of fetal development and birth. Both mechanical and hormonal factors appear to be important for this process. Cryptorchidism is more common in patients with congenital defects in androgen synthesis or action and in patients with congenital gonadotropin deficiency, and experimental studies have demonstrated that DHT is required for normal testicular descent. These observations suggest that prenatal androgen deficiency contributes to the development of cryptorchidism. Environmental endocrine disruptors with estrogen or antiandrogen activity, such as phthalates or bisphenol A, have been implicated as causes of cryptorchidism.

Pathology

Histological studies on cryptorchid testes have demonstrated a decrease in the size of the seminiferous tubules and number of spermatogonia and an increase in peritubular tissue. The Leydig

cells usually appear normal. Abnormalities have been detected as early as 6 months. It is well established that the longer a testis remains ectopic, the more likely it is to show pathologic changes. More severe changes are generally found in intra-abdominal testes than inguinal testes.

It is not known whether pathologic changes in the testes are due to the effects of cryptorchidism or to intrinsic abnormalities in the gonad. Serial testicular biopsies in cryptorchid patients have demonstrated partial reversal of the histologic abnormalities following orchiopexy, suggesting that the environment is partly responsible for the observed pathologic abnormalities. Scrotal testes are significantly cooler (1.5-2°C) than intra-abdominal temperatures; one hypothesis is that higher temperatures contribute to testicular damage.

An intrinsic abnormality in the testes in patients with unilateral cryptorchidism is suggested by the observation that such patients are at increased risk for development of germ cell neoplasms in the scrotal (eutopic) testis.

Clinical Features

A. Symptoms and signs   There are usually no symptoms unless a complication such as testicular torsion, trauma, or malignant degeneration occurs.

Absence of one or both testes is the cardinal clinical finding. This may be associated with a small scrotum (bilateral cryptorchidism) or hemiscrotum (unilateral cryptorchidism). Signs of androgen deficiency are not present.

B. Laboratory findings   Serum AMH, testosterone, FSH, and LH concentrations are normal for age in prepubertal boys with bilateral or unilateral cryptorchidism. Although the diagnosis should be made in early childhood, postpubertal boys, and men with unilateral or bilateral cryptorchidism have normal serum testosterone and LH concentrations, but may have an isolated elevation of serum FSH due to damage to seminiferous tubules and decreased Sertoli cell secretion of inhibin B.

C. Imaging studies   When examined by an experienced clinician, at least 70% of cryptorchid testes are palpable in the inguinal canal. Therefore, imaging is not usually necessary. Ultrasound is not generally useful. Gadolinium-infusion magnetic resonance venography is a sensitive method for localizing the nonpalpable cryptorchid testes, but it is expensive and may require sedation for young children.

Differential Diagnosis

Cryptorchidism must be discriminated from retractile testis (pseudocryptorchidism) that is due to a hyperactive cremasteric reflex. Cold temperature, fear, and genital manipulation commonly activate the reflex, which is most prominent around the age of 5 years. The child should be examined with warm hands in a warm room. Application of a warm towel on the scrotal sac may also allow the testis to descend spontaneously. The testis can usually be milked into the scrotum with gentle pressure over the lower abdomen in the direction of the inguinal canal.

The virilizing forms of congenital adrenal hyperplasia may result in prenatal fusion of the labial-scrotal folds and clitoral hypertrophy (Chapter 14). Females with virilizing congenital adrenal hyperplasia have the appearance of phenotypic males with micropenis and bilateral cryptorchidism. Because of the potentially disastrous consequences (acute adrenal insufficiency) if this diagnosis is missed, male infants with micropenis and bilateral cryptorchidism should always be evaluated for a virilizing form of congenital adrenal hyperplasia.

Congenital bilateral anorchia (discussed later) is associated with low serum AMH concentrations and an absent or subnormal response to stimulation with hCG.

Complications and Sequelae

Cryptorchidism increases the risk of inguinal hernia (due to failure of the processus vaginalis to close) and increases the risk of torsion, but the two most important complications of untreated cryptorchidism are testicular malignancy and infertility.

A. Testicular germ cell malignancy   Cryptorchidism increases the risk of testicular cancer by 3 to 8 fold compared to the risk in boys with normally descended testes. The incidence of such tumors is greater in patients with intra-abdominal testes than in patients with inguinal testes. Seminomas are the neoplasms most commonly associated with maldescended testes. In addition, there is an increased risk for development of testicular intraepithelial neoplasia (carcinoma in situ). Surgical correction with orchiopexy before puberty appears to modestly reduce the risk of malignancy.

Because of the increased risk of neoplasia, many urologists recommend orchidectomy for a unilaterally undescended testicle in a patient first seen after puberty. Patients who present with bilateral cryptorchidism after puberty should have bilateral orchiopexy and testicular biopsies to assess for neoplasia, preserve testicular endocrine function and make palpation for detection of neoplasia easier.

B. Infertility   Over 75% of untreated bilaterally cryptorchid men are infertile. Spermatogenesis and fertility are often reduced in men with untreated unilateral cryptorchidism, but men with a history of unilateral cryptorchidism that was surgically treated early in life generally have normal fertility.

Treatment

Most testes that are undescended at birth enter the scrotum during the first year of life, and the majority descend during the first 3 months of life. It is rare for a cryptorchid testis to descend spontaneously after the age of 6 months. Because germ cell damage begins very early with rapid decreases in germ cell number after age 12 months, surgical correction of an undescended testis should be performed between ages 6 and 12 months.

A. Medical   Medical treatment with hCG or GnRH agonists was formerly recommended. However, the long-term success rates

of medical therapy are very low compared to orchiopexy. Randomized, blinded studies of hCG demonstrate success rates of ~5% to 20%. GnRH agonists might be marginally more effective, but the best studies demonstrate success rates of only ~5% to 40%. Because the long-term success rate is low and because medical therapy delays definitive surgical therapy with a risk for further germ cell loss, medical therapy is generally not recommended.

B. Surgical treatment   Several procedures have been devised to place the maldescended testis into the scrotum (orchiopexy). The operation may be performed in one or two stages. Inguinal hernia should be repaired if present. The surgery should be performed between 6 and 12 months of age.

CONGENITAL BILATERAL ANORCHIA (VANISHING TESTES SYNDROME)

Congenital bilateral anorchia is found in approximately 1 of 20,000 boys.

Etiology and Pathophysiology

Normal functional testicular tissue (producing normal amounts of fetal testosterone) must be present during the first 14 to 16 weeks of embryonic development in order for Wolffian duct growth and Müllerian duct regression to occur and for development of male external genitalia. Absence of normal fetal testosterone concentration in a male fetus during the first trimester results in varying degrees of ambiguous genitalia. Prenatal testicular injury occurring after 16 weeks of gestation as a result of trauma, vascular insufficiency, infection, or other mechanisms may result in loss of testicular tissue ("vanishing testes") in an otherwise normal phenotypic male.

Testicular Pathology

Wolffian duct structures are generally normal, and the vas deferens and testicular vessels may terminate blindly or in a mass of connective tissue in the inguinal canal or scrotum.

Clinical Features

A. Symptoms and signs   At birth, patients appear to be normal phenotypic males but with an empty scrotal sac and no palpable inguinal testes. Growth and development are normal until secondary sexual development fails to occur at puberty. The penis remains small; pubic and axillary hair does not fully develop despite the presence of adrenal androgens; and the scrotum remains empty. If a teenage patient does not receive androgens, eunuchoidal proportions develop.

There are a few case reports of boys undergoing partial spontaneous virilization at puberty. Although anatomically no testicular tissue has been identified in these boys, venous catheterization studies have demonstrated higher testosterone concentrations in venous blood obtained from the spermatic veins than in the peripheral venous circulation. This suggests that functional Leydig cells are present in these rare cases, but these boys have still lacked testicular germinal epithelium or stroma (and therefore cannot produce sperm).

B. Laboratory findings   In boys under age 12 months, teenage boys and men, serum testosterone and AMH concentrations are very low, and both LH and FSH are markedly elevated. Serum testosterone concentrations do not rise following an hCG stimulation test. Chromosomal analysis discloses a 46,XY karyotype.

Differential Diagnosis

Although congenital bilateral anorchia is very rare, it must be distinguished from bilateral cryptorchidism, a much more common disorder. The most commonly used test is measurement of serum AMH. Serum AMH is low in bilateral anorchia and normal in cryptorchidism. The hCG stimulation test is sometimes useful and will demonstrate a normal response in cryptorchidism, but will demonstrate no rise in serum testosterone concentration in congenital bilateral anorchia.

Treatment

A. Medical treatment   Medical treatment is similar to that outlined for patients with Klinefelter syndrome.

B. Surgical treatment   Implantation of testicular prostheses for cosmetic purposes may be beneficial after the scrotum has enlarged in response to androgen therapy.

LEYDIG CELL APLASIA

Defective development of testicular Leydig cells is a very rare cause of male pseudohermaphroditism with ambiguous genitalia.

Etiology and Pathophysiology

Testes are present in the inguinal canals and contain prepubertal-appearing tubules with Sertoli cells and spermatogonia without germinal cell maturation, and there are no or few Leydig cells. The syndrome is caused by inactivating mutations in the LH receptor that alters receptor signal transduction. The presence of vasa deferens and epididymi and absence of Müllerian structures (eg, uterus) in these patients indicates that the local concentration of testosterone and AMH was high enough during embryogenesis to result in differentiation of the Wolffian duct structures and prevent development of Müllerian structures. However, the ambiguity of the genitalia indicates that the androgen concentration in these patients was insufficient to bring about full virilization of the external genitalia.

Clinical Features

A. Symptoms and signs   These patients may present in infancy with variable degrees of genital ambiguity, including a

bifid scrotum, clitoral phallus, urogenital sinus, and blind vaginal pouch. Alternatively, they may appear as normal phenotypic females and escape detection until adolescence, when they present with primary amenorrhea, with or without normal breast development. The gonads are generally located in the inguinal canal. Axillary and pubic hair, although present, may be sparse. Milder defects in the LH receptor may result in Leydig cell hypoplasia with micropenis, hypospadias, and reduced fertility.

B. Laboratory findings   Serum testosterone levels are low (in the female range) and serum gonadotropins are elevated. There is no increase in testosterone following hCG administration.

Differential Diagnosis

Patients with mild forms of Leydig cell aplasia must be distinguished from cryptorchidism and vanishing testes syndrome. Low serum AMH concentrations and lack of response to hCG stimulation test distinguishes Leydig cell aplasia from cryptorchidism. Finding testicular tissue by palpation, imaging or surgical exploration discriminates Leydig cell aplasia from vanishing testes syndrome. More severe forms of Leydig cell aplasia that present with ambiguous genitalia must be discriminated from testosterone biosynthetic defects, disorders of androgen action, and 5α-reductase deficiency; these disorders are discussed in Chapter 14.

Treatment

Patients with mild Leydig cell aplasia who have been raised as boys may respond well to testosterone replacement therapy as outlined for Klinefelter syndrome although genital development and spermatogenesis do not normalize. The management of patients with more severe Leydig cell aplasia and ambiguous genitalia is more controversial; see Chapter 14.

NOONAN SYNDROME (MALE TURNER SYNDROME)

Phenotypic and genotypic males with many of the physical stigmas of classic Turner syndrome have been described under a variety of names, including Noonan syndrome and male Turner syndrome. Noonan syndrome has an incidence of 1:1000 to 1:2500 live births and may occur sporadically or in families. It is inherited in an autosomal dominant fashion with variable penetrance. It is a RASopathy, a syndrome due to a germline mutation affecting the RAS/mitogen-activated protein kinase (MAPK) pathway. Noonan syndrome is associated with a number of structural and functional abnormalities of the male reproductive tract: cryptorchidism, delayed puberty, and decreased spermatogenesis as adults.

Clinical Features

A. Symptoms and signs   The most common clinical features are short stature, webbed neck, hypertelorism, and lentigines. Congenital cardiac anomalies are common and involve primarily the right side of the heart—in contrast to patients with XO gonadal dysgenesis (Turner syndrome).

Cryptorchidism is frequently present. Testicular size is generally small during puberty but gradually grows to normal volumes by adulthood.

B. Laboratory findings   Serum testosterone, LH, and FSH concentrations are usually normal before and during puberty. Serum testosterone concentrations are usually normal, but serum LH and FSH may be slightly elevated in adult men with Noonan syndrome. The karyotype is 46,XY.

Differential Diagnosis

The clinical features of Noonan syndrome are usually sufficiently distinctive to preclude other diagnoses.

Treatment

Treatment of cryptorchidism and hypogonadism is as outlined in the sections under cryptorchidism and Klinefelter syndrome.

CAUSES OF PRIMARY HYPOGONADISM PRESENTING IN ADULTHOOD

MYOTONIC DYSTROPHY

Myotonic dystrophies types 1 and 2 are autosomal dominant disorders of muscle with multisystem clinical features including primary hypogonadism.

Testicular histology varies from moderate derangement of spermatogenesis with germinal cell arrest to regional hyalinization and fibrosis of the seminiferous tubules. The Leydig cells are usually preserved and may appear in clumps.

The testes are normal in affected prepubertal individuals, and puberty generally proceeds normally. After puberty, seminiferous tubular atrophy results in a decrease in testicular size and change of consistency from firm to soft or mushy. Infertility is a consequence of disrupted spermatogenesis. If testicular hyalinization and fibrosis are extensive, Leydig cell function may also be impaired.

Clinical Features

A. Symptoms and signs   The disease usually becomes apparent in adulthood. Progressive weakness and atrophy of the facial, neck, hand, and lower extremity muscles is commonly observed. Severe atrophy of the temporalis muscles, ptosis due to weakness of the levator muscles of the eye with compensatory wrinkling of the forehead muscles, and frontal baldness comprise the characteristic myopathic facies. Myotonia is present in several muscle groups and is characterized by inability to relax the muscle normally after a strong contraction.

Testicular atrophy is not noted until adulthood, and most patients develop and maintain normal facial and body hair growth and libido. Gynecomastia is usually not present.

Associated features include mental retardation (type 1 disease only), cataracts, diabetes mellitus, cardiac arrhythmias, and primary hypothyroidism.

B. Laboratory findings Serum testosterone is normal to slightly decreased. FSH is elevated in the majority of patients. LH is also frequently elevated, even in patients with normal serum testosterone levels. Leydig cell reserve is generally diminished, with subnormal increases in serum testosterone following stimulation with hCG.

Treatment

There is no therapy that will prevent progressive muscular atrophy in this disorder. Testosterone replacement therapy is not indicated unless serum testosterone levels are subnormal.

LATE-ONSET MALE HYPOGONADISM

In contrast to the menopause in women, men do not experience a sharp decline in gonadal function. However, a gradual diminution of testosterone production occurs in many men as part of the aging process. It is not known how many men develop symptoms directly attributable to this phenomenon. The decline in serum testosterone concentrations in older men without a specific identifiable cause other than aging has been described as late-onset hypogonadism. Andropause and male climacteric are inaccurate and misleading descriptors because these terms imply that testicular function declines rapidly in aging men. Even the term "late-onset hypogonadism" is problematic because the term implies that such men are hypogonadal. Low serum testosterone concentration is likely a marker of poor health and not an indicator of testosterone deficiency in many older men.

Etiology, Pathology, and Pathophysiology

During middle age, serum total and free testosterone concentrations begin to decline. The levels of free testosterone decrease to a greater extent because of an increase in SHBG. Leydig cell testosterone production rates decline as Leydig cell responsiveness to LH decreases. Aging also is associated with perturbations in hypothalamo-pituitary function that result in lower LH secretion than normal for a given serum testosterone concentration. As a result of the dual defect in testicular and hypothalamo-pituitary function, aging men tend to have lower serum testosterone concentrations and higher LH concentrations than younger men, but serum testosterone and LH concentrations tend to remain in the low-normal and high-normal range, respectively. Older men often lose the normal circadian rhythm of testosterone secretion; in older men, early serum morning testosterone concentrations might not be significantly higher than late afternoon or early evening serum testosterone concentrations. On the other hand, healthy older men may maintain a normal circadian rhythm and

normal serum testosterone concentrations. Thus, some experts contend that declining hypothalamo-pituitary-testicular function is a marker of declining overall health and not an inevitable physiological effect of aging.

Histologic studies of the aging testes have shown patchy degenerative changes in the seminiferous tubules with a reduction in number and volume of Leydig cells. The pathologic changes are first noted in the regions most remote from the arterial blood supply. In some men, microvascular insufficiency may be the etiologic basis for the histologic tubular changes and the decrease in Leydig cell function noted with aging. In addition, virtually all of the conditions (eg, infection, tumor, infiltrative disease, and vasculopathy) that cause adult seminiferous tubule failure may lead to Leydig cell dysfunction if testicular injury is severe enough.

Clinical Features

A. Symptoms and signs Many symptoms have been attributed to late-onset hypogonadism, including decreased libido, erectile dysfunction, depressed mood, fatigue, decreased strength, and decreased cognitive function and mental concentration. The most specific symptoms of late-onset hypogonadism are sexual dysfunction: decline in libido, sexual fantasies, and early morning erections.

B. Laboratory findings In older men, serum testosterone concentration is often slightly low or low-normal. Serum LH concentration is usually high-normal or slightly above the normal limit, but a number of older men have a borderline low total and free testosterone concentration and a LH concentration that is well within the normal range. Sperm concentrations are often lower in older men. Bone mineral density may be low, but it is unclear whether this finding is causally related to declining serum testosterone production.

Differential Diagnosis

In older men with low serum testosterone concentrations who present with nonspecific symptoms such as decreased energy, depressed mood, sexual dysfunction or weakness, causes other than male hypogonadism must be considered. Depression and systemic illness are often the cause of these symptoms. In men with low serum testosterone concentrations and osteoporosis, other causes of osteoporosis must be excluded before attributing hypogonadism as the cause.

Treatment

There is great controversy about whether and how to treat older men with late onset hypogonadism. There are very little data from randomized, placebo-controlled studies to determine the benefit and risk of testosterone in such men. The best data to date come from early findings from the Testosterone Trial, a large study of men, aged greater than or equal to 65 years, with slightly low serum testosterone concentrations (average of two early morning serum total testosterone concentrations ≤275 ng/dL) and

symptoms of male hypogonadism who were randomized to 12 months of testosterone gel, at a dosage sufficient to raise testosterone concentrations into the normal range, or placebo gel. This study demonstrated a small, but significant benefit in sexual function and physical function in men randomized to testosterone gel. Although there is controversy about the clinical significance of these improvements, testosterone therapy improved multiple aspects of sexual function (including sexual desire, erections, and orgasm frequency). Men who were randomized to testosterone gel reported having an average of about four orgasms per month compared to an average of about three orgasms per month in men in the placebo gel group. In the physical function assessment, almost twice as many men in the testosterone gel group (20.5% vs 12.6%) increased their 6-minute walk test by a clinically important amount (≥50 meters over baseline in 6 minutes; average baseline walk test = approximately 390 meters). Men treated with testosterone also reported improved mood and energy compared to men treated with placebo.

The major safety concerns for testosterone therapy are potential adverse effects on cardiovascular events and prostate cancer. In the 12-month Testosterone Trial, there was no significant difference in adverse cardiovascular events or prostate cancer. There were seven deaths in the placebo group and three in the testosterone group. Men randomized to testosterone gel were more likely to develop erythrocytosis (seven in the testosterone group vs zero in the placebo group) in this study.

At this time, there is insufficient evidence to make a general recommendation about the management of putative late-onset hypogonadism. The authors recommend the following: before considering testosterone therapy for older men with low serum testosterone concentrations and symptoms of hypogonadism, the clinician must (1) confirm that serum testosterone concentrations are consistently low (in two or more early morning blood samples using a reliable testosterone assay); (2) optimize treatment of depression and systemic disease and reduce or eliminate medications that might cause symptoms such as fatigue, sexual dysfunction or altered mood (eg, corticosteroids, opioids, and medications that affect the central nervous system); and (3) assess for common causes of secondary hypogonadism (including Cushing syndrome and hyperprolactinemia; see section on Evaluation of Male Hypogonadism). If the man continues to have symptoms that suggest hypogonadism, serum testosterone concentrations continue to be below the normal range, and no specific cause of secondary hypogonadism has been identified, then the clinician should discuss the potential benefits (improved sense of well-being, improved sexual function, and improved strength) and risks (erythrocytosis and the possibility, albeit unproven and controversial, of increased risk of cardiovascular events and prostate cancer). Before initiating a trial of testosterone therapy for "late onset of hypogonadism," the clinician should document this discussion in the medical record. Some experts recommend that older men sign an "informed consent form" documenting a discussion of the potential benefits and risks of testosterone therapy. If the patient has no improvement of symptoms or objective evidence of improvement (eg, improved bone mineral density), then the clinician should consider discontinuation of testosterone therapy. A 6-month trial of testosterone is sufficient for improvement of symptoms, but a longer trial (up to 2 years) might be necessary to assess improvement in bone mineral density.

SPECIFIC SEQUELAE OF HYPOGONADISM

MALE INFERTILITY

About 15% of married couples have difficulty in conceiving. In about 30% of such couples, only the man has reproductive dysfunction, and an additional 20%, both partners have a reproductive abnormality. In the United States, infertility is classically defined as the inability to conceive after 1 year of frequent vaginal intercourse without the use of contraception. About 50% of young, healthy couples that fail to conceive after 1 year of unprotected intercourse will conceive in the subsequent year. Subfertility is a term used to describe reduced fertility that might require assisted reproductive technology (ART) such as surgical extraction of sperm and ova followed by ICSI into an ovum. Subfertility also describes couples who take longer than 12 months to conceive, but would conceive eventually without treatment. ART is an expensive method to hasten conception in such couples.

Etiology and Pathophysiology

In order for conception to occur, spermatogenesis must be normal, the sperm must complete its maturation and transportation through patent ducts, adequate amounts of seminal plasma must be added to provide volume and nutritional elements, and the male must be able to deposit the semen near the female's cervix. Any defect in this pathway can result in subfertility due to a male factor problem. Spermatozoa must also be able to penetrate the cervical mucus and reach the uterine tubes, where conception takes place.

Table 12–5 lists the identified causes of male infertility. Most male infertility and subfertility are due to primary testicular dysfunction. The most common cause of male subfertility (35%-45%) is due to idiopathic primary testicular dysfunction with abnormal spermatogenesis (idiopathic spermatogenic failure). Idiopathic spermatogenic failure is associated with sperm concentrations less than 10 million/mL (normal >15 million/mL) and is usually associated with abnormal sperm morphology and motility. Men with idiopathic spermatogenic failure have normal serum testosterone and LH concentrations, but many have an isolated elevation in serum FSH.

About 10% to 15% of men with infertility and absent (azoospermia) or very low sperm concentrations (<1 million/mL) have Klinefelter syndrome with low or low-normal serum testosterone and elevated serum gonadotropin concentrations. Other identifiable causes of male infertility and subfertility due to primary testicular dysfunction include genetic mutations (eg, Y chromosome microdeletions), drugs (particularly systemic chemotherapy for neoplastic disease), testicular cancer, cryptorchidism, infection

　Antibodies to sperm or seminal plasma
　Varicocele

(eg, postpubertal mumps orchitis), and pelvic irradiation or surgery. Abuse of tobacco, marijuana, or alcohol is also associated with gonadotoxicity, defective spermatogenesis and subfertility. There is significant controversy about whether varicoceles affect male fertility. Varicoceles are commonly found in subfertile men (25%-40%), but they are also commonly found in men with normal fertility (8%-20%). Large varicoceles might impair spermatogenesis by a variety of mechanisms including compromised testicular cooling and increased intratesticular reactive oxygen species. Autoimmune disturbances that lead to sperm agglutination and immobilization are very rare.

Causes other than primary testicular defects in spermatogenesis include sexual disorders, endocrinopathies that affect the hypothalamo-pituitary axis, and defects in sperm transportation.

Sexual disorders include erectile dysfunction and failure to have frequent vaginal intercourse. These are uncommon causes of infertility and are relatively easy to remedy. To optimize the likelihood of conception, the frequency of vaginal intercourse should be at least two to three times weekly. A very small percentage (<5%) of male subfertility is due to disturbances in hypothalamic, pituitary, adrenal, or thyroid function. Defects in sperm transportation include obstruction of the ejaculatory tract, retrograde ejaculation, or anejaculation. An important cause of ejaculatory tract obstruction is congenital bilateral absence of the vasa deferentia. The majority of men with congenital bilateral absence of the vasa deferentia have mutations of the cystic fibrosis gene. Nearly all men with clinical cystic fibrosis have congenital bilateral absence of the vasa deferentia, but congenital bilateral absence of the vasa deferentia may be the only clinical manifestation of a cystic fibrosis gene mutation.

Clinical Features

A. Symptoms and signs   Men with idiopathic spermatogenic failure (and preserved Leydig cell function) will have no symptoms other than infertility, but men with combined spermatogenic failure and Leydig cell dysfunction may have symptoms of hypogonadism. Most men with infertility due to endocrinopathy will have symptoms related to the endocrinopathy; the clinician should query about symptoms of thyroid dysfunction, corticosteroid excess, or symptoms of a large sellar mass (headaches and visual changes).

B. Laboratory findings   The single most useful test is seminal fluid analysis. Because of significant variation in sperm concentrations, collection an analysis of at least two seminal fluid samples is essential. The sample should be collected after 2 to 7 days of ejaculatory abstinence and analyzed by a laboratory that follows the World Health Organization standards. A normal report indicates normal endocrine function and spermatogenesis and an intact transport system.

Measurement of an early morning serum testosterone, FSH and LH concentrations should be performed, and abnormal results confirmed with repeat testing. Patients with severe oligozoospermia or azoospermia and elevated serum LH and FSH concentrations may have Klinefelter syndrome and should be offered testing for a karyotypic abnormality. In addition, some experts advise testing for Y chromosome deletions in all men with oligozoospermia or azoospermia before treatment with assisted reproductive technology. If vasa deferentia are not palpable or visible on ultrasound, then testing for cystic fibrosis transmembrane conductance regulator gene mutations should be performed.

The female partner should be thoroughly examined to verify patency of the uterus and oviducts, normal ovulation, and normal cervical mucus. This examination must be performed even in the presence of a male factor abnormality, because infertility is due to a combination of male and female factors in about 20% of cases.

C. Imaging studies   In men with low seminal fluid volumes, azoospermia and normal serum testosterone, LH and FSH concentrations, a transrectal ultrasound should be performed to look for ejaculatory duct obstruction. Testicular ultrasound should be performed in men with scrotal masses if the physical examination of the scrotum is difficult or incomplete or if a large varicocele is suspected.

Treatment

A. Endocrine disorders   Correction of hyperthyroidism, hypothyroidism, adrenal insufficiency, and congenital adrenal hyperplasia generally restores fertility. Gonadotropin therapy is often effective in stimulating spermatogenesis in patients with hypogonadotropic hypogonadism. Gonadotropin therapy is initiated with LH replacement therapy in the form of hCG (1000-2000 units subcutaneously two to three times weekly) for 6 months. FSH replacement (75-150 IU units subcutaneously three times per week) is added after 6 months if sperm cells do not

appear in the ejaculate. Gonadotropin therapy often does not normalize sperm concentrations, but may still allow impregnation. Men with postpubertal onset of gonadotropin deficiency may respond to hCG monotherapy.

B. Defects of spermatogenesis   Drugs that interfere with spermatogenesis should be discontinued. These include marijuana, alcohol, monoamine oxidase inhibitors, sulfasalazine, and nitrofurantoin. Many men with oligozoospermia and even azoospermia may conceive with use of ART including *in vitro* fertilization, surgical sperm extraction, and ICSI.

C. Ductal obstruction   Localized obstruction of the vas deferens may be treated by vasovasostomy. Sperm are detected in the ejaculate of 60% to 80% of patients following this procedure. However, the subsequent fertility rate is only 40% to 50%; the presence of anti-sperm antibodies that agglutinate or immobilize sperms probably accounts for the high failure rate.

Epididymovasostomy may be performed for epididymal obstruction. Sperm in the postoperative ejaculate have been found in approximately half of patients treated with this procedure, but subsequent fertility has been demonstrated in only 20% of cases. ART is often used in cases of ductal obstruction.

D. Varicocele   Although there are few data to support treatment of varicoceles to improve fertility, surgical ligation, or radiographic embolization of the incompetent spermatic veins is sometimes performed in men with infertility and large varicoceles.

E. Retrograde ejaculation   Retrograde ejaculation of semen into the urinary bladder may occur following disruption of the internal bladder sphincter or with neuropathic disorders such as diabetic autonomic neuropathy. Phenypropanolamine may improve antegrade ejaculation in patients with retrograde ejaculation. Sperm can also be recovered from urine following masturbation and used for direct intrauterine insemination or other ART procedures.

Course and Prognosis

For male subfertility due to hypogonadotropic hypogonadism and other endocrinopathies, the prognosis for fertility is good. For all other causes of male factor infertility, ART, though expensive, makes it possible for many couples to conceive. For many couples, adoption might be the best option, but adoption may also be expensive and time consuming.

ERECTILE DYSFUNCTION

Erectile dysfunction is the inability to achieve or maintain an erection of sufficient duration and firmness to complete satisfactory sexual activity in more than 25% of attempts. It may occur with or without associated disturbances of libido or ejaculation. Approximately 5% of men have complete erectile dysfunction by age 40 and 15% by age 70. Some degree of erectile dysfunction is present in about 50% of men between ages 40 and 70.

Etiology and Pathophysiology

Penile erection occurs when blood flow to the penile erectile tissue (corpora cavernosa and spongiosum) increases as a result of dilation of the urethral artery, the artery of the bulb of the penis, the deep artery of the penis, and the dorsal artery of the penis following psychogenic or sensory stimuli transmitted to the limbic system and then to the thoracolumbar and sacral autonomic nervous system. The relaxation of the cavernosal arterial and cavernosal trabecular sinusoidal smooth muscle occurs following stimulation of the sacral parasympathetic (S2-4) nerves, which results in the release of acetylcholine, vasoactive intestinal peptide, and an endothelial cell-derived nitric oxide, which activates guanylyl cyclase. Activation of guanyl cyclase and production of intravascular cycle guanosine monophate results in penile arterial vasodilation and significant increases in blood flow to the penis. As penile blood flow increases, the penile sinusoids become engorged and cause compression of the subtunical venous plexus against the tunica albuginea. The compression of the subtunical venous plexus prevents egress of blood from the penis, resulting in very high penile blood pressures and tumescence. Contraction of the bulbocavernosus muscle through stimulation of the somatic portion of the S2 to S4 pudendal nerves further increases the intracavernosal pressure and tumescence. These processes result in the distention, engorgement, and rigidity of the penis that constitute erection.

Broadly speaking, erectile dysfunction may be divided into psychogenic and organic causes. Major epidemiologic factors that have been associated with erectile dysfunction include diabetes mellitus, metabolic syndrome, hypertension, smoking, aging, and cardiovascular disease. Table 12–6 lists various pathologic conditions and drugs that may be associated with erectile dysfunction.

Most organic causes of erectile dysfunction result from disturbances in the neurologic pathways essential for the initiation and maintenance of erection or in the blood supply to the penis. Many of the endocrine disorders, systemic illnesses, and drugs associated with erectile dysfunction affect libido, the autonomic pathways essential for erection, or the blood flow to the penis. Venous incompetence because of anatomic defects in the corpora cavernosa or subtunical venous plexus is an uncommon cause of erectile dysfunction. Local urogenital disorders such as Peyronie disease (idiopathic fibrosis of the covering sheath of the corpus cavernosum) may mechanically interfere with erection. In some patients, the cause of erectile dysfunction is multifactorial. For example, some degree of erectile dysfunction is reported by over 50% of men with diabetes mellitus who have arteriovascular disease, autonomic neuropathy and other contributors to erectile dysfunction such as depression or medications associated with erectile dysfunction. Male hypogonadism may contribute to worsening erectile function, but it is rarely the sole or primary cause of erectile dysfunction.

Clinical Features

A. Symptoms and signs   Patients may complain of constant or episodic inability to initiate or maintain an erection, and/or decreased penile turgidity. The diagnosis is generally made based on the patient's history. The degree of erectile dysfunction can be

assessed by questionnaires such as the International Index of Erectile Function or the Sexual Health Inventory for men, but these questionnaires are generally used only in clinical trials. If an underlying neurologic, vascular, or systemic disorder is the cause of erectile dysfunction, additional symptoms and signs referable to the anatomic or metabolic disturbances may be present. A history of claudication of the buttocks or lower extremities indicates atherosclerosis as a likely cause. A thorough history of medication, herb, illicit drug, and alcohol use should be obtained.

The differentiation between psychogenic and organic erectile dysfunction can usually be made on the basis of the history. Even

though the patient may be selectively unable to obtain or maintain a satisfactory erection to complete sexual intercourse, a history of repeated normal erections at other times is indicative of psychogenic erectile dysfunction. Thus, a history of erections that occur nocturnally, during masturbation, or during foreplay or with other sexual partners eliminates significant neurologic, vascular, or endocrine causes of erectile dysfunction. Patients with psychogenic erectile dysfunction often note a sudden onset of sexual dysfunction concurrently with a significant event in their lives such as loss of a friend or relative, an extramarital affair, or the loss of a job.

Patients with organic erectile dysfunction generally note a more gradual and global loss of erectile function. Initially, such individuals may be able to achieve erections with strong sexual stimuli, but ultimately they may be unable to achieve a fully turgid erection under any circumstances. Patients with organic erectile dysfunction may have a concurrent diminution of libido and erectile function; diminished libido may be an indicator of male hypogonadism.

During the physical examination, the patient's secondary sexual characteristics should be assessed and examination performed for gynecomastia, discordant or diminished radial, femoral, or pedal pulses, reduced testicular volume or consistency, penile plaques, and evidence of peripheral or autonomic neuropathy. The bulbocavernosus reflex tests the integrity of the S2 to S4 nerves. It is performed by inserting a finger into the patient's rectum while squeezing his glans penis. Contraction of the anal musculature represents a normal response. Elicitation of the anal wink reflex also tests S2 to S4 nerve function. Visible contraction of anal musculature after stroking the skin around the anus represents a normal response.

B. Laboratory findings and special examinations The diagnosis of erectile dysfunction is made based on the patient's history. Testing of nocturnal penile tumescence is used only in research studies. Most guidelines indicate that laboratory testing for evaluation of erectile dysfunction should be done based on the clinical setting. Although male hypogonadism is seldom the sole or primary cause of erectile dysfunction, it is reasonable to measure serum testosterone concentrations, particularly in any man with low libido and erectile dysfunction. Many experts recommend a fasting lipid profile and serum glucose (or an A1c). These tests are recommended because erectile dysfunction is highly associated with the risk of future cardiovascular events. These tests are not useful for the diagnosis or management of erectile dysfunction; neither improved glycemic control nor treatment of dyslipidemia are effective treatments for erectile dysfunction. The most important assessment is to determine the risk of exertional cardiac ischemia. Typical sexual intercourse requires about three to four metabolic equivalents (METs). This is equal to walking a mile in 20 minutes or walking a flight of 20 steps in 20 seconds or walking up a flight of stairs (at least 10 risers) without pausing or stopping. If the patient with erectile dysfunction cannot perform these activities, then formal cardiac exercise tolerance testing should be considered before any medical therapy for erectile dysfunction is initiated.

The vascular integrity of the penis may be examined by Doppler ultrasonography with spectral analysis following intracorporeal injection of a vasoactive drug. This method allows detection of venous leaks with a sensitivity of 55% to 100% and specificity of 69% to 88%. Arterial problems are also detected with a sensitivity of 82% to 100% and specificity of 64% to 96%. Other special tests, such cavernosometry, cavernosography, or penile arteriography, are rarely done in the evaluation of erectile dysfunction.

Treatment

If initiation of a medication is temporally related to the onset of erectile dysfunction, then the offending medication should be discontinued. Erectile dysfunction will typically return to baseline. However, if the onset of erectile dysfunction is long after the initiation of medication known to be associated with erectile dysfunction, then discontinuation of that medication will not usually improve erectile function. For psychogenic erectile dysfunction, simple reassurance and explanation, formal psychotherapy, and various forms of behavioral therapy have a reported 40% to 70% success rate.

For psychogenic or organic erectile dysfunction in a patient with a normal physical examination, most clinicians elect to begin with a therapeutic trial of an oral type 5 phosphodiesterase (PDE5) inhibitor that potentiates the effects of nitric oxide by inhibiting the breakdown of cyclic guanosine monophosphate. The initial oral dose is usually 50 mg of sildenafil (Viagra), 10 mg of tadalafil (Cialis), or 10 mg of vardenafil (Levitra). These medications should be tried only if the patient is not taking nitrates, has not had a myocardial infarction in the last 6 months, and does not have unstable angina, hypotension, severe congestive heart failure, or retinitis pigmentosa. These drugs are effective in 70% to 80% of patients with a wide variety of causes of erectile dysfunction, including psychogenic ones. Side effects include headache (16%) and visual disturbances (3%). They are absolutely contraindicated in patients taking nitrates for vascular disease or amyl nitrate that is sometimes taken to enhance sexual pleasure.

Vasoactive drugs including prostaglandin E_1, papaverine hydrochloride, and phentolamine mesylate (either alone or in combination), may induce an erection following intracavernous injection. Of these, the only Food and Drug Administration-approved agent is prostaglandin E_1 (alprostadil). This drug is titrated for each individual to the minimal effective dosage (typically 2.5 to 60 μg per injection). In clinical studies, up to 90% of men with erectile dysfunction developed erections with intracavernosal injections. Side effects include penile pain (up to 50% of injections), hematoma (1%-3%), and, less commonly, penile fibrosis (2%) and priapism (0.5%-1.0%). Intraurethral insertion of a 1.4-mm pellet containing alprostadil leads to satisfactory erections in 60% to 70% of patients, with tumescence beginning within 10 minutes and lasting 30 to 60 minutes. The major side effects are penile or urethral pain (10%), and dizziness (1%-2%). Intracavernosal and intraurethral alprostadil may be effective in patients with erectile dysfunction who have had no or an incomplete response to an oral PDE5 inhibitor. Alprostadil and oral PDE5 inhibitors also act synergistically when used in combination.

Devices have been developed that use suction to induce penile engorgement and constrictive bands to maintain the ensuing erection. Erections are achieved in 90% of patients with an approximately 70% couple satisfaction rate. Alternatively, a surgically implanted semi-rigid or inflatable penile prosthesis provides satisfactory results in 85% to 90% of cases, but these devices are used infrequently. Repair of venous leaks and microsurgical revascularization of arterial lesions have had variable success rates; vascular surgery is seldom used as a treatment for erectile dysfunction.

GYNECOMASTIA

Gynecomastia is common during the neonatal period and is present in about 70% of pubertal males (Chapter 15). Clinically apparent gynecomastia has been noted at autopsy in almost 1% of adult males, and 40% of autopsied males have histologic evidence of gynecomastia.

Etiology and Pathophysiology

The causes of gynecomastia are listed in Table 12–7. Several mechanisms have been proposed to account for this disorder. All involve a relative imbalance between estrogen and androgen concentrations or action at the mammary gland level. Peripubertal gynecomastia is considered to be a normal variant and is due to a relative imbalance in the production of estrogen relative to testosterone early in puberty. Decreased serum free testosterone concentrations due to primary gonadal disease or decreased androgen action in patients with the androgen resistance syndromes results in variable degrees of gynecomastia. Acute or chronic excessive stimulation of the Leydig cells by LH increases aromatization of testosterone to estradiol. This mechanism may be responsible for the more significant gynecomastia seen in hypergonadotropic states such as Klinefelter syndrome and adult Leydig cell failure. The rise of serum gonadotropins during puberty may lead to an estrogen-androgen imbalance by similar mechanisms. Patients who are malnourished or have systemic illness may develop gynecomastia during refeeding or treatment of the underlying disorder. Malnourishment and chronic illness are accompanied by a reduction in gonadotropin secretion, and during recovery, serum LH concentration rises and stimulates Leydig cell production of estrogens relative to testosterone.

Because hCG has LH-like activity, hCG-producing trophoblastic or nontrophoblastic tumors often result in relatively high serum estrogen to testosterone concentrations. In addition, some of these tumors are able to convert estrogen precursors into estradiol. Feminizing adrenocortical and Leydig cell neoplasms may directly secrete excessive quantities of estrogens. The mechanisms by which hyperprolactinemia produce gynecomastia are unclear, but the primary explanation appears be the known suppressive effect of hyperprolactinemia on gonadotropin secretion resulting in lower testosterone production and a lower testosterone:estrogen ratio.

Drugs that cause gynecomastia may reduce androgen synthesis (eg, spironolactone, ketoconazole), peripherally antagonize

Idiopathic

The level of evidence supporting the drug cited as causing gynecomastia varies and is graded as follows.

G = good evidence of causal relationship based on a systematic review of randomized controlled trials, randomized placebo-controlled trial, or prospective cohort studies and a pathophysiological mechanism for gynecomastia.

F = fair evidence of causal relationship based on retrospective studies or case-control studies or case series and a pathophysiological mechanism for gynecomastia.

androgen action (spironolactone, cimetidine), or interact with breast estrogen receptors (spironolactone and phytoestrogens in marijuana). As part of the evaluation of recent onset of gynecomastia, the clinician should review all of the patient's prescription and non-prescription medications, creams, and lotions for potential causes.

Finally, it has been proposed that patients with idiopathic and familial gynecomastia have breast glandular tissue that is inordinately sensitive to normal circulating levels of estrogen or excessively converts estrogen precursors to estrogens.

Pathology

Three histologic patterns of gynecomastia have been recognized. The florid pattern consists of an increase in the number of budding ducts, proliferation of the ductal epithelium, periductal edema, and a cellular fibroblastic stroma. The fibrous type has dilated ducts, minimal duct epithelial proliferation, no periductal edema, and a virtually acellular fibrous stroma. An intermediate pattern contains features of both types.

The duration of gynecomastia is the most important factor in determining the pathologic picture. Approximately 75% of patients with gynecomastia of 4 months' duration or less exhibit the florid pattern, whereas 90% of patients with gynecomastia lasting a year or more have the fibrous type. Between 4 months and 1 year, 60% of patients have the intermediate pattern. The pathologic picture also correlates with the likelihood of resolution of gynecomastia; patients with more florid pathology are more likely to have reduction in breast tissue with treatment of the cause of the gynecomastia.

Clinical Features

A. Symptoms and signs   The principal complaint is unilateral or bilateral concentric enlargement of breast glandular tissue. Nipple or breast pain is present in one-fourth of patients and objective tenderness in about 40%. Breast tenderness and pain may be unilateral. Galactorrhea is very rare in men with gynecomastia. Histologic examination has demonstrated that gynecomastia is almost always bilateral, although it is often asymmetric and is sometimes nonpalpable on one side. Breast or nipple discomfort generally lasts less than 1 year. Other than cosmetic concerns, chronic gynecomastia is virtually always asymptomatic. Symptoms and signs of underlying disorders may be present.

The most important elements of the physical examination are breast and testicular examinations. The clinician must distinguish between pseudogynecomastia (fat tissue) and true gynecomastia. Pinching the tissue between thumb and index finger or between two hands allows the examiner to feel for an edge that represents the interface between normal tissue and rubbery glandular breast tissue. The examiner can often "flip the edge" of this interface so that the discoid breast tissue can be moved up and down or in and out of the plane of the surrounding tissue. Comparision of the consistency with fat tissue in the abdomen is useful. Gynecomastia is considered significant in adult men by some experts when there is more than or equal to 2 cm of palpable breast tissue.

The testicles should be examined for size, consistency, and the presence of a mass. A mass might represent a hormone-producing tumor. In addition to a careful examination of the breasts and testes, the clinician should examine for signs of hyperthyroidism, Cushing syndrome, and acromegaly.

B. Laboratory findings   The vast majority of adult men with nontender gynecomastia will not have an identifiable cause, and extensive laboratory testing is not useful. Breast tenderness suggests growth of breast tissue and recent onset of gynecomastia, and men with tender gynecomastia are more likely to have an endocrinopathy as the cause. Figure 12–8 depicts a rational diagnostic algorithm for the evaluation of nontender and tender gynecomastia.

Specific laboratory testing for liver, kidney or endocrine diseases associated with gynecomastia should be considered based on the history and examination. Measurement of testosterone, LH, and FSH on a serum sample obtained in the early morning is reasonable. Table 12–8 lists the pattern of testosterone, LH, and FSH concentrations seen in various causes of gynecomastia.

Differential Diagnosis

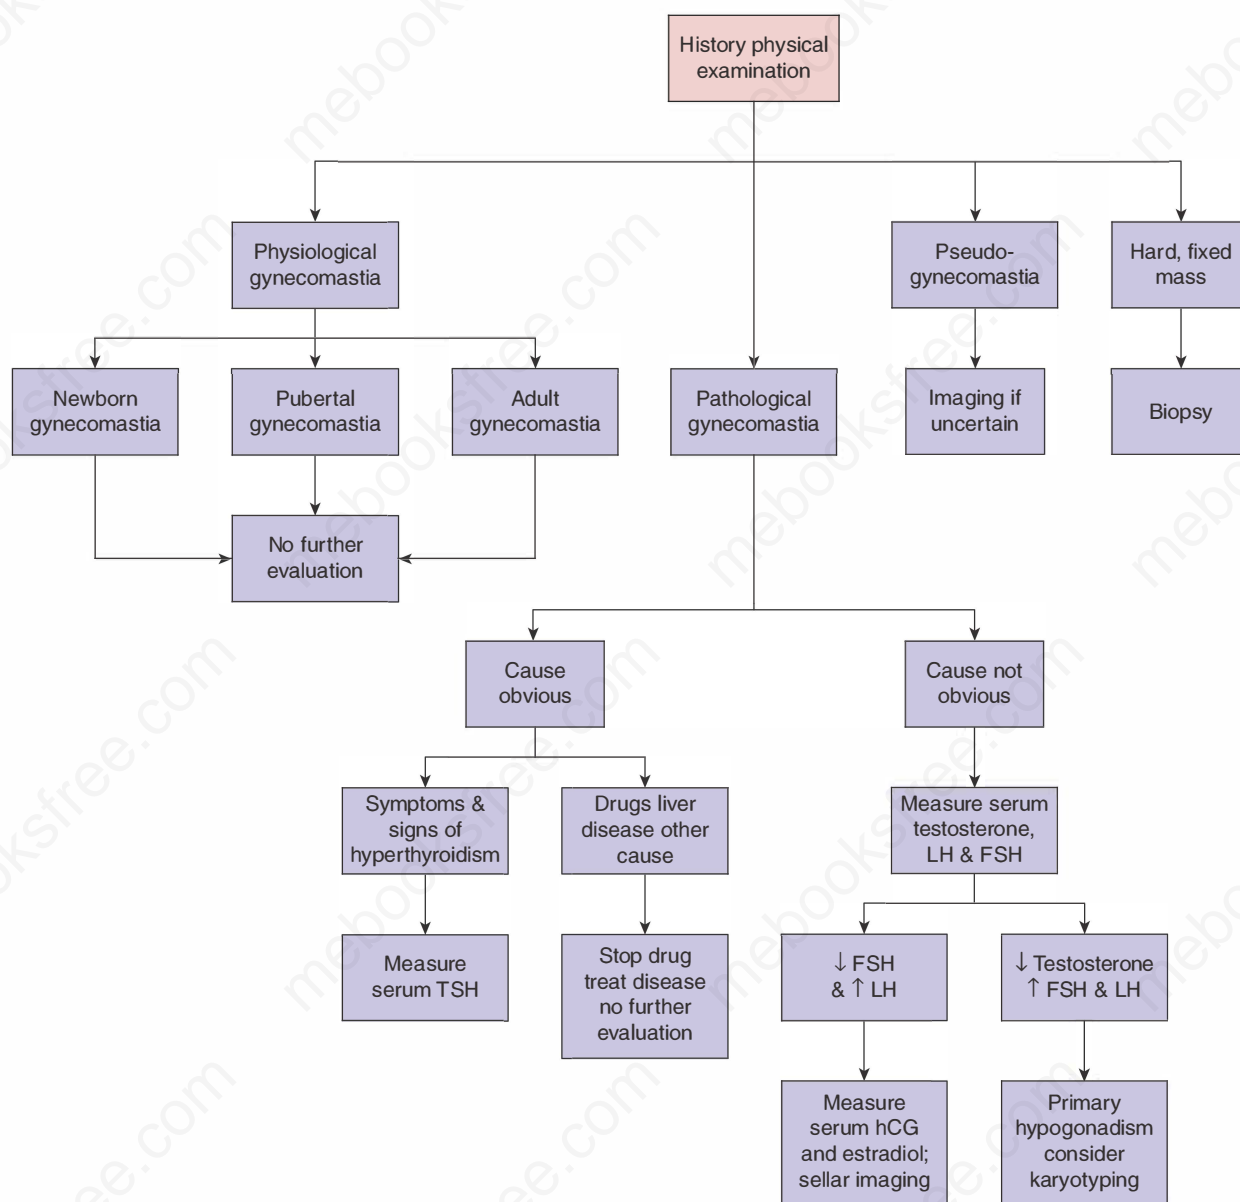
Gynecomastia should be differentiated from pseudogynecomastia due to obesity and from much rarer causes including lipomas, neurofibromas, or carcinoma of the breast. Breast lipomas, neurofibromas, and carcinoma are usually unilateral, painless, and


FIGURE 12–8   Diagnostic evaluation for endocrine causes of gynecomastia (hCG, human chorionic gonadotropin; LH, luteinizing hormone; FSH, follicle stimulating hormone; TSH, thyrotropic hormone).

TABLE 12–8 Typical hormone concentrations in the evaluation of gynecomastia.

eccentric, but gynecomastia characteristically begins in the sub-areolar areas and enlarges concentrically. Lipomas are usually easily recognized as mobile smooth nodules whereas male breast cancer often presents as a hard, fixed mass.

Complications and Sequelae

There are no complications other than emotional distress due to the cosmetic appearance. With the exception of patients with Klinefelter syndrome, individuals with gynecomastia do not have an increased risk of development of breast carcinoma.

Treatment

A. Medical treatment   The underlying disease should be corrected if possible, and offending drugs should be discontinued. Selective estrogen receptor modulators, such as tamoxifen or raloxifene, have been found useful in relieving pain and reversing gynecomastia in some patients. Although it would be expected that reduction of estradiol production by inhibition of aromatase would be effective for gynecomastia, the largest aromatase study to date demonstrated no benefit for anastrazole compared to placebo. Short-term administration of tamoxifen (10-20 mg daily for 3-6 months) may be useful in boys with significantly symptomatic pubertal gynecomastia or men with recent onset of very symptomatic idiopathic gynecomastia. Tamoxifen also effectively prevents the development of gynecomastia in many men who are starting therapy for prostate cancer with antiandrogens. Medical therapy is ineffective for chronic, fibrous gynecomastia.

B. Surgical treatment   Reduction mammoplasty should be considered for cosmetic reasons in any patient with longstanding gynecomastia that is in the fibrotic stage. Causes of gynecomastia should be addressed prior to reduction mammoplasty.

C. Radiation therapy   Low-dosage external beam radiation therapy (900 cGy or less) is effective, but less effective than tamoxifen, for prevention of gynecomastia due to anti-androgen monotherapy for prostate cancer.

Course and Prognosis

Pubertal gynecomastia usually regresses spontaneously within 1 or 2 years. Patients who develop drug-induced gynecomastia generally have complete or near-complete regression of the breast changes if the offending drug is discontinued during the early, florid stage. Once gynecomastia from any cause has reached the fibrotic stage, little or no spontaneous regression occurs, and medical therapy is ineffective.

TESTICULAR TUMORS

Testicular neoplasms account for 1% to 2% of all male-specific malignant neoplasms and 4% to 10% of all genitourinary neoplasms. They are the most frequent type of cancer in men between 20 and 34 years of age. The incidence is 5.4 per 100,000 men in the United States and 4.6 to 7.3 per 100,000 men in Europe. The incidence is lower in nonwhite than in white populations. Ninety-five percent of testicular tumors are of germ cell origin; 5% are composed of stromal or Leydig cell neoplasms.

Etiology and Pathophysiology

The cause of germ cell testicular tumors is not known. Predisposing factors include testicular maldescent, Klinefelter syndrome, Down syndrome, and tobacco use. Exposure to environmental compounds with estrogenic activity has been associated with increased risk of testicular cancer. Although trauma is frequently cited as an etiologic factor in testicular tumors, no causal relationship has been established.

Pathology

A. Germ cell tumors   Seminomas account for 33% to 50% of all germ cell tumors. They are composed of round cells with abundant cytoplasm, prominent nuclei, and large nucleoli. The cells are arranged in cords and nests and have a thin delicate network of stromal connective tissue. Embryonal cell neoplasms comprise 20% to 33% of germ cell tumors. These tumors have multiple histologic patterns composed of cuboidal pleomorphic cells. One distinct pattern of cellular arrangement is the endodermal sinus tumor (yolk sac tumor), the most frequent germ cell neoplasm found in infants. Immunohistochemical techniques have localized alpha-fetoprotein to the embryonal cells. About 10% of germ cell tumors are teratomas, which are composed of well-differentiated cells derived from all three germ layers.

When one or more of the teratoid elements are malignant or are mixed with embryonal carcinoma cells, the term teratocarcinoma is applied. These tumors account for one-tenth to one-third of germ cell neoplasms. Choriocarcinoma is the rarest form of germ cell tumor (2%) and is composed of masses of large, polymorphic, multinucleated syncytiotrophoblastic cells. Although pure choriocarcinoma is rare, many testicular tumors contain an occasional trophoblastic giant cell. Immunohistochemical techniques have shown that these cells are the source of hCG in such tumors. Germ cell tumor sometimes produce enough hCG to cause bilateral gynecomastia.

B. Leydig and Sertoli cell tumors   Leydig cell (interstitial cell) tumors are rare. Most are benign and are composed of sheets of oval to polygonal cells arranged in lobules separated from one another by thin strands of connective tissue. Malignant Leydig cell tumor disseminates by both lymphatic and venous channels, with initial metastatic deposits being found in the regional lymph nodes, followed by metastases to liver, lung, and bone. Leydig cell tumors may produce testosterone or estrogen. Sertoli cell tumors also are rare, are generally benign, and are composed of large tubules, a thick basement membrane with enlarged cuboidal Sertoli cells. There may be extensive calcification within the tumors and the tumors may be multifocal and bilateral. Sertoli cell tumors may produce estrogen.

Clinical Features

A. Symptoms and signs

1. **Germ cell tumors**—Testicular tumors usually present as painless enlargement of a testicle. Thus, about 80% of patients note a testicular swelling or mass, whereas only 25% complain of testicular pain or tenderness. About 6% to 25% of patients give a history of testicular trauma that led to the discovery of the testicular mass. About 5% to 10% of patients present with symptoms of distant metastatic disease, including backache, skeletal pains, gastrointestinal symptoms and abdominal pains, inguinal adenopathy, cough, hemoptysis, and neurological dysfunction.

    A testicular mass or generalized enlargement of the testis is often present on examination. In 5% to 10% of patients, a coexisting hydrocele may be present. In the presence of metastatic disease, supraclavicular and retroperitoneal lymph node enlargement may be present.

2. **Leydig and Sertoli cell tumors**—In children, Leydig cell tumors of the testes may produce sexual precocity, with rapid skeletal growth and development of secondary sexual characteristics. Adults with Leydig cell tumors usually present with a testicular mass and occasionally with tender gynecomastia. Sertoli cell tumors may be associated with gynecomastia and feminization due to excessive aromatase activity. Sertoli tumors are associated with the Peutz-Jeghers syndrome (gastrointestinal polyposis and oval, irregularly pigmented lip macules) and the Carney complex (cardiac myxomas, spotty cutaneous pigmentation, primary pigmented nodular adrenocortical disease with hypercortisolism).

B. Laboratory findings

1. **Germ cell tumors**—The tumor markers hCG, alpha-fetoprotein, and lactate dehydrogenase (LDH) should be measured in every male presenting with a testicular mass. hCG is found in the sera of 5% to 10% of males with seminoma, over half of patients with teratocarcinoma or embryonal cell carcinoma, and all patients with choriocarcinoma. hCG should be measured as the beta subunit or other hCG-specific immunoassay method. Elevated serum immunoreactive alpha-fetoprotein concentrations are found in almost 70% of patients with nonseminomatous forms of germ cell neoplasms. Both markers are elevated in over 50% of patients with nonseminomatous germ cell tumors, and at least one of the markers is elevated in 85% of such patients. These markers can also be used to monitor the results of therapy. Serum LDH concentrations reflect tumor growth rate and cellular proliferation, and high serum concentrations are associated with a poor prognosis. Serum LDH is increased in about 80% of patients with advanced seminomas and 60% of advanced nonseminomatous tumors.

2. **Leydig and Sertoli cell tumors**—Serum DHEA sulfate and estrogen concentrations may be normal or increased, while serum testosterone concentrations tend to be low or within the normal adult range in patients with Leydig cell tumors. Individuals with Sertoli cell tumors may have elevated serum estradiol concentrations.

C. Imaging studies   Scrotal ultrasonography is useful for the evaluation of any testicular mass and may be required to visualize small testicular tumors. Staging of testicular tumors requires chest and abdominal CT scans and other radiologic procedures depending on the type of tumor and the symptoms.

Differential Diagnosis

Testicular tumors are sometimes misdiagnosed as epididymitis or epididymo-orchitis. An inflammatory reaction of the epididymis often involves the vas deferens. Therefore, both the vas and the epididymis are thickened and tender on examination during the acute disease. Because hydrocele may coexist with testicular tumor, all patients with large hydroceles (large enough to make the testicular examination difficult) should have a scrotal ultrasound.

Other conditions in the differential diagnosis include inguinal hernia, hematocele, hematoma, torsion, spermatocele, varicocele, and (rarely) sarcoidosis, tuberculosis, and syphilitic gumma. Ultrasonic examination of the scrotum may help distinguish between testicular tumors and extratesticular disease such as acute or chronic epididymitis, spermatocele, or hydrocele.

Benign Leydig cell tumors of the testes must be differentiated from adrenal rest tumors in patients with congenital adrenal hyperplasia. Because the testes and the adrenals are derived from the same embryologic source, ectopic adrenal tissue may be found to migrate with the testes. Testicular adrenal rests enlarge under the stimulus of higher serum ACTH concentrations in patients with congenital adrenal hyperplasia or Cushing disease. Adrenal

rests tend to be bilateral, whereas Leydig cell tumors are generally unilateral. Both may be associated with elevated serum DHEA sulfate and estradiol concentrations.

Treatment

A. Germ cell tumors   Seminomas are quite radiosensitive, and disease localized to the testes is usually treated with radical inguinal orchidectomy and 2000 to 4000 cGy of conventional radiotherapy, delivered to the ipsilateral inguinal-iliac and bilateral para-aortic lymph nodes to the level of the diaphragm. For disease that has spread to the lymph nodes below the diaphragm, additional whole abdominal radiotherapy and prophylactic mediastinal and supraclavicular lymph node irradiation are usually given. Widely disseminated disease is generally treated with a combination of radiotherapy and chemotherapy, especially with bleomycin, etoposide, and cisplatin.

Nonseminomatous tumors are treated with orchidectomy, retroperitoneal lymph node dissection, and, if necessary, radiotherapy or chemotherapy (or both). Although many chemotherapeutic agents have been used, combinations of etoposide, bleomycin, and cisplatin currently appear to produce the best overall results. Patients with nonseminomatous tumors treated by these means should be monitored with serial measurements of serum hCG and alpha-fetoprotein.

B. Leydig and Sertoli cell tumors   Leydig and Sertoli cell tumors of the testes are treated by unilateral radical inguinal orchidectomy. Objective remissions of malignant Leydig cell tumors have been noted following treatment with mitotane.

Course and Prognosis

A. Germ cell tumors   In patients with seminoma confined to the testicle, the 5-year survival rates after orchidectomy and radiotherapy are 98% to 100%. Disease in the lymph nodes below the diaphragm also has an excellent prognosis, with 5-year survival rates of 80% to 85%. Disease above the diaphragm and disseminated disease have overall 5-year survival rates of about 70%.

In patients with nonseminomatous germ cell tumors, aggressive surgery and combination chemotherapy have raised the 5-year survival rates from less than 20% to 60% to more than 95%.

B. Leydig and Sertoli cell tumor   Removal of a benign Leydig or Sertoli cell tumor is accompanied by regression of iso- or heterosexual precocious puberty in children or feminization in adults. The prognosis for malignant Leydig cell tumor is poor, with most patients surviving less than 2 years from the time of diagnosis.

EMBRYOLOGY AND ANATOMY

No gene has yet been identified that generates an ovary from an undifferentiated gonad. It is only in the absence of the sex-determining region of the Y gene (*SRY*) that the gonad develops into an ovary. (For more details, see the discussion of sexual differentiation in Chapter 14.) Primordial germ cells, which give rise to oocytes or spermatogonia, are first identifiable in the yolk sac endoderm (hindgut) at 3 to 4 weeks of gestation. Once specified, they migrate and proliferate en route through the dorsal mesentery into the gonadal ridge, which is located lateral to the dorsal mesentery of the gut and medial to the mesonephros (Figure 13–1). Studies in mice have suggested that the process of proliferation and navigation to the gonad depends on several genes, including *Steel* (kit ligand and receptor), β_1 *integrin, pog* (proliferation of germ cells), and many cytokines. Failure of primordial germ cells to develop or migrate into the gonadal ridge results in failure of ovarian development. In contrast, it is suggested that male gonadal development may continue to develop into functional testis despite the absence of germ cells.

The germ cells that reach the gonadal ridge (6 weeks of gestation) continue to proliferate and are referred to as oogonia (premeiotic germ cells). At 10 to 12 weeks of gestation, some oogonia leave the mitotic pool and begin meiosis, where they arrest in prophase I (dictyotene stage). These arrested germ cells are now called primary oocytes. By 16 weeks, primordial follicles are first identified, making a clear distinction for gonadal differentiation into an ovary. At approximately 20 weeks of gestation, a peak of 6 to 7 million germ cells (two-thirds of them primary oocytes and one-third oogonia) are present in the ovaries. During the second half of gestation, the rate of mitosis rapidly decreases, and the rate of oogonial and follicular atresia increases. Those oogonia that are not transformed into primary oocytes will undergo atresia before birth. This leads to a reduction in the number of germ cells, resulting in a total of 1 to 2 million germ cells at birth. No germ cell mitosis occurs after birth, whereas follicular atresia continues, with the result that the average girl entering puberty has only 300,000 to 400,000 germ cells.

The ovary is organized into an outer cortex and an inner medulla. The germ cells are located within the cortex. Along the outer surface of the cortex is the germinal epithelium. This cell layer is composed of cuboidal cells resting on a basement membrane and forms a continuous layer with the peritoneum. Even though it is called the germinal epithelium, there are no germ cells within this layer. During embryonic development, the epithelial cells proliferate and enter the underlying tissue of the ovary to form cortical cords. When the primordial germ cells arrive at the genital ridge, they are incorporated into these cortical cords. At the same time the germ cells migrate from the yolk sac, the stromal cells of the ovary (granulosa and interstitial cells) migrate from the mesonephric tubules into the gonad. **Primordial follicles** form within the cortical cords. They are composed of a primary oocyte and one layer of granulosa cells with its basement membrane. Oocytes not surrounded by granulosa cells are lost, probably by apoptosis. This finite follicle population represents the pool of germ cells that will ultimately be available to enter the follicular cycle.

During fetal development, the gonad is held in place by the suspensory ligament at the upper pole and the gubernaculum at the lower pole. The final location of the gonad is dependent on hormone production. In the presence of testosterone, the gubernaculum grows while the suspensory ligament regresses. As the gubernaculum continues to grow, the gonad (testis) descends into the scrotum. In contrast, when testosterone is absent, the suspensory ligament remains, and the gubernaculum regresses. This process maintains the gonad (ovary) in the pelvis.

The remainders of the female internal reproductive organs are formed from the paramesonephric (Müllerian) ducts. In the absence of anti-Müllerian hormone (AMH), the paramesonephric system develops into the uterine (fallopian) tubes, uterus, cervix, and upper third of the vagina. Unlike Wolffian duct differentiation, the development of the female reproductive tract is not
FIGURE 13–1   A. (Reproduced with permission from Langman J, Sadler TW. *Langman's Medical Embryology.* 8th ed. Philadelphia: Lippincott Williams & Wilkins; 2000.)

dependent on hormone production. (For more details, see "Human Sex Differentiation" in Chapter 14.) Briefly, the Müllerian buds are formed lateral to the Wolffian ducts and the gonadal ridge after 37 days of gestation (Figure 13–2). These buds elongate, extend caudally, and cross medially to the Wolffian ducts by 8 weeks of gestation. By 10 weeks, the adjacent paired Müllerian ducts meet in the midline as they join the Müllerian tubercle (urogenital sinus). Over the next couple of weeks, the Wolffian ducts degenerate, and the paired Müllerian ducts fuse and begin to canalize. The intervening septum resorbs between the 12th and 16th weeks of gestation, resulting in a single uterine cavity. The most cranial parts of the Müllerian ducts remain unfused and form the uterine tubes, which remain patent with the coelom (future peritoneal cavity). The caudal segments stimulate solid cords to extend from the Müllerian tubercle to the sinovaginal bulbs from the posterior aspect of the urogenital sinus. In turn, the sinovaginal bulbs extend cranially and fuse with the vaginal cords, forming the vaginal plate. The vagina is subsequently formed by canalization of the vaginal plate. It is ultimately the cervix and the upper one-third of the vagina that are derived from the Müllerian structures, and the remaining lower two-thirds are formed from the urogenital sinus.

The uterus is composed of endometrium (innermost lining), myometrium, and serosa. The adult uterus is a pear-shaped hollow organ. The cervical portion extends approximately 2 cm into the vagina, and the remaining corpus extends approximately 6 cm into the abdomen. The normal adult uterus weighs 40 to 80 g.

The uterus is located in the pelvis and rests on the pelvic floor. From 70% to 80% of the time, the uterine position is anteflexed (cervical-uterine corpus angle) and anteverted (cervical-vaginal angle). Therefore, when a woman is standing, the corpus of the uterus is horizontal and resting on top of the bladder. The uterus has several paired ligaments that develop from thickenings of the peritoneum and serve to maintain this anatomic position. The cardinal ligament (Mackenrodt) is the main supporting ligament. It attaches to the lateral margins of the cervix at the upper vagina and extends to the lateral pelvic wall. The remaining ligaments—uterosacral, round, and broad—have a lesser role in supporting the uterus.

The uterine artery originates from the anterior division of the internal iliac artery (hypogastric), enters the cardinal ligament, and supplies the uterus. The uterine artery divides into a descending branch and an ascending branch known as the vaginal and arcuate arteries, respectively. The arcuate arteries anastomose with each other and form a vascular network around the uterus. The radial arteries branch off from the arcuate network and penetrate the uterus to supply the myometrium. Smaller basal branches and spiral arteries supply the endometrium.

The ovary is suspended in the pelvis and has three associated ligaments. The average adult ovary is 2.5 to 5 cm × 2.5 cm × 1 cm in size and weighs 3 to 8 g. The position of the ovary is variable, but in a nulliparous woman it is often located in a peritoneal depression on the pelvic sidewalls between the ureter and external iliac vein. The suspensory (infundibulopelvic) ligament attaches to the cranial pole of the ovary and extends to the pelvic brim. This ligament suspends the ovary in the pelvis and contains the ovarian vessels, lymphatics, and nerves. The utero-ovarian ligament attaches to the inferior pole of the ovary and extends to the uterus. The mesovarium connects the anterior portion of the ovary to the posterior leaf of the broad ligament. The blood supply of the ovary originates from the abdominal aorta, passes through the suspensory ligament, and enters the mesovarium to form an anastomotic network with branches from the uterine artery. The ovarian artery enters the ovarian hilum and branches into spiral arteries that enter the medulla and extend to the ovarian cortex. Other branches from the anastomotic network, located in the mesovarium, supply the uterine tubes.

OVARIAN STEROIDOGENESIS

The ovaries are not only the store for germ cells—they also produce and secrete hormones that are vital for reproduction and the development of secondary sexual characteristics. The next section will briefly discuss the biosynthesis of ovarian hormones.

In the ovary, the major source of hormone production is the maturing follicle. The components of the follicle are the theca cells, the granulosa cells, and the primary oocyte. The theca cells produce androgens, and the granulosa cells produce estrogens. The other stromal cells that contribute to androgen production can be divided into two populations of cells: the secondary interstitial cells (derived from theca) and the hilum cells. These cells are the major ones involved in ovarian hormone production during menopause (see later).

The ovarian hormones are derived from cholesterol. Steroidogenic cells acquire the cholesterol substrate from one of three sources. The most common source is plasma lipoprotein-carrying cholesterol, primarily in the form of low-density lipoprotein (LDL). Other minor sources include *de novo* synthesis from acetate and liberation from stored lipid droplets (cholesterol esters). Stimulation of ovarian cells by trophic hormones such as follicle-stimulating hormone (FSH) and luteinizing hormone (LH) facilitate uptake of cholesterol by increasing the number of LDL receptors on the cell surface. The LDL particle is subsequently internalized and degraded in the lysosome. The free cholesterol that is liberated from the lysosome is delivered to the mitochondria by an unknown mechanism, possibly via microfilaments and microtubules. The cholesterol is then translocated into the mitochondria by the steroidogenic acute regulatory protein (StAR). Thus, StAR is the rate-limiting step regulating substrate availability for steroidogenesis.

Although acute alterations in steroid production result from changes in delivery of cholesterol to the mitochondria, the long-term control of steroid synthesis results from regulation of gene expression. Most of the genes involved in steroidogenesis contain at least one steroidogenic factor-1 (SF-1) response element in the promoter region. These elements are critical for the regulation of steroidogenic genes as well as the development of adrenal gland, ovary, and testis. The importance of SF-1 for steroidogenesis is highlighted in knockout mice deficient in this transcription factor which lack adrenal glands and gonads. Although SF-1 is essential, the specific expression of each gene involves many other transcription factors that work independently or in concert with SF-1.

The rate-determining step that commits cholesterol to steroid synthesis is the cholesterol side chain cleavage enzyme reaction (P450scc) (Figure 13–3). This reaction converts cholesterol to pregnenolone, the precursor of steroid hormones, and takes place in the mitochondria. Pregnenolone is transported out of the
FIGURE 13–3 Pathways of steroid biosynthesis. The pathways for synthesis of progesterone and mineralocorticoids (aldosterone), glucocorticoids (cortisol), androgens (testosterone and dihydrotestosterone), and estrogens (estradiol) are arranged left to right. The enzymatic activities catalyzing each bioconversion are written in the boxes. For those activities mediated by specific cytochrome P450, the systematic name of the enzyme (*CYP* followed by a number) is listed in parentheses. CYPB2 and CYP17 have multiple activities. The planar structures of cholesterol, aldosterone, cortisol, dihydrotestosterone, and estradiol are placed near the corresponding labels. (Reproduced with permission from White PC, Speiser PW. Congenital adrenal hyperplasia due to 21-hydroxylase deficiency. *Endocr Rev*. 2000 Jun;21(3):245-291.)

mitochondrion, and the remaining steps in sex steroid production take place primarily within the smooth endoplasmic reticulum (SER).

Once pregnenolone is formed, the particular hormones that are synthesized are dependent on the endocrine organ and cell type. For example, the main sources of sex steroids in the female come from the adrenal gland, ovary, and the periphery. The specific type of hormone synthesized is dependent on the specific gene expression within each cell type.

In the adrenal gland, there are three zones: zona glomerulosa, zona fasciculata, and zona reticularis. The cells in the different zones start with the same hormone precursor but differ in their secretory products. The glomerulosa produces mainly aldosterone, whereas cortisol and androgen are produced by the zona fasciculata and zona reticularis, respectively. The major androgen produced by the adrenal gland is dehydroepiandrosterone sulfate (DHEAS). Differences in enzymatic activity among cells in the various zones are what regulate hormone production. The zona reticularis and zona fasciculata lack 18 hydroxylase/oxidase (11β2-hydroxylase) activity, which is necessary for aldosterone synthesis (see Figure 13–3; see also Chapters 9 and 10). The zona glomerulosa lacks 17-hydroxylase and 17,20-lyase (CYP17), which are necessary for sex steroid synthesis.

Ovarian cells similarly secrete different hormones due to differential enzyme activity. The theca interstitial and secondary interstitial cells lack aromatase and hence are the androgen producers in the ovarian cortex. The granulosa cells, on the other hand, lack CYP17 and, therefore, secrete estrogens—mainly estradiol—from thecal cell-derived androgens in the proliferative phase and progesterone in the luteal phase (see later).

Adipose and skin make significant contributions to plasma concentrations of some sex steroids. Adipose tissue is able to sequester most steroids due to their lipid solubility. Fat also expresses genes capable of sex steroid metabolism (ie, aromatase). Skin significantly contributes to the plasma concentration of testosterone by utilizing circulating DHEAS and androstenedione as precursors.

The major circulating androgens include DHEAS, androstenedione, and testosterone. During the reproductive years, the ovaries are directly responsible for one-third of the testosterone production. The remaining two-thirds come from the periphery (17β-hydroxysteroid dehydrogenase [HSD] types 3 and 5) and is derived from ovarian and adrenal gland precursors—notably androstenedione, which is produced in equal proportions by the adrenal gland and the ovary. The adrenal gland may directly secrete testosterone, but its major contribution is derived from its production of precursors. Therefore, the ovaries are responsible for nearly two-thirds of the circulating testosterone. This differs from males, in whom only 5% of the circulating testosterone is derived from peripheral conversion of androstenedione. It is also estimated that more than 60% of the most potent androgen, dihydrotestosterone (DHT) in women, is produced in the skin (5α-reductase type 1 and 2) and originates from androstenedione. DHEAS is the major androgen produced by the adrenal gland. The adrenal gland is responsible for more than 95% of the circulating DHEAS levels. Although it is the most abundant androgen circulating in the body, it contributes minimally to serum testosterone levels. The relative strengths of androgens are listed in Table 13–1.

TABLE 13–1 Relative androgenic activity of androgens.

Steroid	Activity
Dihydrotestosterone	300
Testosterone	100
Androstenedione	10
DHEA, DHEAS	5

The circulating estrogens include estrone, estrone sulfate, estradiol, and estriol (pregnancy). More than 95% of estradiol in the circulation is produced from the ovary. In contrast to estradiol, approximately one-half of the circulating estrone is secreted from the ovary, while the remaining is derived from peripheral conversion. The most significant precursor, androstenedione, is aromatized in the adipose tissue, hair follicles, and the liver to estrone. Estrone is also derived from estradiol through 17β-HSD type 2 activity or from estrone sulfate (steroid sulfatase). Almost all estriol is produced during pregnancy and is secreted from the placenta (see Chapter 16).

Ultimately, the serum concentration of sex steroids is dictated by the secretion rate (SR), production rate (PR), and metabolic clearance rate (MCR), as shown in Table 13–2. The SR of sex steroids from each organ determines the PR of the hormone. If the SR for a specific hormone in the ovary equals the PR, then there is no extragonadal formation. However, if there is extragonadal formation, then the PR exceeds the SR.

MCR is the volume of blood per unit of time cleared of the hormone. The MCR of sex steroids is inversely related to the affinity for sex hormone–binding globulin (SHBG) and/or albumin. Prior to excretion, steroids are conjugated to make them water soluble. The bulk of testosterone is bound to SHBG (~65%) and to a lesser extent albumin (~35%); only 1% (*free* hormone) is active and available for metabolism. The remaining androgens have negligible binding affinity for SHBG. Free testosterone may be converted to more potent androgens such as DHT or may be metabolized through androstenedione. Metabolites of androstenedione and DHT are conjugated with a sulfate or glucuronide and are excreted in the urine. The majority of estradiol is also bound, although it has less binding affinity than testosterone for SHBG (38%) and more for albumin (60%); approximately 2% is unbound. Estradiol may be directly conjugated (16α-hydroxylated or 2-hydroxylated) or is metabolized to estrone prior to conjugation. The remaining estrogens are weakly bound to proteins. Progesterone is metabolized into many intermediates prior to conjugation. Pregnanediol glucuronide is the major metabolite observed in the urine.

A variety of clinical conditions results from or cause deviations in normal secretion rates, leading to disturbances in the menstrual cycle. This chapter discusses the normal physiology and touches on several of these hormonal disturbances.

TABLE 13–2 Production rate (PR), secretion rate (SR), and metabolic clearance rate (MCR) of plasma steroids in women.

Compound	MCR of Compound in Peripheral Plasma (L/d)	Phase of Menstrual Cycle	Concentration in Plasma		PR of Circulating Compound (mg/d)	SR by Both Ovaries (mg/d)

PHYSIOLOGY OF FOLLICULOGENESIS AND THE MENSTRUAL CYCLE

The menstrual cycle is regulated by complex interactions between the hypothalamic-pituitary-ovarian (HPO) axis and the uterus. Briefly, the hypothalamus secretes gonadotropin-releasing hormone (GnRH), which stimulates the pituitary to release FSH and LH. These gonadotropins then trigger the ovary to release an oocyte that is capable of fertilization. Concurrently, the ovary secretes hormones, which act on the endometrial lining of the uterus to prepare for implantation. In addition, the ovarian hormones feed back to the hypothalamus and pituitary, regulating the secretion of gonadotropins during the phases of the menstrual cycle. This complex interaction will be discussed in greater detail later. The hormonal changes associated with menstruation are summarized in Figure 13–4.

The Hypothalamic-Pituitary Axis

GnRH is the central initiator of reproduction. GnRH is a 10 amino acid peptide with a short half-life of 2 to 4 minutes. It is processed in specialized secreting neurons that originate in the olfactory placode during development and migrate to the arcuate nucleus of the medial basal hypothalamus (MBH). These neurons project from the median eminence and secrete GnRH, with inherent rhythmic behavior (pulse generator), into the portal vessels to reach the gonadotropes within the anterior pituitary. Kisspeptins (KiSS-1), which are natural ligands for the orphan G protein-coupled receptor (GPCR) known as GPR54, are key regulators in modulating GnRH activity for the onset of puberty (see Chapter 15)

as well as maintaining its activity in the adult (Figure 13–5). GnRH binds to its receptor, a member of the G protein–coupled 7-transmembrane-spanning receptor superfamily. 1,4,5–inositol triphosphate and diacylglycerol act as second-messengers for GnRH. The pulsatile frequency of GnRH secretion regulates gonadotropin synthesis and the secretion of pituitary gonadotropes (see Chapter 4).

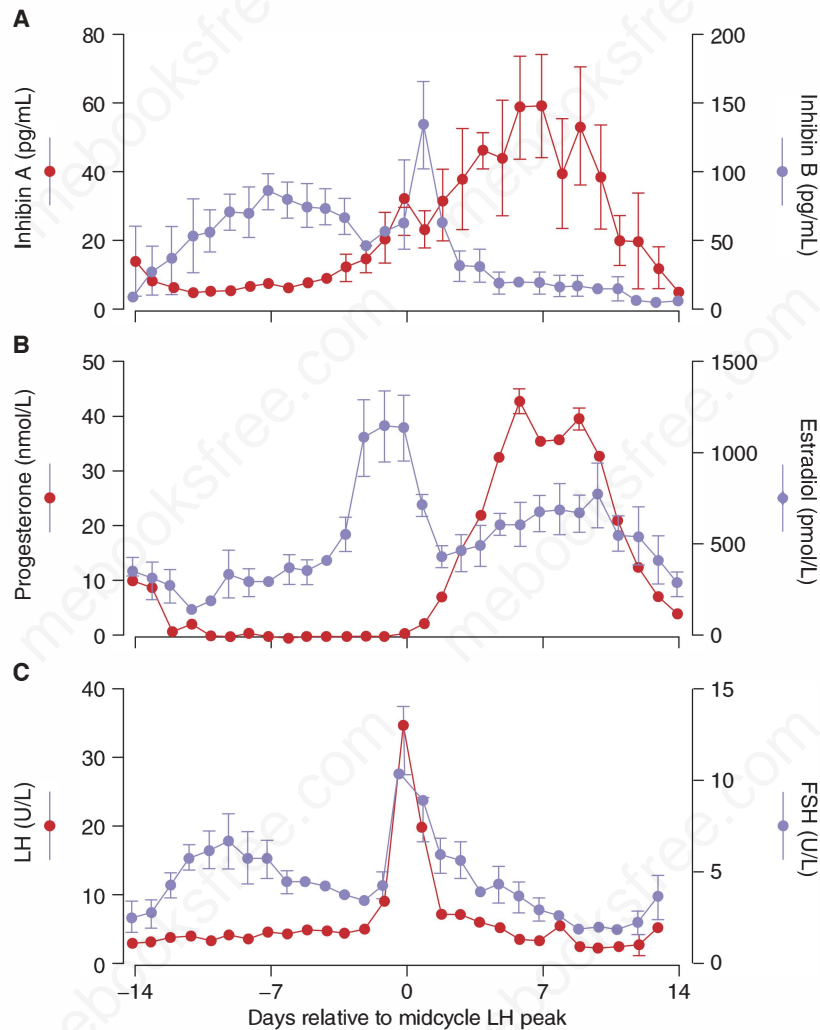
During the late luteal-follicular phase, the slower pulsatile release of GnRH—every 90 to 120 minutes—favors FSH secretion. In response to FSH, the maturing follicle in the ovary secretes estradiol. This hormone is involved in a negative feedback loop that inhibits the release of FSH by indirectly decreasing the production of GnRH via gamma-aminobutyric acid neurons, in addition to possibly having a direct effect on the pituitary gland. Estradiol is also involved in a positive feedback loop that increases the frequency of GnRH pulses to every 60 minutes during the follicular phase and acts directly on the pituitary to stimulate LH secretion. LH stimulates the ovary to further increase estradiol production (see Two-cell Theory later). There is no further change in GnRH pulsatility at this point in the cycle; however, estradiol and other regulatory factors (see later) increase pituitary sensitivity to GnRH. This increased sensitivity results in a rapid elevation of LH production—the LH surge—which stimulates ovulation. After ovulation, the ruptured follicle (corpus luteum) secretes progesterone. This hormone is involved in a negative-feedback loop, indirectly through increased endogenous opioid activity and possibly directly through a reduction in GnRH pulsatility to every 3 to 5 hours. This favors FSH synthesis during the luteal-follicular transition. As progesterone levels fall again, GnRH pulsatility increases, favoring FSH release.


FIGURE 13–4 The endocrinology of the luteal-follicular transition in women. Data are mean ± SE of daily serum concentrations of FSH, LH, estradiol, progesterone, and immunoreactive inhibin in women with normal cycles. Note the secondary rise in plasma FSH in the late luteal phase (~2 days before menses). (Reproduced with permission from Lobo R. Menopause: Biology and Pathobiology. *Academic Press*; 2000.)

Role of the Pituitary

Gonadotropes are located in the adenohypophysis and make up approximately 10% of the cells in the pituitary. These cells synthesize and secrete FSH and LH. These hormones, thyroid-stimulating hormone (TSH) and human chorionic gonadotropin (hCG), all belong to a family of glycoprotein hormones. Gonadotropins are functional as heterodimers and are composed of an alpha and a beta subunit. The alpha subunit amino acid sequence is identical for all of the glycoprotein hormones while the beta subunits contain different amino acid sequence and confer unique specificity on the glycoproteins.

The synthesis of FSH and LH mostly occur in the same cell, yet their secretion patterns differ. The secretion of FSH is tightly linked to the expression of the FSH beta subunit. This suggests that there is minimal storage of FSH within the gonadotropes, and the majority of secretion follows more of a constitutive pathway. This is in contrast to LH secretion, in which it is first stored in organelles and then released with the appropriate trigger (regulated pathway). The different oligosaccharides on the beta subunits likely facilitate the intracellular sorting that results in different mechanisms of secretion.

The differential gene expression that leads to the production and release of gonadotropins by cells in the pituitary is influenced by GnRH and ovarian hormones through feedback loops. Slower GnRH pulse frequency enhances FSH beta subunit expression and increases LH amplitude. In turn, increased GnRH pulse frequency stimulates LH beta subunit expression while promoting FSH release. As a result, LH amplitude decreases while the mean concentration rises. Thus, ovarian steroid modification of hypothalamic GnRH pulsatility controls pituitary gonadotrophin production.

An intrapituitary network involves several factors that play a role in regulating gonadotropin synthesis and secretion. The gonadotropes produce and secrete peptides that are in
FIGURE 13–5 Kisspeptin is a key regulator of the hypothalamic-pituitary-gonadal (HPG) axis. KiSS-1 neurons in the anteroventral periventricular nucleus (AVPV) and arcuate nucleus (Arc) within the hypothalamus express kisspeptin, which has an important role in triggering the release of gonadotropin releasing hormone (GnRH). The cognate receptor for kisspeptin is GPR54. GnRH stimulates expression and release of gonadotropins (follicle stimulating hormone [FSH], luteinizing hormone [LH]), which stimulate follicular growth and steroid production in the ovaries. These steroids feedback (positive and negative) to further regulate the HPG axis and synchronize the ovarian cycle. (Reproduced with permission from Roseweir AK and Millar RP. The role of kisspeptin in the control of gonadotrophin secretion. *Hum Reprod Update.* 2009 Mar-Apr;15(2): 203-212.)

the transforming growth factor (TGF) family. Activin is a local regulatory protein that is involved in control of gonadotrope function. Slow pulses of GnRH enhance activin synthesis, which subsequently enhances FSH transcription. Follistatin, another TGF-related protein that binds to activin, is stimulated by rapid pulses of GnRH. This decreases the bioavailability of activin and consequently reduces FSH synthesis. In addition to these local modifiers, ovarian TGFs such as inhibin also modulate the expression of gonadotropins (see later).

Role of the Ovary

The ovary is intimately involved in regulating the menstrual cycle via steroid feedback to alter gonadotropin secretion. In addition, the ovary contains an intraovarian network involving factors that are synthesized locally and have a paracrine and autocrine role in the modulation of gonadotropin activity. The intraovarian regulators include the insulin-like growth factor (IGF) family, TGF

superfamily, and epidermal growth factor (EGF) family. Furthermore, it is these factors that assist in the coordination of follicular development, steroidogenesis, and ovulation.

The menstrual cycle of the ovary includes a follicular phase and a luteal phase. The follicular phase is characterized by growth of the dominant follicle and ovulation. It typically lasts 10 to 14 days. It is, however, this phase that is variable in duration and most often accounts for the variability in menstrual cycle length in ovulatory women. The luteal phase starts after ovulation and is the period when the ovary secretes hormones that are essential to accommodate conceptus implantation. This phase is relatively constant and averages 14 days (range, 12-15 days) in duration. The next section will describe the two phases in some detail.

Primordial follicles are the fundamental reproductive units that comprise the pool of oocytes that remain arrested in prophase 1 until just prior to ovulation. The meiotic arrest is maintained with the constitutive activity of a G-protein-dependent signaling pathway (Figure 13–6). Morphologically, they are composed of a primary oocyte that is surrounded by a single layer of squamous granulosa cells and a basement membrane. They have no blood supply. These primordial follicles develop between the sixth and ninth months of gestation and harbor the complete supply of ovarian follicles.

The initiation of follicular growth begins with the transition of the dormant primordial follicle into the growth phase. The exact mechanisms controlling the initial recruitment of the primordial follicle are under investigation. It is suggested that the resting follicular pool is probably under tonic inhibitory control. The initial recruitment process induces growth in some primordial follicles; other neighboring follicles remain quiescent for many months or years. It is thought that the recruitment of these follicles is a continuous process that begins once the germ pool is created and ends with follicular exhaustion. This complex process is gonadotropin-independent. Several studies have suggested that an intraovarian signaling network, involving members of the TGF superfamily, is responsible for primordial follicle recruitment. It is also known that recruitment and growth of the follicle absolutely requires cell-to-cell contact with neighboring granulosa cells and the oocyte. These cells transfer various factors, nutrients, and waste to and from the oocyte through gap junctions derived from connexins. One theory proposes that the oocyte actively influences its own fate by secreting various factors. These include two particular growth factors related to TGF-β, which are produced by the oocyte early in follicular development, growth differentiation factor (GDF)-9 and bone morphogenic protein (BMP)-15. Knockout mouse studies suggest that the oocyte induces granulosa cell proliferation through these growth factors, and the granulosa cell responds with factors (eg, follistatin, c-kit) to decrease the inhibitory influences (eg, activin A, Müllerian-inhibiting substance) and promote stimulators of oocyte growth (Figure 13–7).

Several other local factors have been described to date, and many more will be identified in the future. The ongoing search for these growth factors and hormones will ultimately elucidate the physiology of primordial follicle recruitment. There is a finite number of germ cells, and each successive recruitment further depletes the germ cell pool. Any abnormality that alters the

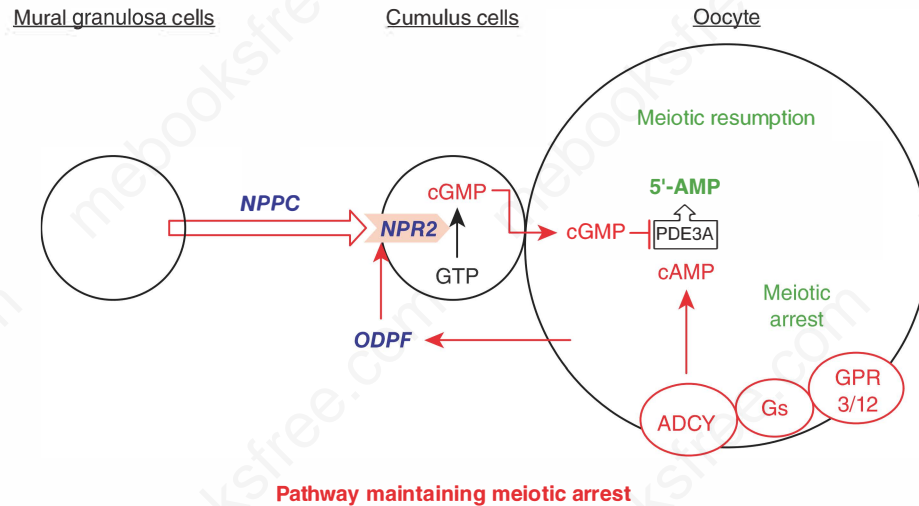
Pathway maintaining meiotic arrest


FIGURE 13–6 The meiotic arrest is maintained with the constitutive activity of a G-protein-dependent signaling pathway. Mural granulosa cells secrete natriuretic peptide, type C (NPPC). NPPC acts on its receptor (NPR2), a particulate guanylyl cyclase that is expressed on the cumulus cells, to produce cGMP. cGMP is transferred to the oocyte via gap junctional communication. In the oocyte, cGMP inhibits the degradation of another cyclic nucleotide, cyclic adenosine monophosphate (cAMP). cAMP levels are controlled primarily by the type 3 phosphodiesterase (PDE3), an enzyme whose activity is antagonized by cGMP. The oocyte is dependent on cAMP to maintain arrest. cAMP production within the oocyte is maintained through constitutive activation of G-protein-coupled receptors (ie, GPR3, GPR12) which stimulate adenylyl cyclase. (Reproduced with permission from Zhang M, Su Y-Q, Sugiura K, et al. Granulosa cell ligand NPPC and its receptor NPR2 maintain meiotic arrest in mouse oocytes. *Science*. 2010 Oct 15;330(6002):366-369.)
FIGURE 13–7 A theoretical model of follicular recruitment into the growth phase. Initiation of follicular growth may be regulated by many local inhibitory and stimulatory factors (ie, inhibin A, follistatin, kit ligand) and begins with transformation of the granulosa cells from squamous to cuboidal shape. Oocytes subsequently commence growth and regulate proliferation and differentiation of granulosa cells with members of the transforming growth factor β superfamily (ie, GDF-9, BMP15). Phase 1: transition of granulosa cells from flattened to cuboidal. Phase 2: oocyte growth and proliferation and differentiation of granulosa cells. (Adapted with permission from Braw-Tal R. The initiation of follicle growth: the oocyte of the somatic cells? *Mol Cell Endocrinol*. 2002 Feb 22;187(1-2):11-18.)

number of germ cells or accelerates recruitment could perhaps lead to early ovarian follicular depletion and, therefore, early reproductive failure (see section on Infertility later).

Primary follicle development is the first stage of follicular growth (Figure 13–8). Primary follicles differ from primordial follicles in several ways. The oocyte begins to grow. As growth progresses, the zona pellucida is formed. This is a thick layer of glycoprotein that is most likely synthesized by the oocyte. It completely surrounds the oocyte and forms a barrier between the oocyte and the granulosa cell layer. It serves a number of biologic functions that are critical for protection of the oocyte and conception. Finally, the granulosa cells undergo a morphologic change from squamous to cuboidal. This stage of development may last 150 days.

The progression to a **secondary follicle** includes attainment of maximal oocyte growth (120 μm in diameter), proliferation of granulosa cells, and acquisition of theca cells (see Figure 13–8). The exact mechanism involved in acquiring theca cells is not completely understood, but they are thought to be derived from the surrounding ovarian mesenchyme (stromal fibroblasts) as the developing follicle migrates to the medulla. It is the development of this layer that gives rise to the theca interna and theca externa. With theca cell development, these follicles gain an independent blood supply, although the granulosa cell layer remains avascular. In addition, the granulosa cells in the secondary follicle develop

FSH, estrogen, and androgen receptors. This phase of follicular development may take as long as 120 days, probably because of the long doubling time (>250 hours) of granulosa cells.

Further follicular development leads to the tertiary follicle or early antral phase (see Figure 13–8). This phase is characterized by the formation of an antrum or cavity in the follicle. The antral fluid contains steroids, proteins, electrolytes, proteoglycans, and an ultrafiltrate that forms from diffusion through the basal lamina. Other changes in this phase include further theca cell differentiation. Subpopulations of thecal interstitial cells develop within the theca interna, acquire LH receptors, and are capable of steroidogenesis. The granulosa cells, as well, begin to differentiate into distinct cell layers: the mural granulosa cells line the follicle wall and abut the basement membrane, and the cumulus cells are those adjacent to the oocyte. These two cell populations have different gene expression profiles and exhibit highly divergent behaviors during folliculogenesis, oocyte maturation, and ovulation.

This differentiation process is influenced by FSH and unidentified signals originating from the oocyte. It is suggested that oocyte-derived GDF-9, is an important factor in this process, where the relative concentration of GDF-9 dictates the specific subtype of granulosa cell.

An example of how the granulosa cell layers differ in activity is in the maintenance of oocyte meiotic arrest (see Figure 13–6). Both cell types acquire FSH receptors. However, the mural
FIGURE 13–8 The chronology of folliculogenesis in the human ovary. Folliculogenesis is divided into two major periods: preantral (gonadotropin independent) and antral (FSH dependent). In the preantral period, a recruited primordial follicle develops into the primary/secondary (class 1) and early tertiary (class 2) stages, at which time cavitation or antrum formation begins. The antral period includes the small graafian (0.9-5 mm, classes 4 and 5), medium graafian (6-10 mm, class 6), large graafian (10-15 mm, class 7), and preovulatory (16-20 mm, class 8) follicles. Time required for completion of preantral and antral periods is approximately 300 and 40 days, respectively. Number of granulosa cells (gc), follicle diameter (mm), and atresia (%) are indicated. (Reproduced with permission from Gougeon A. Regulation of ovarian follicular development in primates: facts and hypotheses. *Endocr Rev.* 1996 Apr;17(2):121-155.)

granulosa cells respond to FSH by secreting an oocyte maturation inhibitor (OMI), natriuretic peptide, type C (NPPC). NPPC acts on its receptor, the type 2 natriuretic peptide receptor (NPR2), a particulate guanylyl cyclase that is expressed on the cumulus cells, to produce cGMP. cGMP is transferred to the oocyte via gap junctional communication. In the oocyte, cGMP inhibits the degradation of another cyclic nucleotide, cyclic adenosine monophosphate (cAMP). cAMP levels are controlled primarily by the type 3 phosphodiesterase (PDE3), an enzyme whose activity is antagonized by cGMP. The oocyte is dependent on cAMP to maintain arrest. cAMP production within the oocyte is maintained through constitutive activation of G-protein-coupled receptors (ie, GPR3, GPR12) which stimulate adenylyl cyclase. The oocyte maintains meiotic arrest through folliculogenesis and resumes just prior to ovulation (see later).

Both granulosa cell types—most likely in response to FSH—start producing activin, a member of the TGF family, in this phase. Activin is composed of two types of beta subunits, βA and βB, which are held together by disulfide bonds. It is the combination of these subunits that generates the various activins (activin AA [βA,βA], AB [βA,βB], or BB [βB,βB]). It is unlikely that activin has an endocrine role, because serum activin levels do not change throughout the menstrual cycle and the free-activin level in the serum is negligible. Activin's primary activity is within the ovary, where it plays an autocrine role by enhancing FSH receptor gene expression in the granulosa cells and accelerating folliculogenesis.

Follicular growth during the early antral phase occurs at a slow and constant pace. The follicle achieves a diameter of 400 μm. FSH-stimulated mitosis of granulosa cells is the major contributor to follicular growth at this stage. Until this point, follicular growth and survival are largely independent of gonadotropins. In fact, prepubertal females and women taking oral contraceptives may have follicles arrested at various phases up until this point. It is at this phase in follicular development that FSH is critical for growth and survival. If FSH does not rescue these follicles, they undergo atresia.

The morphologic follicular unit, consisting of theca cells and granulosa cells, is also a functional hormonal unit capable of substantial estrogen production (Two-cell Hypothesis; Figure 13–9). The thecal interstitial cells and granulosa cells are under the direct influence of LH and FSH, respectively. The gonadotropins increase cyclic adenosine monophosphate (cAMP) production and the activity of the transcription factor SF-1 in the respective cell types.

In the theca cell, LH increases the number of LH receptors on the cell surface and the expression and activity of StAR, P450scc, 3β-HSD-II, and P450c17 to increase androgen production. FSH increases the expression of aromatase and 17β-HSD within the granulosa cell.

The pathway of androgen synthesis is shown in Figure 13–3. Androgens may be formed in one of two ways: (1) Δ5 pathway, which entails dehydroepiandrosterone (DHEA) as the precursor to androgens, and (2) Δ4 pathway, which synthesizes androgen through 17-OH progesterone. However, in the human, the contribution of the Δ4 pathway for androgen production appears minimal. This is due to 17,20-lyase activity having a much higher affinity for 17-OH pregnenolone than 17-OH progesterone. Therefore, the main precursor to sex steroids in the human is DHEA.

The androgens—mainly androstenedione—then diffuse through the basal lamina of the follicle and are the main precursors that granulosa cells utilize for estrogen production through the activity of the aromatase enzyme. However, the pathway of estradiol biosynthesis is dictated by the type of 17β-HSD that is expressed. In humans, seven 17β-HSDs have been identified, each having different affinities for particular steroids. In the granulosa cell, it is type 1 17β-HSD that is expressed preferentially reducing estrone to yield estradiol. Type 3 17β-HSD preferentially reduces androstenedione to testosterone and is expressed in the Leydig cells and not in the ovary. However, type 5 17β-HSD is expressed in the theca cells and is likely the catalyst for the final step in testosterone synthesis from androstenedione in the ovary. In summary, the major pathway of estradiol biosynthesis within the granulosa cell entails androstenedione aromatization to estrone by aromatase, followed with a reduction to estradiol by type 1 17β-HSD.

The importance of estradiol on folliculogenesis with respect to its negative and positive feedback effects on gonadotropin secretion is well established. However, the role of estradiol in local oocyte maturation and follicular growth remains controversial. There is evidence that estrogen is synergistic with FSH during the follicular phase by increasing FSH and LH receptors, stimulating proliferation of granulosa cells and gap junctions as well as aromatase activity. The aromatase knockout (ArKO) mouse suggests a local role for estrogen. The ArKO mouse initially has large antral follicles, but after the first year, there are no remaining antral follicles or secondary follicles, and atresia is evident among the remaining primary follicles. However, the ArKO oocytes are capable of *in vitro* maturation and blastocyst formation. There is evidence that both estrogen receptors are expressed in the granulosa and theca cells. Studies with the estrogen receptor α knockout mice show these mice are infertile and lack graafian follicles. However, the estrogen receptor β knockouts are fertile but produce smaller litters. In humans, there are cases where follicular development has occurred in the absence of estradiol secretion. This was observed in a woman with CYP17α deficiency where promotion of follicular growth was noted with gonadotropins. Embryo development followed *in vitro* fertilization, but unfortunately no pregnancy resulted.

Intraovarian factors play a major modulatory role in both folliculogenesis and steroidogenesis. The oocyte-derived factor GDF-9 is expressed throughout folliculogenesis. It is thought not only to promote granulosa cell differentiation but also to have a stimulatory effect on theca cells and an inhibitory effect on luteal cell formation. The IGFs enhance the response to FSH. *In vitro* studies have shown that both IGF-1 and IGF-2 increase granulosa cell proliferation and estradiol secretion. However, it is suggested that IGF-2 rather than IGF-1 plays a dominant role in follicular maturation. This may be explained by the absence of IGF-1 expression in the granulosa cells of dominant follicles. Furthermore, women with Laron syndrome (IGF-1 deficiency) can be induced to ovulate by ovarian stimulation with gonadotropins.
FIGURE 13–9 Two-cell hypothesis. **A.** The preovulatory follicle produces estradiol through a paracrine interaction between theca and granulosa cells. The theca cells provide the substrate, androstenedione, to the granulosa cell for estradiol production. The granulosa cells express the enzymes necessary for transformation of androstenedione to estradiol (P450 aromatase, 17β hydroxysteroid dehydrogenase-1). **B.** In the corpus luteum, granulosa-lutein cells gain vascularity, LH receptors, and the enzymes necessary for progesterone synthesis. The theca-lutein cells remain the source of androstenedione for estradiol production in granulosa-lutein cells. Gonadotropins, steroidogenic factor-1 (SF-1), and steroidogenic acute regulatory protein (StAR) play crucial roles in steroidogenesis with the ovary (ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; FSH-R, follicle-stimulating hormone receptor; LH-R, luteinizing hormone receptor; P450 arom, P450 aromatase; 17β-HSD-I, 17β hydroxysteroid dehydrogenase-I). (Modified with permission from Larsen PR. *Williams Textbook of Endocrinology*, 10th ed. Philadelphia: Saunders; 2003.)

This scenario suggests that IGF-1 is not critical for folliculogenesis.

The granulosa cells produce other hormones (members of the TGF-β family) that regulate folliculogenesis (see Activin discussed earlier). The granulosa cells synthesize the alpha subunit, which combines with beta subunits to create a heterodimer known as inhibin A (αβA) or inhibin B (αβB). The role of inhibins in folliculogenesis and steroidogenesis is largely indirect; it suppresses pituitary FSH secretion. The serum concentrations of inhibin A and B are influenced by the menstrual rhythm. The circulating levels of inhibin A rise late in the follicular phase and remain elevated in the luteal phase whereas the concentration of inhibin B mirrors the menstrual pattern of serum FSH levels (see Figure 13–4). Although inhibin B expression is increased within the granulosa cell on stimulation with FSH, the follicular concentration of inhibin B does not change with follicular size. It has been suggested that the serum concentration of inhibin B reflects the volume of granulosa cells within the ovary, thereby serving as an indicator of the size of the growing cohort of follicles (ovarian reserve). Because inhibin B is the primary inhibitor of pituitary production of FSH in the follicular phase in the absence of estradiol, measuring baseline FSH circulating levels early in the follicular phase (cycle day 3) serves as indirect marker of ovarian reserve (see section on Infertility later).

The antral growth phase of follicular development is characterized by rapid follicle growth (1-2 mm/d) and is gonadotropin-dependent. In response to FSH, the antral follicle rapidly grows to a diameter of 20 mm, primarily as a result of accumulation of antral fluid. The theca interna continues to differentiate into interstitial cells that produce increasing amounts of androstenedione for aromatization to estrone. The granulosa cell layers have continued to differentiate from each other. The mural layer, through the action of FSH, acquires LH receptors. This differs from the cumulus layer, which has low or undetectable levels of LH receptors. The final progression to a mature graafian follicle is a selection process that in most cases generates one dominant follicle destined for ovulation.

The selection process actually begins in the midluteal phase of the previous cycle. The rise in estrogen level that is generated by the preovulatory follicle augments FSH activity within the follicle, while exerting negative feedback on the pituitary release of FSH. The decrease in pituitary release of FSH results in withdrawal of gonadotropin support from the smaller antral follicles, promoting their atresia. The dominant follicle continues to grow, despite decreasing levels of FSH, by accumulating a greater mass of granulosa cells with more FSH receptors. Increased vascularity of the theca cells allows preferential FSH delivery to the dominant follicle despite waning FSH levels. Increased estrogen levels in the follicle facilitate FSH induction of LH receptors on the granulosa cells, allowing the follicle to respond to the ovulatory surge of LH levels. Without estrogen, LH receptors do not develop on the granulosa cells.

The generation of the LH surge is absolutely required for oocyte maturation (meiotic resumption). The amplified production of LH in the midcycle is due to an increase in pituitary sensitivity to GnRH. The sensitization is mediated by the positive feedback effect of the exponential rise in estrogen and possibly inhibin A. This surge results in the resumption of meiosis I in the oocyte with release of a polar body just prior to ovulation. Evidence suggests the mechanism of meiotic resumption commences with the pre-ovulatory LH surge which decreases C-type natriuretic peptide secretion and consequently leads to a decrease in cGMP production within the granulosa cells. As a result, cGMP concentrations are decreased within the oocyte, and oocyte-specific PDE3 activity increases which decreases cAMP concentrations. The decrease in cAMP leads to activation of an enzyme cascade that allows a burst in Ca^{++} and meiosis resumes.

Just prior to the ovulation, progesterone production increases, and this may be responsible, at least in part, for the midcycle peak in FSH and the coordination of the LH surge. The FSH peak stimulates the production of an adequate number of LH receptors on the mural granulosa cells for luteinization. FSH, LH, and progesterone induce expression of proteolytic enzymes that degrade the collagen in the follicular wall, thereby making it prone to rupture. Prostaglandin (PG) production increases and may be responsible for contraction of smooth muscle cells in the ovary, aiding the extrusion of the oocyte.

The LH surge lasts approximately 48 to 50 hours. Thirty-six hours after onset of the LH surge, ovulation occurs. The feedback signal to terminate the LH surge is not known. Perhaps the rise in progesterone production results in a negative feedback loop and inhibits pituitary LH secretion by decreasing the pulsatility of GnRH. In addition, just prior to ovulation, LH downregulates its own receptors, which decreases the activity of the functional hormonal unit. As a result, estradiol production decreases.

Following ovulation and in response to LH, the mural granulosa cells and thecal interstitial cells that remain in the ovulated follicle differentiate into granulosa lutein and theca lutein cells, respectively, to form the corpus luteum. In addition, LH induces the granulosa lutein cells to produce vascular endothelial growth factor (VEGF), which plays an important role in developing the corpus luteum vascularization. This neovascularization penetrates the basement membrane and provides the granulosa lutein cells with LDL for progesterone biosynthesis. After ovulation, the luteal cells upregulate their LH receptors by an unknown mechanism. This is critical in that it allows basal levels of LH to maintain the corpus luteum. Rescue of the corpus luteum with hCG from the developing conceptus works through the LH receptor, which is vital for embryonic life.

Hormone production by the corpus luteum requires the cooperation of theca lutein and granulosa lutein cells, much like the preovulatory follicle (see Figure 13–9). In response to LH and hCG, the theca lutein cells increase the expression of all the enzymes responsible for androstenedione production (see earlier). Aromatase activity is increased in the granulosa lutein cells by LH to aromatize the androgens to estrogen. A notable difference in the granulosa lutein cells, as opposed to the preovulatory granulosa cells, is that LH also induces the expression of P450scc and 3β-HSD, which enables the cell to synthesize progesterone. The secretion of progesterone and estradiol is episodic and correlates with the LH pulses. FSH has minimal influence on progesterone production but continues to stimulate estrogen production during

the luteal phase. The progesterone levels rise and reach a peak on approximately day 8 of the luteal phase. The luteal phase lasts approximately 14 days.

The corpus luteum starts to undergo luteolysis (programmed cell death) approximately 9 days after ovulation. The mechanism of luteal regression is not completely known. Once luteolysis begins, there is a rapid decline in progesterone levels. A number of studies suggest that estrogen has a role in luteolysis. It has been shown that direct injection of estrogen into the ovary containing a corpus luteum induces luteolysis and a fall in progesterone levels. Experimental data suggest that there is increased aromatase activity in the corpus luteum just prior to luteolysis. The rise in aromatase activity is secondary to gonadotropin (FSH and LH) stimulation, although later in the luteal phase, FSH probably plays a more important role. Consequently, estrogen production increases, and this decreases 3β-HSD activity. This may result in a decline in progesterone levels and lead to luteolysis. Furthermore, local modifiers such as oxytocin, which is secreted by luteal cells, have been shown to modulate progesterone synthesis. Other evidence supports the role of PGs in luteolysis. Experimental data suggest that $PGF_{2\alpha}$, which is secreted from the uterus or ovary during the luteal phase, stimulates the synthesis of cytokines such as tumor necrosis factor; this causes apoptosis and, therefore, may be linked to corpus luteum degeneration.

The process of luteolysis is known to involve proteolytic enzymes. Evidence suggests that matrix metalloproteinase (MMP) activity is increased during luteolysis. hCG is a known modulator of MMP activity. This may play an important role in early pregnancy, when hCG rescues the corpus luteum and prevents luteal regression. However, in the absence of pregnancy, the corpus luteum regresses, resulting in a decrease in progesterone, estradiol, and inhibin A levels. The decrease in these hormones allows for increased GnRH pulsatility and FSH secretion. The rise in FSH will rescue another cohort of follicles and initiate the next menstrual cycle.

Role of the Uterus

The sole function of the uterus is to accommodate and support a fetus. Furthermore, it is the endometrium, the lining of the uterine cavity, that differentiates during the menstrual cycle so that it can support and nourish the conceptus. Histologically, the endometrium is made up of an epithelium, composed of glands and a stroma that contains stromal fibroblasts and extracellular matrix. The endometrium is divided into two layers based on morphology: the basalis layer and the functionalis layer. The basalis layer lies adjacent to the myometrium and contains glands and supporting vasculature. It provides the components necessary to develop the functionalis layer. The functionalis is the dynamic layer that is regenerated every cycle. More specifically, it is this layer that can accommodate implantation of the blastocyst.

During the menstrual cycle, the endometrium responds to hormones secreted from the ovaries. Somewhat like the other endocrine organs, it contains a network of local factors that modulate hormonal activity. The endometrial phases are coordinated with ovulatory phases. During the follicular phase, the endometrium goes through the proliferative phase. It begins with the onset of menses and ends at ovulation. During the luteal phase, the endometrium undergoes the secretory phase. It starts at ovulation and ends just before menses. If implantation does not occur, a degenerative phase follows the secretory phase within the endometrium. It is this phase that results in menstruation. The next section will discuss the phases of the endometrium in more detail.

During the follicular phase, the ovary secretes estrogen, which stimulates the glands in the basalis to initiate formation of the functionalis layer. Estrogen promotes growth by enhancing gene expression of cytokines and a variety of growth factors, including EGF, TGFα, and IGF. These factors provide a microenvironment within the endometrium to modulate the effects of hormones. At the beginning of the menstrual cycle, the endometrium is thin—usually less than 2 mm in total thickness. The endometrial glands are straight and narrow and extend from the basalis toward the surface of the endometrial cavity. As the epithelium and the underlying stroma develop, they acquire estrogen and progesterone receptors. The spiral blood vessels from the basalis layer extend through the stroma to maintain blood supply to the epithelium. Ultimately, the lining (functionalis) surrounds the entire uterine cavity and achieves a thickness of 3 to 5 mm in height (total thickness 6-10 mm). This phase is known as the proliferative phase.

After ovulation, the ovary secretes progesterone, which inhibits further endometrial proliferation. This mechanism may be mediated by antagonizing estrogen effects. Progesterone downregulates estrogen receptors in the epithelium and regulates estradiol metabolism within the endometrium by stimulating 17β-HSD activity and converting estradiol into the weaker estrogen, estrone. During the luteal phase, the glandular epithelium accumulates glycogen and begins to secrete glycopeptides and proteins—along with a transudate from plasma—into the endometrial cavity. It is this fluid that provides nourishment to the free-floating blastocyst. Progesterone also stimulates differentiation of the endometrium and causes characteristic histologic changes. The glands become progressively more tortuous, and the spiral vessels coil and acquire a corkscrew appearance. The underlying stroma becomes very edematous as a result of increased capillary permeability, and the cells begin to appear large and polyhedral, with each cell developing an independent basement membrane. This process is termed predecidualization. These cells are very active and respond to hormonal signals. They produce PGs along with other factors that play an important role in menstruation, implantation, and pregnancy. This phase is known as the secretory phase.

If there is no implantation of an embryo, the endometrium enters the degenerative phase. Estrogen and progesterone withdrawal promotes PG production—$PGF_{2\alpha}$ and PGE_2. These PGs stimulate progressive vasoconstriction and relaxation of the spiral vessels. These vasomotor reactions lead to endometrial ischemia and reperfusion injury. Eventually, there is hemorrhage within the endometrium with subsequent hematoma formation. The progesterone withdrawal triggers MMP activity, which facilitates degradation of the extracellular matrix. As ischemia and degradation progress, the functionalis becomes necrotic and sloughs away as

menstruum consisting of endometrial tissue and blood. The amount of blood lost in normal menses ranges from 25 mL to 60 mL. Although $PGF_{2\alpha}$ is a potent stimulus for myometrial contractility and limits postpartum bleeding, it has minimal impact on cessation of menstrual bleeding. The major mechanisms responsible for limiting blood loss involve the formation of thrombin-platelet plugs and estrogen-induced healing of the basalis layer by reepithelialization of the endometrium, which begins in the early follicular phase of the next menstrual cycle.

If conception takes place, implantation can occur in the endometrium during the midsecretory (midluteal) phase, at which time it is of sufficient thickness and full of sustenance. The syncytiotrophoblast subsequently secretes hCG, which rescues the corpus luteum and maintains progesterone secretion, essential for complete endometrial decidual development.

In summary, the ovary has two phases during the menstrual cycle: the follicular phase and the luteal phase. The endometrium has three phases and is synchronized by the ovary. The complex feedback loops between the ovary and the hypothalamic-pituitary axis regulate the menstrual cycle. During the follicular phase, the ovary secretes estradiol, which stimulates the endometrium to undergo the proliferative phase. After ovulation (luteal phase), the ovary secretes estrogen and progesterone, which maintains the endometrial lining and promotes the secretory phase. In a nonpregnant cycle, luteolysis occurs, resulting in cessation of hormone production. This hormone withdrawal results in the degenerative phase and the onset of menses.

MENSTRUAL DISTURBANCES

AMENORRHEA

The mean age of menarche is 12.8 years. Normally, this event marks the completion of puberty. The onset of regular cyclicity in the menstrual cycle is determined by the duration of the maturation process of the HPO axis, which is quite variable. As a result, anovulation can occur in 50% to 80% of girls 2 years after menarche, and in more than 20% of girls, it can persist until 5 years after menarche. This period of time can be frustrating for many girls and their parents. The evaluation should include a clinical examination and reassurance. If positive findings are noted, limited, pertinent diagnostic tests (see later) are indicated.

Amenorrhea can be defined as either the absence of menarche by age 16 or no menses for more than three cycles in an individual who has previously had cyclic menses. The definition, although arbitrary, nonetheless gives a general guideline to the clinician for further evaluation. Although amenorrhea does not cause harm, in the absence of pregnancy, it may be a sign of genetic, endocrine, and/or anatomic abnormalities. If the outflow tract is intact, amenorrhea is most likely the result of disruption in the HPO axis. These aberrations can affect any level of control in the menstrual cycle and, thus, result in menstrual abnormalities.

Amenorrhea was formerly classified as primary or secondary depending on whether the individual had experienced menses in the past. This classification may lead to misdiagnosis of the cause of amenorrhea. Although primary amenorrhea is more often associated with genetic and anatomic abnormalities, each individual should be assessed by means of the history and clinical findings, including the presence or absence of secondary sexual characteristics (Table 13–3). The causes of amenorrhea are grouped according to the level of involvement in the regulatory systems that govern normal menstrual activity (ie, hypothalamic, pituitary, ovarian, and uterine). An algorithm for the workup of amenorrhea or oligomenorrhea in the presence of secondary sexual characteristics is illustrated in Figure 13–10.

HYPOTHALAMIC AMENORRHEA

Isolated GnRH Deficiency

The hypothalamus is the source of GnRH, which directs the synthesis and secretion of pituitary gonadotropins. Dysfunction at this level leads to hypogonadotropic hypogonadism or eugonadotropic hypogonadism. Disorders of GnRH production can be due to genetic or hormonal causes within the hypothalamic-pituitary-adrenal axis (Figure 13–11) and result in a wide range of clinical manifestations. The individual's appearance is dependent on the age at onset and the degree of dysfunction.

Isolated GnRH deficiency results in hypogonadotropic hypogonadism. Female patients present with amenorrhea, and females and males present with absent or incomplete pubertal development secondary to absent or diminished sex steroids (estradiol in females, testosterone in males). They have normal stature with a eunuchoidal body habitus. Because the adrenal glands are unaffected by the absence of GnRH, body hair distribution is not affected.

A. Genetic origin Several genetic lesions associated with GnRH deficiency have been described. The best characterized form of GnRH deficiency is Kallmann syndrome, which involves the *Kal-1* gene as well as a number of other genes. The *Kal-1* gene normally codes for anosmin, an adhesion molecule that appears to be involved in the migration of GnRH and olfactory neurons from the olfactory placode to the hypothalamus. The *Kal-1* gene is located on the short arm of the X chromosome. Most cases of Kallmann syndrome are sporadic, although the disorder has also been observed to have a familial pattern, and most often it is transmitted by X-linked recessive inheritance. Autosomal recessive and dominant patterns have been reported but are much less common. When mutations exist in the *Kal-1* gene, there may be associated defects, including anosmia and, less frequently, midline facial defects, renal anomalies, and neurologic deficiency. The disorder affects both sexes, but because of the X-linked inheritance pattern it is more common in boys. Unlike males, the specific genetic mutations in the *Kal-1* gene in females with hypogonadotropic hypogonadism have not been identified, suggesting there are other genetic mutations that cause this disorder. Recently, it was determined that heterozygous mutations in fibroblast growth factor receptor 1 (*FGFR1*) gene, known as the *Kal-2*, were identified in cases of Kallmann syndrome. *FGFR1* and *Kal-1* are coexpressed at the same sites during development and are thought to

TABLE 13–3 Assessment of patients with amenorrhea.

I. **Absent breast development; uterus present**
   A. Gonadal failure
      1. Gonadal agenesis
      2. Gonadal dysgenesis
         a. 45,X (Turner syndrome)
         b. 46,X abnormal X (eg, short- or long-arm deletion)
         c. Mosaicism (eg, X/XX, X/XX/XXX)
         d. 46,XX or 46,XY (Swyer syndrome) gonadal dysgenesis
   B. Defects in estrogen biosynthesis (46,XX)
      1. 17,20-Lyase deficiency
      2. CYP17α deficiency
   C. Hypothalamic failure secondary to inadequate GnRH release
      1. Insufficient GnRH secretion
         a. FHA
         b. Anorexia nervosa and bulimia
         c. CNS neoplasm (craniopharyngioma, gliomas)
         d. Excessive exercise
         e. Constitutional delay
      2. Inadequate GnRH synthesis (Kallmann syndrome)
      3. Developmental anatomic abnormalities in central nervous system
   D. Pituitary failure
      1. Isolated gonadotropin insufficiency
      2. GnRH resistance
      3. Pituitary tumors (hyperprolactinemia)
      4. Pituitary insufficiency
         a. Infections (mumps, encephalitis)
         b. Newborn kernicterus
      5. Prepubertal hypothyroidism
II. **Breast development; uterus absent**
   A. Androgen resistance (androgen insensitivity syndrome)
   B. Congenital absence of uterus (uterovaginal agenesis)
III. **Absent breast development; uterus absent**
   A. Defects in testosterone biosynthesis (46,XY)
      1. 17,20-Lyase deficiency
      2. CYP17α deficiency
      3. 17β-Hydroxysteroid dehydrogenase deficiency
   B. Testicular regression syndrome (46,XY)

IV. **Breast development; uterus present**
   A. Pregnancy

      2. Asherman syndrome

have a functional interaction. Mutations in the *Kiss-1* derived peptide receptor, GPR54, have also been identified in these patients. Several mechanisms of how GPR54 may regulate gonadotropin production via GnRH function or production have been proposed. Several studies have shown that females with presumed Kallmann syndrome demonstrate variable responses to exogenous GnRH administration, which suggests a GnRH receptor defect. In fact, mutations in the GnRH receptor have been identified in both sexes and are inherited in an autosomal recessive fashion.

Management of hypogonadotropic hypogonadism involves scheduled hormone replacement therapy (HT) to stimulate the development of secondary sexual characteristics and increase bone mineral density (BMD). If pregnancy is desired, treatment involves the administration of pulsatile GnRH or gonadotropin treatment.

B. Endocrine causes

1. **Functional hypothalamic amenorrhea**—Functional hypothalamic amenorrhea is one of the most common types of amenorrhea and accounts for 15% to 35% of cases. It is an endocrine disorder, although the exact mechanism has not been definitively determined. It is characterized by a reduced GnRH drive (decrease in pulse frequency and amplitude),

leading to low or low-normal serum levels of FSH and LH and resulting in anovulation. The ratio of serum FSH to LH in these patients is often equivalent to that of a prepubertal female with a relative FSH dominance.

The adipocyte hormone, leptin, has been implicated in the development of this disorder. Leptin is an important nutritional satiety factor, but it is also necessary for maturation of the reproductive system. The potential link to the reproductive system is thought to be through leptin receptors, which have been identified in the hypothalamus and gonadotropes. This is supported by the observation that leptin can stimulate GnRH pulsatility and gonadotropin secretion. Several studies suggest that women with functional hypothalamic amenorrhea have lower serum leptin levels in comparison with eumenorrheic controls. This relative deficiency may lead to a dysfunctional release of GnRH, possibly mediated through a kisspeptin pathway, and subsequent development of functional hypothalamic amenorrhea.

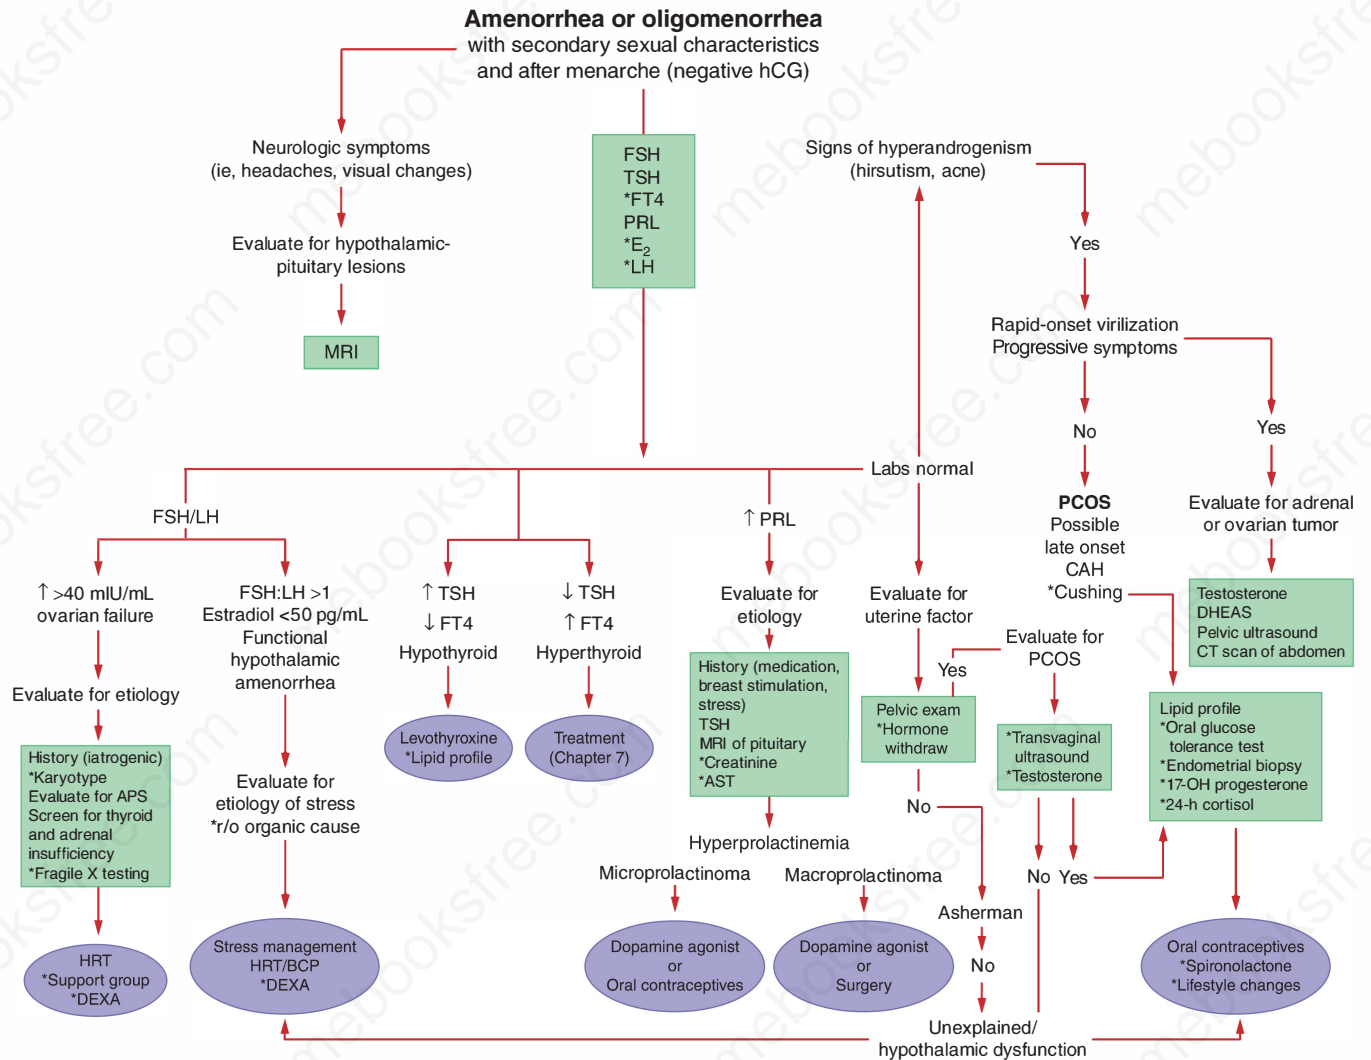
Abnormal, and often subtle, activation of the hypothalamic-pituitary-adrenal axis is associated with functional hypothalamic amenorrhea. The inciting event may be excessive production of corticotropin-releasing hormone (CRH), which has been shown to decrease the pulse frequency of GnRH and increase cortisol levels *in vivo*. In contrast, another study


FIGURE 13–10 An algorithm for women who have developed secondary sexual characteristics, have experienced menarche, and are presenting with amenorrhea or oligomenorrhea. A negative human chorionic gonadotropin test documents the nonpregnant state. All women should be screened for known causes of oligomenorrhea, whether or not hyperandrogenism is present. Hyperandrogenism suggests either polycystic ovarian syndrome (PCOS) or late-onset congenital adrenal hyperplasia (CAH). If rapid in onset, progressive virilization requires an evaluation for an androgen-secreting tumor. Management of late-onset CAH and PCOS is similar. Clinical history and physical findings suggesting hypoestrogenism, stress, or thyroid dysfunction are indications for measurement of estradiol (E_2), luteinizing hormone (LH), and free thyroid hormone (FT4) levels in plasma (APS, autoimmune polyglandular syndrome). *As indicated (refer to text).

suggests that although acute elevations of CRH can suppress GnRH release, this suppression cannot be maintained with CRH alone. The cause of functional hypothalamic amenorrhea often remains unclear, but the associated hypercortisolemia suggests that it is preceded by psychologic stress, strenuous exercise, or poor nutrition. There is support for the concept that these factors may act synergistically to further suppress GnRH drive. In fact, patients with functional hypothalamic amenorrhea, resulting from psychologic stress, are usually high achievers who have dysfunctional coping mechanisms when dealing with daily stress. The severity of hypothalamic suppression is reflected by the clinical manifestations. The significant interpatient variability in the degree of psychologic or metabolic stress required to induce a menstrual disturbance explains the heterogeneity of clinical presentations, ranging from luteal phase defects to anovulation with erratic bleeding to amenorrhea.

Functional hypothalamic amenorrhea is reversible. Interestingly, the factors that have predicted the rate of recovery are body mass index and basal cortisol levels. When patients recover, ovulation is preceded by return of cortisol levels to baseline. Some experts have shown that cognitive behavioral therapy, teaching the patient how to cope with stress—and nutritional consultation—reverse this condition. Complete reversal may be less likely if the functional insult occurs during the period of peripubertal maturation of the HPO axis.

The diagnosis of functional hypothalamic amenorrhea can be made if the FSH-LH ratio is greater than 1 in the presence of hypoestrogenemia. However, a minor disturbance of hypothalamic dysfunction may present with normal laboratory
FIGURE 13–11 Potential hormonal mediators of amenorrhea. There are several conditions that influence the production of hormones which modulate GnRH release. Conditions (ie, stress, Cushings disease) which increase CRH and/or cortisol levels suppress gonadotropin-releasing hormone (GnRH) release and/or decrease LH responsiveness to GnRH. Low leptin levels and likely increased FGF-21 levels (ie, starvation) possibly suppress GnRH release by decreasing kisspeptin expression. Increased thyrotropin releasing hormone (TRH) levels (ie, primary hypothyroidism) stimulate prolactin release. Hyperprolactinemia suppresses GnRH release by decreasing kisspeptin expression, and possibly through a CRH-mediated pathway. High androgen and progesterone levels may be seen in congenital adrenal hyperplasia (CAH), and these hormones likely suppress GnRH release. (Reproduced with permission from Fourman LT, Fazeli PK. Neuroendocrine causes of amenorrhea—an update. *J Clin Endocrinol Metab*. 2015 Mar;100(3):812-824.)

findings, a clinical history that coincides with stress, and a negative evaluation for other causes of anovulation. Interestingly, most of these patients, despite hypoestrogenism, do not have symptoms. The estrogen status should still be evaluated given the strong correlation between hypoestrogenemia and the development of osteoporosis. Estrogen status can be determined by means of the progesterone withdrawal test or by measurement of serum estradiol (<50 pg/mL). If there is no withdrawal or the estradiol is less than 50 pg/mL, HRT with combination contraceptive hormones (or traditional HRT) should be instituted. If withdrawal bleeding occurs, any cyclic progestin-containing therapy is adequate to combat unopposed estrogen and the development of endometrial hyperplasia.

2. **Amenorrhea in the female athlete**—Hypothalamic dysfunction has been observed in female athletes. Competitors in events such as gymnastics, ballet, marathon running, and diving can show menstrual irregularities ranging from luteal phase defects to amenorrhea. The **female athletic triad** as defined by the American College of Sports Medicine is characterized by disordered eating, amenorrhea, and osteoporosis. The associated nutritional deficiencies can lead to impaired growth and delayed sexual maturation. The neuroendocrine abnormalities are similar to those of women with functional hypothalamic amenorrhea.

These patients have very low body fat, often below the tenth percentile. There is evidence that a negative correlation between body fat and menstrual irregularities exists. In addition, there appears to be a critical body fat level that must be present in order to have a functioning reproductive system. Several studies have shown that these amenorrheic athletes have significantly lower serum leptin levels, which further supports leptin's role as a mediator between nutritional status and the reproductive system. The strenuous exercise these athletes engage in amplifies the effects of the associated nutritional deficiency. This synergism causes severe suppression of GnRH, leading to the low estradiol levels.

Amenorrhea alone is not harmful. However, low serum estradiol over a period of time may lead to osteoporosis and delayed puberty. An analysis of estrogen status may be obtained with measurement of serum estradiol levels or with the progestin withdrawal test (see earlier). If estrogen is low, BMD should be assessed by dual-energy x-ray absorptiometry (DXA) scan. All patients diagnosed with female athletic triad need combination contraceptive therapy or HT.

3. **Amenorrhea associated with eating disorders**—Anorexia nervosa is a disorder characterized by relentless dieting in pursuit of a thin body habitus. Approximately 95% of cases occur in females, and the onset is chiefly in adolescence. The clinical features include extreme weight loss leading to a body weight less than 85% of normal for age and height, a distorted body image, and intense fear of gaining weight. These patients usually have a preoccupation with food and are hyperactive, with an obsessive-compulsive personality. The associated symptoms include hypothermia, mild bradycardia, dry skin, constipation, and symptoms of hypoestrogenemia. Furthermore, as part of

the diagnostic criteria, they must experience at least 3 months of no menses.

The dysfunction in the neuroendocrine system is similar to but often more severe than that described in association with functional hypothalamic amenorrhea. The severe reduction in GnRH pulsatility leads to suppression of FSH and LH secretion, possibly to undetectable levels, and results in anovulation and low serum estradiol levels. Given the severe psychologic and metabolic stress experienced by these individuals, the hypothalamic-pituitary-adrenal axis is activated. The circadian rhythm of adrenal secretion is maintained, but both cortisol production and plasma cortisol levels are persistently elevated secondary to increased pituitary secretion of adrenocorticotropic hormone (ACTH). Serum leptin levels in these individuals are significantly lower than normal healthy controls and correlate with percentage of body fat and body weight. A rise in leptin levels in response to dietary treatment is associated with a subsequent rise in gonadotropin levels. This further suggests leptin's role as a potential link between energy stores and the reproductive system.

The self-induced starvation state associated with anorexia nervosa leads to additional endocrine abnormalities not observed in other causes of hypothalamic amenorrhea. For instance, thyroid hormone metabolism is altered. TSH and T_4 levels are in the low-normal range, but T_3 levels are usually below normal. This is attributable to decreased peripheral conversion of T_4 to T_3 and increased conversion of T_4 to the metabolically inactive thyroid hormone, reverse T_3—a change that often resembles other states of starvation. This may be a protective mechanism in that the relative hypothyroid state attempts to reduce basal metabolic function in response to a highly catabolic state.

Bulimia occurs in about half of patients with anorexia and is defined as binge eating followed by self-induced purging. Not all bulimics have low body weight—in fact, normal-weight bulimic individuals are much more common. These patients also have a variety of neuroendocrine aberrations—often to a lesser degree than those with anorexia—which also lead to menstrual disturbances. Leptin levels are lower than in matched controls but not as low as in individuals with anorexia nervosa. They also have neurotransmitter abnormalities—notably low serotonin levels—which might help explain the often coexisting psychologic difficulties.

Anorexia nervosa is a life-threatening illness with a significant mortality rate due to its metabolic consequences. Anorexic patients should be considered for inpatient therapy and management with a multidisciplinary approach that includes nutritional counseling and psychotherapy. Force-feeding may be necessary in some patients. If weight gain cannot be achieved with oral intake, meals may need to be supplemented by enteral or parenteral feeding. Because anorexia nervosa is a hypoestrogenic state and there is a high potential for the development of osteoporosis, all patients should receive hormone therapy either in the form of HT or combination contraceptive pills. It is important to note that many patients with anorexia will continue to have reduced bone size regardless of sex steroid administration presumably due to the concurrent malnutrition and metabolic compromise. Weight rehabilitation and recovery is associated with bone accretion; however, the loss of bone may not be completely reversible.

In summary, the hypothalamic amenorrhea endocrine syndromes are probably a continuum of disordered eating and nutritional deficiencies resulting in increasingly severe abnormalities in the reproductive system. Furthermore, the age at onset affects the potential complications of these disorders. If low estradiol levels are present before age 20, bone mineralization may be profoundly affected, because this period is critical for building peak bone mass. In addition, if these conditions occur prior to puberty, it may result in stunted growth and delayed development of secondary sexual characteristics.

C. Anatomic causes   Numerous anatomic abnormalities within the central nervous system can result in menstrual disturbances. These include developmental defects, brain tumors, and infiltrative disorders. The most common anatomic lesion associated with delayed puberty and amenorrhea is a craniopharyngioma. It is derived from Rathke pouch and extends into the hypothalamus, pituitary, and third ventricle. The symptoms include headaches, visual loss, and hypoestrogenism.

Infiltrative disorders that involve the hypothalamus are uncommon but can result from systemic diseases, including sarcoidosis, histiocytosis, hemochromatosis, and lymphoma. These diseases do not initially present with amenorrhea. However, in the presence of these diseases, the hypothalamus may be affected, so they should be part of the differential diagnosis of amenorrhea.

PITUITARY AMENORRHEA

There are a few genetic mutations affecting the pituitary that cause amenorrhea. Rare autosomal recessive mutations may cause deficiencies in FSH, LH, TSH, prolactin (PRL), and growth hormone (GH). The clinical manifestations may include delayed puberty, a hypoestrogenic state, and infertility.

A. Genetic causes   A deficiency in FSH and LH may be a result of *GnRH receptor* gene mutations. Such mutations are primarily compound heterozygous mutations that affect GnRH receptor–dependent signal transduction. The phenotype of these individuals is similar to that of those with isolated GnRH deficiency. In fact, some investigators speculate that these receptor mutations may be the cause of isolated GnRH deficiency in women, given that no mutations have yet been identified in the ligand or *Kal-1* gene. The estimated prevalence of GnRH receptor mutations in women with hypothalamic amenorrhea is 2%. In a family with other affected females, the prevalence is 7%.

Other rare genetic defects have been associated with amenorrheic women. Mutations in the *FSH*β gene have been reported. These have an autosomal recessive pattern of inheritance and lead to low serum FSH and estradiol levels and high plasma LH levels. The clinical features include minimal development of secondary sexual characteristics and amenorrhea with no history of menses. Combined hormone deficiencies have also been described. Mutations in *Prop-1*, a pituitary transcription factor for Pit-1, lead to deficiencies in gonadotropins, TSH, PRL, and GH. These patients present with stunted growth, hypothyroidism, and delayed puberty in addition to amenorrhea.

B. Endocrine causes   *Hyperprolactinemia* is one of the most common causes of amenorrhea, accounting for 15% to 30% of cases. In the absence of pregnancy or postpartum lactation, persistently elevated PRL is almost always associated with a hypothalamic-pituitary disorder. Normal PRL secretion is regulated by several stimulatory and inhibitory factors (see Chapter 4). PRL secretion is primarily under tonic inhibition by dopamine, so that any interference with dopamine synthesis or transport from the hypothalamus may result in elevated PRL levels. In addition to menstrual disturbances, individuals with hyperprolactinemia may present with galactorrhea. In fact, hyperprolactinemia is a common cause of galactorrhea, and up to 80% of patients with amenorrhea and galactorrhea have elevated PRL levels. Other associated symptoms include headaches, visual field defects, infertility, and osteopenia.

The mechanism whereby hyperprolactinemia causes amenorrhea is not completely known. Studies have shown that PRL can affect the reproductive system in several ways. PRL receptors have been identified on GnRH neurons and may directly suppress GnRH secretion. Others have postulated that elevated PRL levels inhibit GnRH pulsatility indirectly by increasing other neuromodulators such as endogenous opioids. There is also evidence that GnRH receptors on the pituitary may be downregulated in the presence of hyperprolactinemia. Furthermore, PRL may affect the ovaries by altering ovarian progesterone secretion and estrogen synthesis. The best data now available suggest that hyperprolactinemia causes amenorrhea primarily by suppression of GnRH secretion.

Approximately half of patients with elevated PRL levels have radiologic evidence of a pituitary tumor. The most common type is a PRL-secreting tumor (prolactinoma), accounting for 40% to 50% of pituitary tumors. Prolactinomas are composed mainly of lactotrophs, and they secrete PRL. Occasionally these tumors secrete both GH and PRL.

The diagnosis of a pituitary adenoma is usually made by examination of the pituitary with magnetic resonance imaging (MRI). These tumors are categorized into two groups based on their dimensions—microadenomas are those less than 10 mm in diameter and macroadenomas are larger than 10 mm. These tumors are usually located in the lateral wings of the anterior pituitary. Microadenomas are typically wholly contained within the confines of the pituitary gland. Very rarely, a microadenoma infiltrates the surrounding tissue, including the dura, cavernous sinus, or adjacent skull base. A macroadenoma may expand farther and grow out of the sella to impinge on surrounding structures, such as the optic chiasm or may extend into the sphenoid sinus. As a result, macroadenomas are more frequently associated with severe headaches, visual field defects, and ophthalmoplegia. The incidence of a microadenoma progressing to a macroadenoma is relatively low, only 3% to 7%. During pregnancy the risk of a microprolactinoma enlarging is also low, but in the presence of a macroprolactinoma, the chance of tumor growth is up to 25%.

Some investigators have found a correlation between pituitary adenoma size and serum PRL levels. If the serum PRL is less than 100 ng/mL, a microprolactinoma is more likely, whereas if it is greater than 100 ng/mL, a macroprolactinoma is often present.

Although this correlation has been reported, the evidence supporting it is not strong. In fact, low PRL levels may also be associated with nonfunctioning macroadenomas. This is thought to reflect impingement of the adenoma on the pituitary stalk leading to reduced dopamine secretion and loss of the tonic suppression of prolactin secretion. These nonfunctioning tumors may synthesize glycoproteins such as FSH, LH, or their free alpha subunits. Rarely, functioning tumors may arise from other pituitary cells, resulting in excessive hormone secretion. If a macroadenoma is present, measurement of IGF-1, alpha subunit, TSH, and 24-hour urinary cortisol will begin to exclude other functioning adenomas.

Other tumors of nonpituitary origin may also result in delayed puberty and amenorrhea. The most common of these is a craniopharyngioma. Although craniopharyngiomas are commonly located in the suprasellar region, they can also involve the sella. These tumors have not been shown to produce hormones, but because they may compress the infundibulum, they can interfere with the tonic inhibition of PRL secretion and result in mildly elevated PRL levels.

Hyperprolactinemia in a patient with amenorrhea is defined as a PRL level greater than 20 ng/mL, although the upper limit of normal may vary between laboratories. Normal PRL release follows a sleep-circadian rhythm, but PRL may also be secreted in response to stress, physical exercise, breast stimulation, or a meal. Therefore, PRL should be measured in the midmorning hours and in the fasting state. Other causes of mildly elevated PRL include medications such as oral contraceptives, neuroleptics, tricyclic antidepressants, metoclopramide, methyldopa, and verapamil. Hyperprolactinemia has also been observed in several chronic diseases, including cirrhosis and renal disease. Furthermore, inflammatory diseases such as sarcoidosis and histiocytosis can infiltrate the hypothalamus or pituitary and result in hyperprolactinemia. Elevated PRL levels may be a physiologic response. During pregnancy, PRL levels may be two to four times baseline. With postpartum breastfeeding, the PRL level should be below 100 ng/mL after 7 days and below 50 ng/mL after 3 months. If a woman is not breastfeeding, PRL levels should return to baseline by 7 days postpartum.

Persistently elevated PRL levels may also be present in primary hypothyroidism. Approximately 40% of patients with primary hypothyroidism present with a minimal increase in prolactin (25-30 ng/mL), and 10% present with even higher serum levels. Individuals with primary hypothyroidism have an increase in thyrotropin-releasing hormone (TRH) from the hypothalamus, which stimulates TSH and PRL release and leads to hyperprolactinemia. Patients with longstanding primary hypothyroidism may eventually manifest profound pituitary enlargement due to hypertrophy of thyrotrophs. This mass effect with elevated PRL levels mimics a prolactinoma. Therefore, all patients with hyperprolactinemia should have their thyroid function investigated to exclude hypothyroidism as the cause.

Prolactinomas are the most common cause of persistent hyperprolactinemia. All patients with elevated PRL levels should have the test repeated for verification. In addition to blood tests, a careful clinical and pharmacologic history and physical examination

should be performed to exclude other causes of hyperprolactinemia. If elevated PRL levels persist or if any measurement is found to be above 100 ng/mL, MRI of the hypothalamic-pituitary region should be performed. If a microadenoma is observed, the diagnosis of microprolactinoma can be made. If a macroadenoma is observed, other pituitary hormones should be measured to exclude other functioning adenomas or hypopituitarism. All patients diagnosed with macroadenoma should have a visual field examination.

The treatment of choice for prolactinoma is dopamine agonist therapy. These drugs (bromocriptine, cabergoline, pergolide, quinagolide) are very effective at lowering PRL levels, resolving symptoms, and causing tumor shrinkage. Treatment results in a rapid reduction in PRL levels in 60% to 100% of cases. Following reduction of PRL levels, 60% to 100% of women resume ovulatory menses within 6 weeks, and galactorrhea disappears within 1 to 3 months after starting treatment. Reduction in tumor size is usually evident after 2 to 3 months of drug therapy, but it may occur within days after initiation of treatment. The extrasellar portion of the tumor appears to be particularly sensitive to drug therapy, which explains the improvement in symptoms such as visual impairment or ophthalmoplegia with drug therapy. In patients diagnosed with a microadenoma that is manifested only as a menstrual disturbance, observation should only be considered if the patient does not desire conception. These individuals should be offered oral contraceptives to control the bleeding pattern and to protect bone from estrogen deficiency. However, the long-term sequelae of persistently elevated PRL levels are unknown. If dopamine agonist treatment is initiated for a microadenoma, therapy may be continued long term. If the tumor responds, the dose may be tapered and stopped after menopause. Many individuals with a macroadenoma take dopamine agonist therapy indefinitely. All patients diagnosed with a prolactinoma should have follow-up imaging, determination of serum PRL levels, and visual field examinations. Alternatively, patients with a micro- or macroprolactinoma may be offered discontinuation of therapy. Dopamine agonist therapy may be tapered and ultimately discontinued if follow-up PRL levels are normal, and follow-up MRI scans show no evidence of tumor (or tumor reduction of at least 50%, with the tumor at a distance of more than 5 mm from the optic chiasm and no evidence for tumor invasion of adjacent structures), and if follow-up after withdrawal is assured.

An alternative to medical management of pituitary tumors is transsphenoidal surgery, after which resolution of symptoms may be immediate. However, the success and recurrence rates vary and are dependent on the size of the tumor and the depth of invasion. The larger and more invasive the tumor is, the less chance there is for complete resection and the greater the chance of recurrence. In general, the success rate of surgery for a microadenoma in some centers may be 70% or higher; surgical cure rates for macroadenomas are generally less than 40%. Overall, the recurrence rate following surgery is approximately 50%. Surgery is a good alternative for resistant tumors or for patients intolerant of medical treatment. Because non-PRL-secreting pituitary tumors often do not respond well to medical therapy, operation is the treatment of choice for these tumors as well. The risks of surgery include infection,

diabetes insipidus, and panhypopituitarism. Complete pituitary testing should be performed prior to surgery.

Women with hyperprolactinemia who desire to conceive should be administered dopamine agonist therapy. Elevated PRL levels can lead to anovulation and hormonal disturbances that can result in difficulty in achieving pregnancy. Once pregnant, patients with microadenomas may have their medication discontinued. If a macroadenoma is present, thought should be given to continuing dopamine agonist therapy throughout pregnancy. Women with prolactinomas may breastfeed since there is no evidence that it stimulates tumor growth. If breastfeeding, dopamine agonist therapy should be discontinued since these agents will interfere with lactation.

C. Anatomic causes

1. **Pituitary destruction**—Amenorrhea may be the result of not only pituitary neoplasms but also pituitary destruction. Infiltrative disorders that involve the hypothalamus can affect the pituitary. Other disorders that cause pituitary insufficiency may be situational. A rare autoimmune disease, lymphocytic hypophysitis, can cause pituitary destruction during the puerperium and ultimately results in panhypopituitarism. Pituitary necrosis may also occur secondary to a hypotensive event. Typically, 80% to 90% of the pituitary must be damaged before pituitary failure ensues, and the robust blood supply to the pituitary makes this an uncommon event. If pituitary ischemia and necrosis are related to postpartum hemorrhage, it is known as Sheehan syndrome; otherwise, it is called Simmond disease. Because this type of injury typically affects the entire pituitary, most often more than one or all the pituitary hormones may be deficient. Observation has suggested that hormone loss follows a pattern, starting with the gonadotropins, followed by GH and PRL; however, this is highly variable.

OVARIAN AMENORRHEA

The physiologic period in a woman's life when there is permanent cessation of menstruation and regression of ovarian function is known as menopause (see later). The cause of ovarian failure is thought to be depletion of ovarian follicles. The median age at menopause is 51.1 years. Premature menopause is defined as ovarian failure prior to age 40, which is reported to occur in 1% of the population. The etiology of premature ovarian failure (POF) may have a genetic basis. Several mutations that affect gonadal function have been identified and include defects in hormone receptors and steroid synthesis. Other potential causes include autoimmune ovarian destruction, iatrogenic ovarian injury, and idiopathic ovarian failure. The most severe form of POF presents with absent secondary sexual characteristics and is most often due to gonadal agenesis or dysgenesis (see Chapter 14). Less severe forms may result only in diminished reproductive capacity.

The other ovarian cause of amenorrhea is repetitive ovulation failure or anovulation. Other than menopause, it is the most common cause of amenorrhea. Chronic anovulation may be secondary to disorders of the hypothalamic-pituitary axis and has been

previously discussed. Anovulation may also be due to systemic disorders. The causes of ovarian failure and anovulation due to peripheral disorders will be discussed later.

Ovarian failure is diagnosed based on the clinical picture of amenorrhea and the demonstration of elevated FSH (>40 IU/L). This may occur at any time from embryonic development onward. If it occurs prior to age 40, it is called POF. The presence or absence of secondary sexual characteristics defines whether ovarian activity was present in the past. The most common cause of hypergonadotropic amenorrhea, in the absence of secondary sexual characteristics, is abnormal gonadal development, which occurs in more than half of these individuals. When the gonad fails to develop, this is known as **gonadal agenesis**. The karyotype of these individuals is 46,XX, and the cause of failure is usually unknown. If streak gonads are present, this indicates at least partial gonadal development and is called **gonadal dysgenesis**. The karyotype of these individuals may be normal, but it is more likely that there are alterations in sex chromosomes (see Chapter 14).

Premature Ovarian Failure

A. Genetic origin of POF   Two intact X chromosomes are necessary for the maintenance of oocytes during embryogenesis, and the loss of or any alteration in the sex chromosome leads to accelerated follicular loss. This implies that two intact alleles are required for the normal function of some genes on the X chromosome. Turner syndrome is a classic example of complete absence of one X chromosome. It manifests as short stature, sexual infantilism, amenorrhea, and ovarian dysgenesis. This is a well-recognized condition that occurs in 1:2000 to 1:5000 females at birth. Turner syndrome is associated with a number of other phenotypic abnormalities, including a webbed neck, broad chest, low hairline, and cardiovascular and renal defects. It is interesting that fewer than half of patients with Turner syndrome have a single cell line with the karyotype 45,X. The majority of patients actually present with a mosaic karyotype such as 45,X/46,XX. These patients have varying degrees of the Turner syndrome phenotype and may display some secondary sexual development or may have a history of menstrual function. Some pregnancies have been reported.

The term **mixed gonadal dysgenesis** is used to describe chromosomal aneuploidies with a Y-chromosome component. The most common type is a mosaic pattern that has been associated with Turner syndrome (45,X/46,XY). These patients may have some functional testicular tissue and present with varying degrees of genital ambiguity. If enough testicular tissue is present to produce AMH, these patients may also present with abnormalities of the internal genitalia. Individuals who have both ovarian tissue and testicular tissue along with Wolffian and Müllerian structures internally are termed **true hermaphrodites**. Interestingly, most true hermaphrodites have 46,XX karyotypes (see Chapter 14) but others may have a 46,XY or 46,XX/46,XY chimerism.

Patients with gonadal dysgenesis may be phenotypically normal, and the abnormality may be manifest only as delayed pubertal development and amenorrhea. They probably have normal Müllerian structures and streak gonads. These individuals can display an array of karyotypes, including 46,XY (Swyer syndrome).

Patients with a male karyotype but a female phenotype presumably underwent testicular failure prior to internal or external genitalia differentiation. If a dysgenetic gonad contains a Y chromosome or a fragment of the Y chromosome, there is a 10% to 30% risk for future gonadal malignancy, and the risk is higher if a mutation in the *SRY* gene is present. These tumors may be hormonally active. The onset of spontaneous pubertal development in girls with mixed gonadal dysgenesis may be a clinical marker of tumor development. Gonadal extirpation is performed at the time of diagnosis.

POF is defined as ovarian failure before age 40 but after puberty. Because complete absence of an X chromosome results in a dysgenetic gonad, candidate genes for POF are probably those that escape X inactivation. In mammals, X inactivation occurs in all cells in order to provide dosage compensation for *X-linked* genes between males and females (Lyon hypothesis). Further observation has illustrated that terminal deletions in Xp lead to the classic stigmata of Turner syndrome, whereas other deletions in Xp or Xq present with varying degrees of early reproductive failure. Most of the genes involved in folliculogenesis appear to be located on the long arm of the X chromosome. Several regions on the X chromosome, including POF 1 and POF 2, have been evaluated with knockout models in animals and have shown varying effects on ovarian development (Figure 13–12).

Limited observations have found that deletions occurring closer to the centromere of the X chromosome manifest a more severe phenotype that includes disruption of pubertal development. In contrast, deletions that occur in the distal regions tend to present with early reproductive aging and infertility. An example of a distal mutation on the long arm of the X chromosome is that in the *FMR1* gene (*fragile X gene*). An association has been
FIGURE 13–12 Candidate genes on the X chromosome for premature ovarian failure (POF). (Reproduced with permission from Davison RM, Davis CJ, Conway GS. The X chromosome and ovarian failure. *Clin Endocrinol (Oxf)*. 1999 Dec;51(6):673-679.)

described between the *FMR1* permutation state and POF. The prevalence of *FMR1* gene permutations accounts for approximately 2% to 3% of patients who present with sporadic POF and may be as high as 15% in familial cases. This permutation is also associated with the occurrence of a late-onset neurological disorder in male carriers designated as fragile-X tremor ataxia syndrome (FXTAS). Although a number of genes on the X chromosome have demonstrated involvement in ovarian physiology, the majority of patients with POF have no identifiable mutations on the X chromosome.

Autosomal recessive genes that have been shown to contribute to POF are very rare. FSH receptor mutations have been identified in humans with POF. These individuals present with a phenotype that ranges from absent secondary sexual development to normal development and early reproductive failure. The prevalence of FSH receptor mutations varies but is most common in the Finnish population (1% carriers). This mutation has not been observed in North America. An inactivated LH receptor has been identified in patients with normal puberty and amenorrhea but is quite rare. Mutations in genes involved in steroidogenesis have also been associated with POF. These enzymes include CYP17α and aromatase. Patients with CYP17α mutations may have a 46,XX or 46,XY karyotype. They have a similar phenotype except that those with 46,XY have absent Müllerian structures because AMH is produced from their testes. Individuals with aromatase deficiency present with sexual ambiguity and clitoromegaly. Several other autosomal mutations have been discovered that may have a role in ovarian physiology. However, at this time, most cases of POF with normal pubertal development have not been associated with any specific mutation (see Chapter 14).

B. Autoimmune origin of POF

Autoimmune ovarian destruction is another potential cause of POF. This diagnosis is difficult to make unless it presents with one of the autoimmune polyglandular syndromes (APSs) (see Chapter 2). The circumstantial evidence supporting the diagnosis is found in the high incidence of concomitant autoimmune disease—20% or more in patients with POF. The strongest association is with autoimmune thyroid disease. In addition, 10% to 20% of individuals with autoimmune adrenal disease experience POF. Conversely, 2% to 10% of patients with idiopathic POF develop adrenal insufficiency.

Autoimmune-associated POF is often diagnosed based on the presence of another autoimmune disease or detection of autoantibodies. Thyroid antibodies are most frequently screened. However, these antibodies are present in 15% to 20% of reproductive-aged women. Others have suggested measuring ovarian-specific autoantibodies. There is, however, significant inconsistency in the testing methodology, and this is not recommended. Although the diagnosis is imprecise, all patients suspected of having POF should be screened regularly for thyroid dysfunction. In addition, these patients should be evaluated for the APS and particularly tested for adrenal insufficiency, especially if there is no identifiable cause of POF. Testing for Addison disease can be performed using provocative ACTH testing or alternatively

adrenal antibodies to identify patients at risk. There are commercially available tests for both antiadrenal antibodies and antibodies to 21-hydroxylase. The sensitivity of these ACTH testing for the diagnosis of adrenal insufficiency is 100%, the specificity 98%, and the PPV is 67%. If a patient has either of these antibodies they have a 25% to 50% risk of developing adrenal insufficiency within 5 to 10 years.

C. Iatrogenic causes of POF

Iatrogenic causes of POF include radiation therapy, chemotherapy, and ovarian insults resulting from torsion or surgery. The risk of POF following radiation and chemotherapy is proportionate to the patient's age. If the radiation dose is higher than 800 Gy, all women experience ovarian failure. Displacing the ovaries out of the radiation field (ovarian transposition) has shown to be very effective at preserving ovarian function in patients receiving pelvic radiation. Therefore, patients wishing to preserve their fertility should be offered this procedure. Chemotherapy alone, particularly with alkylating agents, may induce temporary or permanent ovarian failure. Studies have shown that the likelihood of experiencing amenorrhea during treatment is 50% to 100%, and on average 40% of patients experience irreversible menopause. In general, younger individuals with chemotherapy-induced ovarian injury are more likely to recover. In women older than age 40, the chance of recovery is less 10%. Modifications of chemotherapy drugs, duration of treatment, and dosing are modifiers of permanent ovarian injury.

D. Resistant ovary syndrome

A rare cause of hypergonadotropic amenorrhea associated with numerous unstimulated ovarian follicles is the resistant ovary syndrome. These patients classically have no history of ovulatory dysfunction and present with secondary sexual characteristics and symptoms suggestive of estrogen deficiency. This diagnosis was established in an era when ovarian biopsy was used to determine the cause of menstrual disturbances. However, the definition of resistant ovary syndrome is not universally accepted. In fact, in the original series, cases were included in which patients had demonstrated ovulatory function in the past but later developed a clinical picture suggestive of ovarian resistance. This pattern is more typical of ovarian aging and follicular depletion.

The cause is not known. Histologic features of ovarian biopsy demonstrate that there is no plasma cell or lymphocytic infiltration, indicating that it is not caused by autoimmune destruction. The presence of numerous follicles indicates that POF is not due to follicular depletion. Several studies have looked at gonadotropins, FSH receptors, and antibodies that serve as blockers to the gonadotropin receptors, and the literature to date is inconclusive about the cause.

Diagnosis can be established with certainty only with ovarian biopsy. However, current recommendations for management of amenorrhea do not include surgery to make a diagnosis. The diagnosis is, therefore, one of exclusion. In the absence of autoimmune disease and of any history of ovulation, karyotyping should be performed to exclude chromosomal abnormalities. In patients with normal karyotypes, the diagnosis of POF and resistant ovary

syndrome is difficult to make without biopsy. Improvements in ultrasound technology may make it possible to differentiate these entities by the measurement of ovarian volumes and antral follicle counts.

E. Summary   In more than half of patients with POF, no specific cause can be identified. The age defining POF is somewhat arbitrary. By definition, menopause is preceded by reproductive failure. It is thought that the time interval between menopause and the end of fertility may be approximately 10 years, and we know that approximately 10% of women reach menopause by 46 years of age and 1% by 40 years. Therefore, women who experience menopause at 45 years of age probably encounter a decline in reproductive potential or even reproductive failure at 35 years of age. This has obvious implications for women who are delaying childbearing. Several studies have described a significant association between the menopausal ages of mothers and daughters, twins, and sisters. A number of studies have identified new genes that are involved in ovarian physiology. It is hoped that these investigations will help in the treatment of subfertility and result in a reduction in infertility. At a minimum, they may allow better prospective individual prediction of reproductive risk.

Women diagnosed with POF that is not readily explained must have an evaluation that consists of a karyotype, testing for fragile-X (FMR) permutation, and evaluation for APS. If a patient has an FMR permutation, one should offer screening to her father. If there is no identifiable cause of POF, screening for adrenal insufficiency is obligatory. All patients with POF should be considered for combination HT. The increased risks associated with breast cancer are likely no greater than the age-adjusted risk of women with intact ovaries. Patients with absent secondary sexual characteristics should initially be given estrogen-only therapy in low doses and titrated every 3 to 6 months (see Chapters 14 and 15 and see later for management of menopause).

ANOVULATION

Chronic anovulation may be defined as repetitive ovulation failure, which differs from ovarian failure in that viable oocytes remain in the ovary. Anovulation is the most common cause of amenorrhea during the reproductive years. There are several causes; those associated with hypothalamic and pituitary disorders have previously been mentioned and will not be considered in this section. Other conditions that cause anovulation include the peripheral endocrinopathies. These disorders result in a hormonal imbalance—mainly elevated androgens or estrogens—and lead to inappropriate feedback mechanisms and ovulatory failure. The peripheral endocrine disorders will be discussed later in greater detail.

Hyperandrogenism and Anovulation

A. Polycystic ovarian syndrome   Hyperandrogenic anovulation accounts for more than 30% of cases of amenorrhea and up to 75% of all cases of anovulation. Most often it is due to polycystic ovarian syndrome (PCOS). The reported prevalence of PCOS depends on the criteria used to define it. Although there remains considerable controversy over the definition, most investigators, until recently, have focused on the 1990 National Institutes of Health-National Institute for Child and Human Development (NIH-NICHD) diagnostic criteria (Table 13–4). This definition puts forth ovarian hyperandrogenism and anovulation as the cardinal features of PCOS. The criteria include ovulatory dysfunction with evidence of hyperandrogenism, either clinically or by laboratory testing, in the absence of identifiable causes of hyperandrogenism. Using these criteria, the prevalence of unexplained hyperandrogenic chronic anovulation approximates 4% to 6%, and it is considered the most common endocrine disorder in women of reproductive age. However, in 2003 the diagnostic criteria were revised by the Rotterdam consensus conference (see Table 13–4). The Rotterdam criteria consider a broader spectrum of ovarian dysfunction than previous definitions. Some experts criticized the definition, because it encompasses many more women, notably those with hyperandrogenism and ovulatory cycles, in addition to women with anovulation without androgen excess. This is contrast to the 1990 NIH-NICHD definition, which required *both* androgen excess and irregular cycles. Most recently, the Androgen Excess Society task force proposed the criteria should be defined by the presence of hyperandrogenism and ovarian dysfunction (see Table 13–4). This definition expands upon the 1990 NIH-NICHD criteria and requires that all patients with PCOS are hyperandrogenic at some level. Although the revised criteria can include women with ovulatory cycles, the remaining discussion on PCOS focuses on women who have anovulatory cycles (Table 13–5).

Approximately 50% of women diagnosed with PCOS are obese, and most have polycystic ovaries present on sonography (see later). Underlying these features are numerous biochemical abnormalities that have been associated with this syndrome, including elevated circulating total testosterone, free testosterone, DHEAS, and insulin as well as decreased SHBG and an elevated LH-FSH ratio. However, these abnormalities are not present in all PCOS patients. In fact, 40% of women who present with only hirsutism (see later) have elevated total testosterone levels, and

TABLE 13–4 Revised diagnostic criteria for polycystic ovary syndrome.

1990 criteria (both 1 and 2)
1. Chronic anovulation
2. Clinical and/or biochemical signs of hyperandrogenism and exclusion of other etiologies
Revised 2003 criteria (2 of 3)
1. Oligo or anovulation
2. Clinical and/or biochemical signs of hyperandrogenism
3. Polycystic ovaries and exclusion of other etiologies (congenital adrenal hyperplasia, androgen-secreting tumors, Cushing syndrome)

30% to 70% have elevated DHEAS levels. Similarly, the evaluation of increased LH pulsatility, in association with low-normal FSH levels (LH-FSH ratio), is not a reliable diagnostic test. Although elevated LH-FSH ratios are common findings in thin women, in obese patients with PCOS, the ratio is within the normal range about half of the time. The short half-life of LH (~20 minutes) is likely another major contributor to the inaccuracy of LH testing. Hyperinsulinemia has recently been hypothesized to play a major role in the pathogenesis of PCOS (see later). The prevalence of insulin resistance may approximate 50% to 60%, compared with 10% to 25% observed in the general population. However, insulin resistance is difficult to measure in the clinical setting. Part of the difficulty is that there is no universally agreed on definition of insulin resistance, and the laboratory tests are not standardized. Furthermore, baseline insulin levels vary depending on population and body weight. For example, up to 60% of ovulatory obese patients have demonstrated some form of insulin resistance. Nonetheless, there is good evidence that a subset of normal-weight women and obese women with PCOS have a greater degree of insulin resistance and compensatory hyperinsulinemia compared with weight-matched controls.

There is increasing evidence for a strong genetic component in the etiology of PCOS. Several candidate genes have been investigated, including genes involved in steroidogenesis and carbohydrate metabolism, but none has been conclusively linked with the disease. PCOS is heterogeneous clinically, raising the possibility of different genetic causes and a variable environmental contribution to the syndrome.

1. **Diagnosis of PCOS**—The diagnosis of PCOS is typically based on clinical features (irregular menstrual cycles, acne, hirsutism), although additional information may be obtained with biochemical testing and sonographic examination. Known causes of hyperandrogenism and anovulation should be excluded in all patients (ie, androgen-secreting tumors, thyroid and adrenal gland dysfunction, hyperprolactinemia).

In most situations, the manifestations of PCOS emerge in the peripubertal years, occasionally with premature pubarche, and likely irregular cycles that persist through much of reproductive life. The diagnosis may be challenging, however, because adolescent girls commonly display irregular cycles during the 5 years following menarche. Ultrasonography may help to solidify the diagnosis of PCOS in children given that the likelihood of restoration of normal ovarian morphology is small as long as irregular menses persist.

Polycystic ovaries tend to be enlarged and have been defined in multiple ways: (1) the presence of 10 or more cystic follicles that are between 2 and 8 mm in diameter and arranged along the subcapsular edge of the ovary in a string of pearls fashion; and (2) 12 or more follicles 2 to 9 mm in either ovary and/or an ovarian volume of 10 cm^3 or greater. The increased ovarian volume and displacement of follicles toward the periphery may be explained by the hyperplastic stroma. The stroma contains hilar cells and secondary interstitial cells (theca cells) that are capable of androgen synthesis.

Polycystic-appearing ovaries (PCAO) are very common in women with clinical features suggestive of hyperandrogenism, independent of menstrual disturbances. This finding suggests that ovarian hyperandrogenism can occur in ovulatory states and should be considered in the spectrum of PCOS, if polycystic ovaries are present. However, the finding of polycystic ovaries alone does not establish the diagnosis of PCOS. In fact, based on the Rotterdam definition, more than 30% of normal women have this ovarian morphologic feature. The prevalence is significantly impacted by age. Approximately 60% of women with regular cycles between the ages of 25 to 30 have morphologic characteristics consistent with polycystic ovaries compared to 7% of women between the ages of 41 and 45. Furthermore, the morphogenesis of polycystic ovaries is not unique to PCOS as it has been observed in other scenarios (ie, late-onset congenital adrenal hyperplasia, HIV, epilepsy). Given the prevalence of PCOA, a new definition has been proposed: PCAO or polycystic ovarian morphology (PCOM) is a follicle count of more than or equal to 25 within one ovary, but only when using newer technology that affords maximal resolution of ovarian follicles (ie, transducer frequency ≥8 MHz). If such technology is not available, ovarian volume cutoff of more than 10 cm^3 is suggested. This definition is supported by a threshold, when discriminating between controls and PCOS, of 26 follicles having the best compromise between sensitivity (85%) and specificity (94%) compared to 69% sensitivity and 90% specificity with a follicle count cutoff of 12 or a 81% sensitivity and 84% specificity with ovarian volume (10 cm^3).

2. **Hyperandrogenism**—The origin of sex steroids is from two sources: the gonads and the adrenal gland. The adrenal gland is responsible for most of the precursor hormones in the general circulation, which serve as reservoirs for the more potent androgens and estrogens. The ovary produces bioactive androgens and estrogens as well as precursor hormones. Figure 13–13 illustrates the relative contribution of each organ to the pool of circulating sex steroids. DHEAS is the most abundant steroid in the circulation, and serves as a precursor to the more potent androgens and estrogens. Over 98% of
FIGURE 13–13 The origin of circulating sex steroids: the relative contribution of each organ to the pool of circulating sex steroids.

DHEAS is secreted from the adrenal gland. Approximately half of the circulating levels of androstenedione are equally derived from the adrenal gland and gonads and the remaining half from conversion of DHEAS (DHEA) in the periphery. DHEAS also serves as a substrate for the ovary to produce bioactive sex steroids. It is evident that the majority of bioactive androgen is derived from precursor steroids that undergo peripheral conversion. It is suggested over 60% of the testosterone is derived from circulating androstenedione, and the remaining is by direct secretion. The contribution of testosterone from the ovary and the adrenal gland is not completely known. The fact that the various methods to obtain secretion rates are difficult and that assays used to measure testosterone can be unreliable with resultant variability contributes to the uncertain interpretation.

A common clinical sign of hyperandrogenism is hirsutism. Hirsutism affects approximately 5% to 15% of the population. The prevalence depends on the population and the method used to establish the diagnosis. The most common scoring method used to diagnose hirsutism is based on the Ferriman and Gallwey system. It is based on evaluating 9 to 11 body areas and assigning a score of 0 to 4 based on the density of hair. This method is primarily used for research purposes. Clinically, it is often diagnosed by history and the presence of excess hair growth in centrally located regions, not commonly found in women. For example, those areas most affected are the face (sideburns, mustache, and beard), chest, linea alba, or the inner aspect of the thighs. The characteristics and distribution of body hair may be influenced by ethnic or racial factors. Alternatively, hyperandrogenism may present as acne or alopecia.

The diagnostic evaluation of hirsutism should include a thorough history and physical examination (Figure 13–14). The etiology can be divided between non-androgenic and androgenic causes. Organic causes of hyperandrogenism must be excluded. Non-androgenic causes include chronic skin irritation, anabolic medications, and rarely acromegaly. The most common androgenic cause is PCOS which affects at least 70% of hirsute women. Less common is late-onset congenital adrenal hyperplasia, which affects approximately 5% of patients. PCOS is a diagnosis of exclusion—measurements of serum androgen levels should play only a limited role in the evaluation. Most patients who have hyperandrogenemia present with obvious clinical manifestations, and the presence of normal androgen levels in a patient with hirsutism or acne does not exclude the diagnosis of PCOS. However, there are subsets of amenorrheic patients (ie, Asians) who are hyperandrogenemic without clinical manifestations, most likely as a result of their relative insensitivity (due to low 5α-reductase activity) to circulating androgens. It is in these patients that assessing androgen levels may be of value in determining the cause of amenorrhea. More commonly, androgens such as DHEAS and testosterone are measured to exclude other causes of hyperandrogenic anovulation such as nonclassic adrenal hyperplasia and androgen-secreting tumors (see later).

Another cause of hirsutism, made only after excluding other diagnoses, is characterized by regular menstrual cycles, normal androgen levels, and the absence of PCAO; it is termed idiopathic hirsutism. This common disorder occurs more frequently in certain ethnic populations, particularly those of Mediterranean descent. It is thought that the etiology of hirsutism in these patients is related to higher 5α-reductase activity (increased sensitivity) within the pilosebaceous unit.

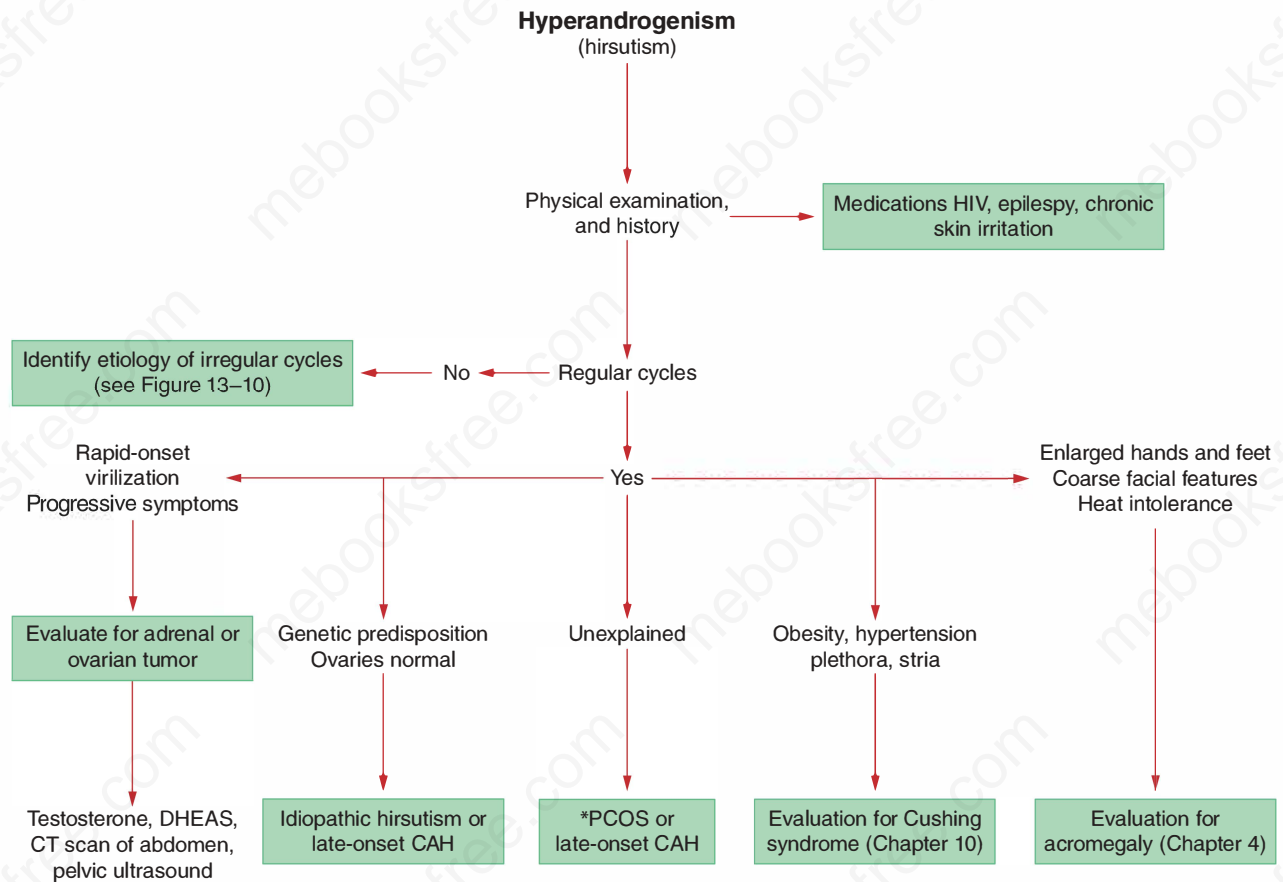
3. **Mechanism of anovulation**—The mechanism of anovulation in PCOS remains unclear. It is evident that the population of antral follicles is increased and that follicular development is arrested. It is also known that the development of preantral follicles is not primarily under hormonal control. Evidence supports the components of the intraovarian network as regulators of antral follicle development. It is known that many of the accumulated follicles in PCOS remain steroidogenically


FIGURE 13–14 An algorithm for women with hirsutism. All women should be screened for known causes of hyperandrogenism. Hyperandrogenism suggests either PCOS or late-onset congenital adrenal hyperplasia (CAH). If hirsutism is rapid in onset or rapidly progressive in nature or the patient is frankly virilized, an evaluation for an androgen-secreting tumor is required. Management of hirsutism in late-onset CAH or PCOS is similar. *Late-onset CAH can present with regular cycles. Depending on the specific criteria (see Table 13–4), PCOS can present with regular cycles. Serum hormones are not required for the diagnosis of idiopathic hirsutism or PCOS.

competent and are capable of producing estrogen and progesterone. In fact, it is interesting that women with PCOS produce both androgens and estrogen (estrone) in excess.

One of the most frequently described characteristics of PCOS is the functional derangement of LH secretion. Numerous studies have shown that frequency, amplitude, and mean levels of LH are increased. The aberration in LH secretion may be a result of heightened pituitary responsiveness and increased hypothalamic GnRH activity. Under normal conditions, follicles respond to LH after they reach approximately 10 mm in diameter. However, polycystic ovarian follicles acquire responsiveness to LH at a much smaller diameter, which may lead to inappropriate terminal differentiation of granulosa cells and result in disorganized follicular development. It has been suggested that the theca cells increase their expression of steroidogenic enzymes following stimulation by LH, whereas the granulosa display resistance to FSH (see later). The elevated LH levels and relative hyperinsulinemia that exist in some PCOS patients may synergistically potentiate disordered folliculogenesis. Although hyperandrogenism is part of the diagnostic criteria for PCOS, its direct impact on folliculogenesis is not clear. It is conceivable that androgens contribute to the effects of LH and insulin on follicular maturation. It is also possible that the excess estrogens may result in a negative-feedback loop to inhibit FSH release and prevent further follicular development.

Most experts are of the opinion that excess androgen production is a fundamental abnormality in women with PCOS. Androgens within the ovary are produced mainly by the thecal interstitial cells that surround the follicle and to a lesser extent by the secondary interstitial cells located in the stroma (see earlier). The CYP17α complex is thought to be the key enzyme in biosynthesis of ovarian androgens. Under normal conditions, a large proportion of the androgens produced by the theca cells diffuses into the granulosa cell layer of the follicle where they are rapidly converted to estrogen as shown in Figures 13–9 and 13–13 (two-cell theory). The intrinsic control of androgen production in the ovary is modulated by intraovarian factors and hormones (see section on ovarian steroidogenesis at the beginning of this chapter). It is the dysregulation of hormone production that is most likely responsible for PCOS.

Several studies have shown that women with PCOS have an exaggerated ovarian androgen response to various stimuli. To illustrate, hyperstimulation of 17-hydroxyprogesterone levels was noted when women diagnosed with PCOS were given a

GnRH agonist or hCG, suggesting increased CYP17α activity. This study is supported by *in vitro* studies in which measurement of steroids in cultured human theca cells from polycystic ovaries revealed concentrations of androstenedione, 17α-hydroxyprogesterone, and progesterone that were respectively 20-fold, 10-fold, and 5-fold higher than levels in control cells. Additional studies have found increased expression of the genes encoding CYP17α hydroxylase, P450scc, the LH receptor, and StAR. These findings reflect a global enhancement of steroidogenesis. This situation is compounded by the hypertrophy of theca cells that is present in women with PCOS.

Several studies have evaluated intraovarian modulators as participants in the pathogenesis of PCOS (Figure 13–15). IGF-binding proteins (IGFBPs), especially IGFBP-2 and IGFBP-4, are found to be increased in the follicular fluid of polycystic ovaries. They may act locally to decrease free IGF-2 and, thus, decrease the effects of FSH on the oocyte and granulosa cells. Alternatively, the granulosa cells may downregulate their insulin receptors as a result of hyperinsulinemia. This would deprive the granulosa cells of their co-gonadotropin, IGF-2, and account for the relative FSH insensitivity. Inhibin is also a likely candidate, because a large proportion of women with PCOS have relative FSH suppression (see Figure 13–15). However, studies have not shown consistent results, suggesting that if inhibin is involved, the effect is minimal. Follistatin, the activin-binding protein, was in the past thought to play an important role in the development of PCOS. It was initially implicated because activin functions to inhibit androgen production and enhance FSH expression. However, current studies do not demonstrate a significant association between abnormalities in follistatin and PCOS.

The adrenal gland may be significantly involved in the pathogenesis of some cases of PCOS. The connection seems plausible because adrenal androgens can be converted to more potent androgens in the ovary. Furthermore, a significant portion of women with congenital adrenal hyperplasia have polycystic ovaries (see later). Several studies have shown that DHEAS is elevated in 25% to 60% of patients with PCOS. However, ACTH levels are normal in PCOS women. Interestingly, it has been reported that there is an increased response of androstenedione and 17α-hydroxyprogesterone to exogenous ACTH. These findings suggest an underlying abnormality in the CYP17α expressed in the adrenal gland as well as in the ovary. However, minimal data support CYP17α dysfunction in the adrenal gland. It has also been shown that ovarian steroids can stimulate adrenal androgen production; however, additional findings suggest that the ovary is not the primary cause of adrenal hyperresponsiveness. The critical role played by adrenal androgens during the pubertal transition has not been fully investigated as a potential contributor to the development of PCOS.

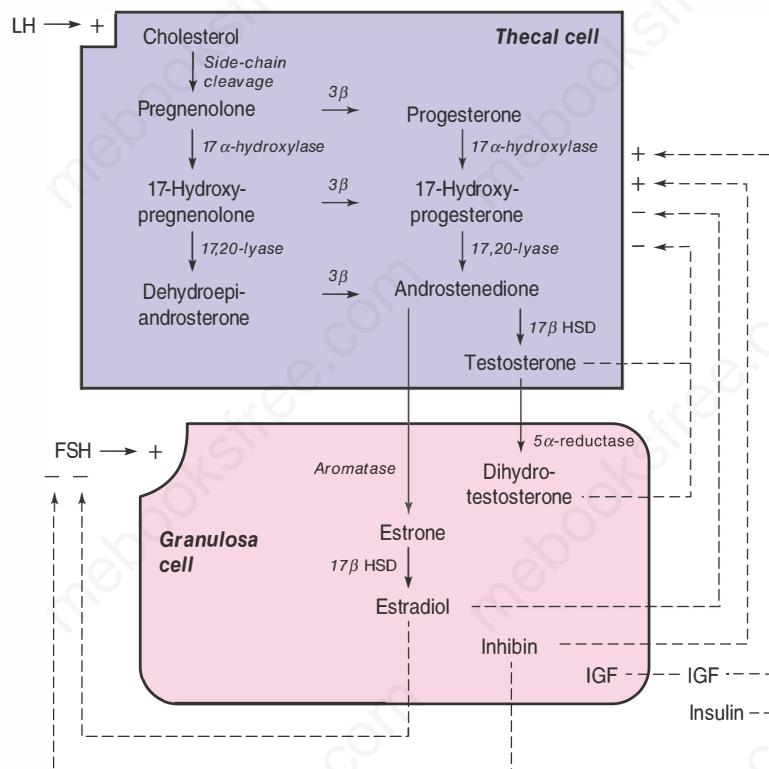
4. **Hyperinsulinemia and PCOS**—A relationship between insulin and hyperandrogenism has been postulated based on several observations. This association may be demonstrated in the peripubertal years with premature pubarche, which is more commonly associated with insulin resistance than with congenital adrenal hyperplasia or androgen excess. Various case


FIGURE 13–15 Regulation of sex steroid production in the theca and granulosa cells of the ovary. Several autocrine and paracrine factors such as insulin and insulin-like growth factors (IGFs) work synergistically with luteinizing hormone (LH) to stimulate androgen production through increased 17α-hydroxylase activity. (Reproduced with permission from Ehrmann DA, Rosenfield RL, Barnes RB, et al. Detection of functional ovarian hyperandrogenism in women with androgen excess. *N Engl J Med*. 1992 Jul 16;327(3):157-162.)

reports have shown that **acanthosis nigricans**—hyperpigmentation of skin in the intertriginous areas—is associated with severe insulin resistance. A number of these patients also presented with hyperandrogenism and anovulation. The relationship was substantiated when it was observed that the degree of hyperinsulinemia was correlated with the degree of hyperandrogenism. Further studies revealed that hyperinsulinemia is frequently identified in women with PCOS.

It has been shown that the cause of hyperinsulinemia is insulin resistance and that the defect lies in the postreceptor signaling pathway. The frequency and degree of hyperinsulinemia in women with PCOS is amplified in the presence of obesity. Although many women with PCOS exhibit insulin resistance, some do not. However, insulin resistance is also observed in some thin PCOS patients.

Insulin may cause hyperandrogenism in several different ways, although the exact mechanism has not been well defined. It has been suggested that insulin has a stimulatory effect on CYP17α. There is evidence from *in vitro* models that insulin may act directly on the ovary (see Figure 13–15). It has been shown that the ovary possesses insulin receptors and IGF receptors. In addition, several studies have reported that insulin stimulates ovarian estrogen, androgen, and progesterone secretion and that its effects are greatly enhanced by the addition of gonadotropins. Administration of an insulin-sensitizing agent (eg, metformin or a thiazolidinedione) to obese women with PCOS leads to a substantial reduction in 17α-hydroxyprogesterone levels, reflecting decreased CYP17α activity. However, clinical studies, in which insulin infusions were administered to normal women, failed to demonstrate increased testosterone production, and there were no changes in androgen levels when normal women were given insulin-sensitizing agents. These observations suggest that insulin has more of a modifying rather than a predisposing effect on androgen production.

The relationship between insulin and adrenal androgen production is less clear. Some studies have shown that insulin increases secretion of 17α-hydroxyprogesterone and DHEAS in response to ACTH. Other studies have shown that DHEAS decreases after acute insulin infusions are administered to normal men and women. Furthermore, when insulin-sensitizing agents were administered to women with PCOS, a decrease in DHEAS was observed. Although there is less evidence to support the association of insulin and adrenal androgen production, if there is an insulin effect, it is as a modulator of adrenal secretory activity.

Insulin may indirectly affect androgen levels. Several studies have reported that insulin directly inhibits SHBG production. There is an inverse correlation between insulin levels and SHBG, so that decreasing insulin levels would decrease the circulating bioavailable androgen level (via increases in SHBG). It has also been shown that insulin decreases IGFBP-1. This would increase free IGF-1, which could modulate ovarian androgen production in a fashion similar to insulin (see Figure 13–15). Although these indirect mechanisms may play a role, the literature suggests that insulin acts directly to augment androgen production (see Figure 13–15). However, it appears that a dysregulation in steroidogenesis must also exist in order for insulin to cause hyperandrogenism.

Increasing attention is being directed to the possibility that PCOS begins before adolescence. In fact, the initial insult may begin in utero, where there is ample exposure to androgens derived from the fetal adrenal gland and ovary. This hormonal environment may reprogram the ovary and alter steroidogenesis in a manner that predisposes to PCOS. The phenotypic expression of PCOS would then be determined by environmental factors such as diet and exercise.

The various biochemical abnormalities associated with PCOS have led to studies investigating metabolic sequelae of this syndrome. Long-term health problems, such as the development of cardiovascular disease and diabetes, have been linked to PCOS. In fact, several studies have suggested that the metabolic syndrome is significantly more prevalent in women with PCOS. However, studies looking at whether women with PCOS actually experience increased cardiovascular events are limited. Several observational studies have demonstrated that women with PCOS have alterations in their lipid profiles, including increased triglycerides and LDL and decreased high-density lipoprotein (HDL) compared with weight-matched controls. Furthermore, the degree of dyslipidemia has been correlated with the magnitude of insulin resistance. The fact that insulin resistance occurs with greater frequency in women with PCOS suggests that they are at higher risk for the development of diabetes mellitus. It is known that up to 30% to 40% of women with PCOS have impaired glucose tolerance, although it is most often seen in patients who are obese. Limited retrospective studies have suggested that women with PCOS have an increased frequency of developing type 2 diabetes. In summary, as demonstrated by surrogate markers, the available data show that these patients have increased risk factors for cardiovascular events and diabetes. Long-term prospective studies will be required to determine if these patients are actually at risk for increased mortality and morbidity.

The fact that hyperinsulinemia underlies many of the potential adverse sequelae raises a question about whether insulin resistance should be assessed in all patients diagnosed with PCOS. There are several methods of measuring insulin resistance (Table 13–6). However, the potential impact of hyperinsulinemia is unknown. Furthermore, there is no universal laboratory criterion or standardization for establishing the diagnosis of insulin resistance, which raises doubts about whether any potential adverse sequelae can be prevented if insulin resistance is identified. Further data are necessary, prior to widespread use of medications such as metformin or a thiazolidinedione to reduce insulin resistance in patients with PCOS to determine (1) if these patients are indeed at risk for

cardiovascular events, (2) if hyperinsulinemia is an independent risk factor, and (3) whether long-term treatment with any insulin-sensitizing agent will decrease the potential sequelae.

5. **Additional risks associated with PCOS**—Another concern is that women who are anovulatory do not produce a significant amount of progesterone. This leads to a situation in which the uterine lining is stimulated by unopposed estrogens, which is a significant risk factor for development of endometrial cancer. In fact, an association has been found between endometrial cancer and PCOS. There is also evidence to suggest an association of PCOS with both breast cancer and ovarian cancer, but PCOS has not been conclusively shown to be an independent risk factor for either disease.

6. **Management of PCOS**—The management of PCOS should be dictated by the patients' risk factors for cardiovascular disease, diabetes, malignant sequelae, and symptomatology (see also "Infertility"). All patients should have a lipid profile measured. In addition, oral glucose tolerance tests should be performed—at least in obese women. In patients who have a long history of irregular cycles (>1 year), an endometrial biopsy should be considered.

Cardiovascular risk factors, weight loss, and progression to diabetes can be improved with diet and exercise. In the subset of patients with glucose intolerance, administration of insulin-sensitizing agents should be considered. Metformin, a biguanide, is the most widely studied. Several studies have shown modest transitory weight loss, and possibly a decreased incidence of diabetes in patients with PCOS due to its use. Metformin is not effective for treatment of hyperandrogenic symptomatology. The use of metformin is not recommended unless there is evidence of metabolic derangements that are not fixed with diet and exercise alone.

Irregular bleeding can be improved by the administration of oral contraceptives which induce scheduled withdrawal bleeding. However, another benefit of oral contraceptives has been the significant reduction in endometrial cancer in the general population. It is rational to expect that a similar benefit would accrue to women with PCOS, because the ovarian stimulation is minimized and the progestin would counteract the estrogenic environment.

Acne and hirsutism in women diagnosed with PCOS or of idiopathic origin can be treated with oral contraceptives. The mechanism is not completely known, but oral contraceptives decrease the amount of bioavailable androgens by increased SHBG production and by ovarian suppression. It has also been shown that progestins can inhibit 5α-reductase activity, which further decreases the production of dihydrotestosterone, the major androgen that stimulates hair growth. The maximal effect is evident after 6 months of treatment (the hair cycle length is estimated to be 4 months).

If hirsutism is severe or if oral contraceptives alone are not effective, the addition of spironolactone may be beneficial. Spironolactone is an antimineralocorticoid agent that inhibits androgen biosynthesis in the adrenal gland and ovary, inhibits 5α-reductase, and is a competitive inhibitor of the androgen receptor. Side effects are minimal and include diuresis in the first few days; hyperkalemia, dyspepsia; nausea; skin hypersensitivity;

breast tenderness; and abnormal bleeding, which can be alleviated by increasing the dose to desired amount over 3 weeks. Spironolactone is used concomitantly with oral contraceptives. Because oral contraceptives and spironolactone act by different mechanisms, the combined effect is synergistic. It is important to note spironolactone can cause hyperkalemia and should be avoided in women with renal compromise. Additionally spironolactone is teratogenic. Therefore, concomitant contraception treatment should be administered in women of reproductive age. The only topical agent approved for hirustism by the FDA is Vaniqa (Eflornithine) cream, which is an inhibitor of L-ornithine decarboxylase. It has been shown to be effective for control of facial hair. Similar to spironolactone, Eflornithine is also teratogenic, and therefore concomitant contraception treatment should be administered in women of reproductive age. Long-acting GnRH agonists and 5α-reductase inhibitors (finasteride) have been used for refractory cases with some success. Shaving, bleaching, chemical depilation, plucking, or waxing is temporary measure to control unwanted hair growth. However, several of these methods can cause skin irritation and result in progressive hair growth. Permanent techniques such as electrolysis or laser depilation have shown promising results.

B. Congenital adrenal hyperplasia   Congenital adrenal hyperplasia is another disorder that may cause hyperandrogenism. It presents in a wide range of clinical forms, ranging from severe—which may be classified as *classic, salt-wasting,* or *simple virilizing*—to milder forms known as *acquired, adult-onset, nonclassic,* or *late-onset* congenital hyperplasia. The clinical manifestations reflect the severity of the enzymatic defect. Severe or classic forms are discussed in Chapter 14 and will not be considered here. This section will discuss the nonclassic forms, which affect 1% to 10% of the population, depending on the ethnicity of the patient. The clinical features are similar to those of patients diagnosed with PCOS and include menstrual irregularities, hyperandrogenism, and infertility, and up to 50% have polycystic ovaries.

The adrenal gland consists of a cortex and a medulla. The cortex is divided into three functional zones based on location and the principal hormone secreted (see Chapter 9). The zona glomerulosa is the outermost zone and lies adjacent to the adrenal capsule. It is primarily responsible for aldosterone production. The zona fasciculata lies immediately below the glomerulosa. It principally secretes glucocorticoids, although it is capable of producing androgens. The zona reticularis is located beneath the zona fasciculata and overlies the adrenal medulla. It is this zone that principally secretes androgens. Both the zona fasciculata and the zona reticularis are regulated by ACTH. It is the secretory activity of these two zones that results in nonclassic adrenal hyperplasia.

Congenital adrenal hyperplasia is an autosomal recessive disorder that is caused by mutations of genes involved with adrenal steroidogenesis. The mutations mostly occur in the 21-hydroxylase gene (*P450c21B*) and rarely in the 3β-hydroxysteroid dehydrogenase gene or 11β-hydroxylase genes (*P450c11B* and *P450c11AS*). In classic forms, the enzymatic defects are severe, affect both alleles, and result in cortisol deficiency diagnosed at birth. Owing to the cortisol deficiency, there is ACTH excess and

hyperstimulation of the adrenal gland. The adrenal precursors produced proximal to the enzymatic defect accumulate and promote the synthesis of DHEA and androstenedione through the androgen synthetic pathway. These are converted in the periphery to more potent androgens, resulting in symptoms of hyperandrogenism. Approximately 50% of patients diagnosed with nonclassic congenital adrenal hyperplasia are compound heterozygotes with one of the mutant alleles coding for a severe defect. Typically, patients who are carriers have a normal phenotype. Therefore, most patients with nonclassic adrenal hyperplasia do not demonstrate deficient cortisol production or excess ACTH. It is suggested that most of the androgen excess in nonclassic adrenal hyperplasia arises as a consequence of subtle alterations in enzyme kinetics. Furthermore, some studies report a generalized adrenocortical hyperactivity rather than deficient enzyme activity.

The diagnosis can be established by measuring early morning basal 17-hydroxyprogesterone levels. Levels greater than 800 ng/dL (24.24 pmol/L) are diagnostic of 21-hydroxylase deficiency. However, the elevation in 17-hydroxyprogesterone is often not impressive and does not differ from that observed in PCOS. If the basal 17-hydroxyprogesterone levels are greater than 200 ng/dL (6.06 pmol/L) and less than 800 ng/dL (24.2 pmol/L), a provocative test with ACTH (250 μg intravenously) should be performed. If 17-hydroxyprogesterone levels are greater than 1000 ng/dL (30.30 pmol/L) 1 hour after administration of ACTH, the diagnosis of 21-hydroxylase deficiency can be made. Elimination of a false elevation in 17-hydroxyprogesterone due to ovulation must be excluded by simultaneous measurement of progesterone. A 17-hydroxyprogesterone screening level greater than 200 ng/dL has 100% sensitivity, but only 7% positive predictive value for the diagnosis of nonclassic adrenal hyperplasia. The other rare enzymatic defects that result in nonclassic adrenal hyperplasia can be assessed with measurements of steroid products proximal to the blockade following provocative testing.

Treatment of nonclassic adrenal hyperplasia is similar to that of PCOS, raising a question about whether an etiologic diagnosis is necessary. It is certainly an expense, leading to no change in management except with regard to infertility treatment and management of subsequent pregnancies (see later). Establishing a specific diagnosis may be advisable to facilitate genetic counseling in the woman with adrenal hyperplasia who intends future childbearing and to prepare for in utero treatment should an affected fetus be identified by amniocentesis. Although some experts suggest dexamethasone treatment for symptoms of hyperandrogenism, studies show inconsistent results, and there is concern about the consequent adrenal suppression.

C. Cushing syndrome Chronic glucocorticoid excess, whatever its cause, leads to the constellation of symptoms and physical features known as Cushing syndrome. The most common cause is iatrogenic as a result of glucocorticoid treatment. However, an ACTH-secreting microadenoma (Cushing disease) accounts for more than 70% of cases of endogenous hypercortisolism. Less common causes include primary adrenal disease (tumors or hyperplasia) and ectopic (not hypothalamic-pituitary) ACTH-producing or CRH-producing tumors. Patients with Cushing syndrome

have a range of clinical manifestations that vary with age at onset and etiology. This section will discuss the adult clinical presentation briefly. For a more detailed discussion, see Chapter 9.

Cushing syndrome (noniatrogenic) is rare and occurs in approximately 2.6 patients per million individuals in the population. It is responsible for less than 1% of those individuals who present with hirsutism. Although Cushing syndrome is uncommon, it presents in a manner similar to PCOS and congenital adrenal hyperplasia and needs to be considered in the differential diagnosis of hyperandrogenism and anovulation. Patients with ACTH excess typically have additional clinical features suggestive of glucocorticoid or mineralocorticoid hypersecretion. The most common features include obesity with increased centripetal fat, moon facies, muscle weakness, and striae. Other manifestations may include diabetes, hypertension, and osteoporosis. Women with primary tumors, most commonly adrenocortical carcinomas, tend to have a rapid onset of symptoms and often manifest with severe hyperandrogenism (frank virilization) that includes male pattern baldness, deepening voice, clitoromegaly, and defeminization.

Hirsutism or acne is present in about 60% to 70% of women with Cushing syndrome. However, the exact mechanism of hyperandrogenic effects is not completely known. It is evident that excess ACTH causes hyperstimulation of the zona fasciculata and zona reticularis and results in hypersecretion of cortisol and androgens. It is also known that adrenal tumors may selectively overproduce androgens.

Menstrual irregularities occur in more than 80% of patients with Cushing syndrome. The exact cause of anovulation is unclear. It has already been observed that hyperandrogenemia may have a significant impact on ovulation. However, several studies have shown that glucocorticoids can also suppress the hypothalamic-pituitary axis. Thus, the elevated glucocorticoids may be an additional factor in the pathophysiology of anovulation associated with this syndrome (see Chapters 4 and 9 for the diagnosis and treatment of Cushing syndrome).

D. Androgen-secreting tumor If there is a rapid onset of androgenic symptoms, an androgen-secreting adrenal tumor should be suspected. Elevated testosterone (>200 ng/dL; 6.9 nmol/L) and DHEAS (>700 ng/mL; 19 μmol/L) levels should raise the suspicion of a tumor. However, more than 50% of adrenal androgen-secreting tumors have testosterone levels below 200 ng/dL (6.9 nmol/L). Furthermore, the majority of patients with high testosterone levels do not have tumors. Testosterone levels above 250 ng/dL are only 10% predictive for androgen-secreting tumor. Measurement of DHEAS levels in these patients yields similar inconsistencies. This suggests that laboratory tests have limited value in screening for androgen-secreting tumors, and a clinical history and physical examination are better predictors. The presence of systemic symptoms such as weight loss, anorexia, bloating, and back pain favor an androgen-secreting tumor. If suspicion is high, an abdominal computed tomography (CT) scan confirms the diagnosis. The treatment involves surgical resection, mitotane (adrenolytic), and steroid synthesis inhibitors.

Androgen-secreting tumors can also originate from the ovary. The incidence approximates 1:500 to 1:1000 hyperandrogenic patients. Testosterone levels more than 200 ng/dL (6.9 nmol/L) arouse suspicion, although in 20% of patients with ovarian androgen-producing tumors, testosterone levels are below this value. Again, the best screening procedures are the clinical history and physical examination. In the absence of Cushingoid features, adrenal and ovarian tumors present similarly. Ovarian tumors often have unilateral ovarian enlargement that can be palpated on pelvic examination. Ultrasonography often confirms the diagnosis. In selected cases, selective venous sampling may be performed if CT or sonography cannot identify the source of androgen production.

OBESITY

Obesity is the most prevalent chronic disease in the United States. Adverse health events are dramatically increased in obese subjects (see Chapter 20). These include cardiovascular disease, diabetes, joint disease, respiratory dysfunction, and colon, endometrial, and ovarian cancers. Obesity is often also associated with menstrual irregularities, and the relationship between the two is strengthened the earlier the onset of the obesity. Alterations in sex steroid metabolism are clearly evident in obese females, and the consequences are attenuated release of gonadotropins, which manifests as anovulation. Obese patients have increased production rates and MCRs of androgens; therefore, their serum levels of androgens are largely within the normal range. However, free-testosterone levels tend to be in the high-normal range due to the decreased SHBG levels. A portion of androgen metabolism occurs in body fat. The excess adipose tissue aromatizes these androgens and increases the amount of circulating estrone causing a state of functional hyperestrogenism. In fact, studies have shown that the rate of peripheral conversion of androstenedione to estrone is correlated with body weight. Other studies have illustrated that the conversion of estrone to estradiol in adipose tissue is higher in visceral fat than subcutaneous fat. The increased visceral fat associated with obesity is also associated with hyperinsulinemia, which may have independent effects on ovarian function.

Management of Obesity

The management of obesity includes diet and exercise (see Chapter 20). In patients who have irregular uterine bleeding, an endometrial biopsy must be performed to rule out endometrial cancer. Oral contraceptives are effective at treating the irregular bleeding and reduce the incidence of endometrial cancer. Weight loss reestablishes normal menstrual cycles in the majority of these women.

Anovulation Unrelated to Excess Sex Steroid Production

A. Adrenal insufficiency   Adrenocortical insufficiency may be categorized as primary or secondary. Primary adrenal insufficiency (Addison disease) is caused by destruction of adrenal cortical tissue. Secondary adrenal insufficiency is due to defects in the hypothalamic-pituitary axis resulting in a deficiency in ACTH. Both types lead to cortisol deficiency, which is life threatening.

The main cause of primary adrenal failure is autoimmune destruction of the adrenal cortex. In fact, in the industrialized world, an autoimmune pathogenesis accounts for more than 60% of cases of primary adrenocortical deficiency. The symptoms are typically those of chronic insufficiency and include weakness, fatigue, menstrual disturbances, and gastrointestinal symptoms such as nausea, abdominal pain, and diarrhea. Additional signs may include weight loss, hypotension, and hyperpigmentation of the skin and mucous membranes. These symptoms may appear insidiously with a mean duration of approximately 3 years. Symptoms usually wax and wane until there is complete decompensation.

Autoimmune adrenal failure may occur as an isolated event, but estimates link more than 70% of cases to an APS of two subtypes (types 1 and 2). APS-1 usually presents in childhood with hypoparathyroidism, chronic mucocutaneous candidiasis, adrenal insufficiency, and other autoimmune disorders such as celiac disease and ovarian failure. It is caused by mutations in the autoimmune regulator gene (*AIRE*) and has an autosomal recessive inheritance. APS-2 (Schmidt syndrome) has its onset in adulthood (usually the third decade). Common manifestations include type 1 diabetes mellitus, myasthenia gravis, Hashimoto thyroiditis, ovarian failure, and adrenal insufficiency. Susceptibility to this disorder seems to be inherited as a dominant trait in linkage disequilibrium with the HLA-B region of chromosome 6. Autoimmune adrenal insufficiency is associated with autoantibodies that are directed toward enzymes involved with steroidogenesis. Several studies suggest that the antigens in this disorder include 17α-hydroxylase, 21-hydroxylase, and P450scc. Detection of antibodies directed at these enzymes is helpful in making the diagnosis of autoimmune adrenal failure (see Chapters 2 and 9).

Worldwide, infection—especially tuberculosis—is the most common cause of primary adrenal failure. The adrenal cortex and medulla are involved and may be completely replaced by caseating granulomas. This phenomenon is always associated with other evidence of a tuberculosis infection. Fungal, viral, and bacterial pathogens are less common causes.

The most common cause of secondary adrenal insufficiency is adrenal suppression after exogenous glucocorticoid administration. Adrenal insufficiency is also seen following treatment of Cushing disease and with a variety of hypothalamic-pituitary lesions that result in hypopituitarism. These patients more commonly present with symptoms suggestive of acute adrenal insufficiency. The clinical features include abdominal pain, hypotension, fever, severe volume depletion, and possibly profound shock.

Menstrual disturbances are a frequent presentation in patients with adrenal insufficiency. Autoimmune adrenal insufficiency is often accompanied by gonadal failure. In the two forms of APS, POF develops in APS-1 in 50% of patients and in APS-2 in 10% of patients. It has been shown that antibodies—particularly to CYP17α and P450scc—are associated with POF. Other causes of adrenal failure are associated with menstrual disorders more than 25% of the time. The cause of anovulation is not known with certainty, but chronic illness itself is probably responsible.

Diagnosis and treatment are discussed in Chapter 9. The screening process includes blood chemistries and basal cortisol levels. The diagnosis is confirmed with provocative tests using exogenous ACTH.

B. Thyroid disorders   The prevalence of overt thyroid dysfunction is 1% to 2% in women of reproductive age. Thyroid disorders can develop secondary to an insult in the hypothalamus, pituitary, or thyroid, the latter being most common. In order to understand the pathophysiology of these disorders, it is important to be familiar with the normal physiologic regulation (see Chapter 7). This section will briefly review the common causes of hyperthyroidism and hypothyroidism, their manifestations after the onset of puberty, and their impact on reproductive function.

1. **Hyperthyroidism**—Hyperthyroidism is the clinical syndrome associated with excessive thyroid hormone activity. The clinical presentation of hyperthyroidism (thyrotoxicosis) depends on the age at onset and the degree of thyrotoxicosis. The clinical manifestations can involve most organ systems, and the presentation ranges from asymptomatic to thyroid storm. Typical features include nervousness, malaise, palpitations, heat intolerance, weight loss, and inability to concentrate. Additional features may involve the eyes and include lid lag, proptosis, and ophthalmoplegia. The reproductive abnormalities include menstrual abnormalities, infertility, and spontaneous abortions.

   The most common cause of hyperthyroidism is an autoimmune process that affects thyroid hormone production (Graves disease). Antibodies bind to the TSH receptor and stimulate the thyroid gland to secrete increased amounts of thyroid hormone. Less common causes include subacute thyroiditis, toxic multinodular goiter, and struma ovarii.

   Excess thyroid hormone has an impact on sex steroids. Thyroid hormones stimulate hepatic production of SHBG. As a result, total serum estradiol, estrone, testosterone, and dihydrotestosterone are increased, yet free levels of these hormones remain within the normal range. The metabolic clearance pathways appear to be altered, which can be explained in part by the increased binding. The conversion rates of androstenedione to estrogen and testosterone are increased. The significance of the alterations in metabolism has not been determined.

   Menstrual irregularities frequently occur in hyperthyroid states. The exact mechanism is unclear. Altered levels of TRH and TSH do not appear to have a significant impact on the HPO axis. The LH surge may be impaired, although studies have shown that hyperthyroid patients have normal FSH and LH responses to exogenous GnRH. It is possible that the weight loss and psychologic disturbances associated with this disease may contribute to the menstrual abnormalities. It is interesting to note that endometrial biopsies of many amenorrheic patients with hyperthyroidism have demonstrated a secretory endometrium, indicating that many of these women remain ovulatory. Menstrual abnormalities return to normal with treatment.

2. **Hypothyroidism**—A more common disorder than hyperthyroidism in women of reproductive age, hypothyroidism results from inadequate thyroid hormone production. Manifestations can involve almost any organ system, and the presentation can range from asymptomatic to myxedema coma. Common symptoms include lethargy, memory defects, cold intolerance, dry skin, hair loss or occasionally excess hair growth, deepening of the voice, nausea, and constipation. Physical findings include somnolence; bradycardia; mild hypertension; dry skin; periorbital puffiness; nonpitting edema of the hands, face, and ankles; and decreased tendon reflexes. Reproductive abnormalities include menstrual disorders, infertility, and spontaneous abortions.

   The most common cause is autoimmune destruction of the thyroid (Hashimoto thyroiditis). It is mediated by humoral and cell-mediated processes. The antibodies are directed toward thyroglobulin (anti-Tg) and thyroid peroxidase (anti-TPO antibody). Histologic specimens show lymphocytic infiltration. Other causes include ablative therapy of the thyroid gland (postsurgery or radioactive iodine), end-stage Graves disease, and transient thyroiditis (viral, drug-induced, or postpartum).

   Inadequate thyroid hormone levels influence the metabolism of sex steroids. The production of SHBG is decreased. As a result, serum estradiol and testosterone concentrations are decreased, but free-hormone levels remain within the normal range. However, the metabolism of these steroids is altered and differs from that found in individuals with hyperthyroidism.

   The mechanism underlying menstrual abnormalities in hypothyroidism is incompletely understood. Because primary hypothyroidism is associated with elevated serum PRL in up to one-third of patients, it is plausible that hyperprolactinemia is a contributing factor (see Chapter 4). However, menstrual abnormalities are also observed in the absence of elevated PRL. Alterations in FSH and LH levels have been investigated, and studies have shown inconclusive results, although several studies suggest that the midcycle surge is absent. Menstrual function returns to normal with thyroid hormone replacement.

   Thyroid dysfunction often presents with nonspecific symptoms, which delays the diagnosis. If only menstrual abnormalities are present, it is prudent to screen for thyroid abnormalities. Most cases are detected by TSH assays. Confirmation is obtained with a repeat TSH level and serum thyroid hormone levels.

OUTFLOW TRACT DISORDERS

The true prevalence of Müllerian tract abnormalities is not known. It is reported in as many as 45% of women. The reproductive consequences depend on the type of abnormality identified. A septate uterus is the most common defect described. These patients often present with infertility or obstetric complications. Other abnormalities include unicornous, bicornous, and didelphic uteri. These abnormalities present most commonly with reproductive or obstetric complications. Müllerian agenesis, androgen insensitivity syndrome, and congenital outflow obstruction defects are abnormalities that present with primary amenorrhea with no history of menses. In the following section these two abnormalities are discussed in greater detail.

A. Müllerian agenesis   Müllerian agenesis (Mayer-Rokitansky-Küster-Hauser syndrome) is the second most common cause of primary amenorrhea. It is a congenital condition that occurs in

1 in 5000 female births. These individuals have normal ovarian development, normal endocrine function, and normal female sexual development. The physical findings are a shortened or absent vagina in addition to absence of the uterus, although small masses resembling a rudimentary uterus may be noted (see the section "Embryology and Anatomy" at the beginning of this chapter). About one-third of patients have renal abnormalities, and several have had bone abnormalities and eighth nerve deafness. These individuals have a 46,XX karyotype.

The exact cause has not been identified. It is known that regression of Müllerian structures in males is controlled by AMH, which is secreted by the Sertoli cells of the testis. One hypothesis assigns the underlying defect to an activating mutation of either the *AMH* gene or its receptor. The genes for both AMH and AMH receptor have been investigated, but no mutations have yet been identified in patients with this syndrome.

B. Androgen insensitivity syndrome   Androgen insensitivity syndrome (AIS) presents in somewhat the same way as Müllerian agenesis. The presentation differs in that individuals with complete AIS have minimal sexual hair. These patients have a male karyotype with a mutation of the androgen receptor on the X chromosome. They have normal testicular development and endocrine function. However, because the internal and external male sexual structures need testosterone for development, they are absent. This results in a female phenotype. Because the testis still secretes AMH, Müllerian regression does occur. Secondary sexual characteristics (female) develop as a result of peripheral conversion of testosterone to estradiol, effectively resulting in unopposed estrogen stimulation.

The diagnosis of either disorder is entertained when pelvic examination reveals a short or absent vagina and no uterus on rectal examination. Confirmation of absent uterus can be obtained with ultrasound, MRI, or laparoscopy. These two disorders can usually be differentiated based on physical examination; patients with AIS have no pubic hair. However, the differential diagnosis becomes more difficult when patients have incomplete AIS. A testosterone level and karyotype can easily differentiate the two syndromes. This disorder is further discussed in Chapter 14.

C. Congenital outflow obstruction   Transvaginal septum and imperforate hymen are typical obstructive abnormalities. These patients usually present with cyclic lower abdominal pain and amenorrhea. The physical findings are a shortened or absent vagina. However, this syndrome differs from Müllerian agenesis in that the pelvic organs are present. Behind either defect is old blood that has not escaped with menses. The differential diagnosis is sometimes difficult, although bulging of the introitus suggests imperforate hymen, because the defect is thinner than a transvaginal septum.

The embryologic formations of the transvaginal septum and imperforate hymen are similar but not identical. Transvaginal septum is due to failure of complete canalization of the vaginal plate (see the section "Embryology and Anatomy" at the beginning of this chapter). The septum can vary in thickness and can be located at any level in the vagina. The hymen represents the junction of the sinovaginal bulbs and urogenital sinus. Typically, the hymen is perforated during fetal development. The hymen is thin and is always at the junction of the vestibule and vagina. It is important to distinguish these defects because the surgical correction procedures are different and require different levels of expertise.

D. Asherman syndrome   Intrauterine adhesions or synechiae (Asherman syndrome) are an acquired condition that may obliterate the endometrial cavity. These patients usually present with a range of menstrual disturbances, infertility, and recurrent spontaneous abortions. The most frequent symptom is amenorrhea.

Intrauterine adhesions result from damage to the endometrial basal layer. A common antecedent factor is a surgical procedure within the uterine cavity, and most often it is endometrial curettage that occurs shortly after pregnancy. The concurrent presence of infection or heavy bleeding increases the risk. Endometrial tuberculosis and septic abortion are rare causes.

The diagnosis is entertained after demonstrating no withdrawal bleeding after administration of estrogen and progesterone. Confirmation is made with a hysterosalpingogram, saline sonogram, or hysteroscopy. Treatment involves lysis of adhesions and hormonal therapy.

MENOPAUSE

The ovary is unique in that the age at which it ceases to function in women appears to have remained constant despite the increase in longevity experienced by women over the last century. Because the loss of ovarian function has a profound impact on the hormonal milieu in women and the subsequent risk of the development of disease resulting from the loss of estrogen production, improving our understanding of reproductive aging is critical for optimal female health.

Human follicles begin development in the fourth gestational month. Approximately 1000 to 2000 germ cells migrate to the gonadal ridge and multiply, reaching a total of 6 to 7 million around the fifth month of intrauterine life. At this point, multiplication stops and follicle loss begins, declining to approximately 1 million by birth. In the human male, the germ cells become quiescent and maintain their stem cell identity. In contrast, in the human female, between weeks 12 and 18, the germ cells enter meiosis and differentiate. Thus, in the female, all germ stem cells have differentiated prior to birth. In the adult woman, the germ cells may remain quiescent, may be recruited for further development and ovulation, or may be destroyed by apoptosis. Over time, the population of oocytes is depleted (without regeneration) through recruitment and apoptosis until less than a thousand oocytes remain and menopause ensues. Approximately 90% of women experience menopause at a mean age of 51.2 years (range, 46-55). The remainder experiences menopause prior to age 46 (often termed early menopause), with 1% of women experiencing menopause before age 40 years (POF, as discussed earlier).

Understanding ovarian aging has been difficult. The variability in definitions has made comparisons from study to study difficult.

Menarche					**FMP (0)**				
Stage	−5	−4	−3b	−3a	−2	−1	+1a	+1b	+1c	+2

FIGURE 13–16 The stages of Reproductive Aging Workshop +10 staging system for reproductive aging in women. (Reproduced with permission from Harlow SD, Gass M, Hall JE, et al. Executive summary of the Stages of Reproductive Aging Workshop + 10: addressing the unfinished agenda of staging reproductive aging. *Menopause*. 2012 Apr;19(4):387-395.)

The participants in the Stages of Reproductive Aging Workshop (STRAW) +10 developed criteria for staging female reproductive aging (Figure 13–16). They utilized menstrual cyclicity and early follicular FSH levels as the primary determinants for this staging system. Stages −5 to −3a include the reproductive interval; stages −2 to −1 are termed the menopausal transition; and stages +1a through +2 are the postmenopause (see Figure 13–16). The telltale sign of the early menopausal transition is increased variability in menstrual cyclicity (>7 days) that is persistent in women with elevated FSH levels, low AMH, and low antral follicle count. Persistence is defined as recurrence within 10 cycles of the first variable cycle length. The duration of this transition is variable among women. The late menopausal transition is believed to last 1 to 3 years and is associated with vasomotor symptoms and interval of amenorrhea of 60 days or longer. This menopausal transition ends with the final menstrual period, which cannot be recognized until after 12 months of amenorrhea. Early postmenopause is defined as the first 6 years following the final menstrual period. The presence of urogenital atrophy is not thought to occur until the late postmenopause which begins 6 years after the final menstrual period and continues until death.

This system is said to include endocrinologic aspects of ovarian aging, but it still depends largely on menstrual cyclicity as a key indicator of ovarian age. The system includes measurement of FSH and AMH; however, by the time FSH is elevated or AMH is low, even in the face of cyclic menstrual cycles, oocyte depletion has already proceeded to such an extent that fertility (as a marker of reproductive aging) is significantly diminished. Evidence suggests that genetic and environmental factors influence both age at menopause and the decline in fertility, although the specific nature of these relationships is poorly characterized. Premature menopause can be due to failure to attain adequate follicle numbers in utero or to accelerated depletion thereafter. Potentially, either of these causes could be affected by genetic and environmental factors. The timing of menopause has a consistent impact on overall health with respect to osteoporosis, cardiovascular disease, and cancer risk. Over the next decade, it is estimated that more than 40 million women in the United States will enter menopause.

OOCYTE DEPLETION

As discussed earlier, the leading theory regarding the onset of menopause relates to a critical threshold in oocyte number. The theory that menopause is primarily triggered by ovarian aging is supported by the coincident occurrence of follicular depletion, elevation of gonadotropins, and menstrual irregularity with ultimate cessation.
FIGURE 13–17 A new model of reproductive aging: the decline in ovarian nongrowing follicle number (primordial follicles) from birth to menopause. (Reproduced with permission from Hansen KR et al. A new model of reproductive aging: the decline in ovarian non-growing follicle number from birth to menopause. *Hum Reprod.* 2008 Mar;23(3):699-708.)

In 1992, Faddy and colleagues developed a mathematical model to predict the rate of follicular decline. They utilized data from multiple sources to construct a model that ultimately showed a biexponential decline with an acceleration in oocyte loss beginning in the late thirties. More recently, Hansen et al utilized newer technology and a single population of specimens. They fit the data to multiple models and found that a pattern of gradually increasing atresia fit the decline in nongrowing follicles (Figure 13–17).
FIGURE 13–18 The antral follicle count (AFC) which declines with age in a Caucasian population is best described as a gradual acceleration in decline with age. Relationship of total AFC and chronological age. (Reproduced with permission from Rosen M et al. Antral follicle count: absence of significant midlife decline. *Fertil Steril.* 2010 Nov;94(6):2182-2185.)

This same model most closely follows the decline in the antral follicles—small (2-10 mm) growing follicles seen on ultrasound—seen across the reproductive-age span (Figure 13–18). As noted earlier, the loss of follicles (oocytes) is a constant process beginning in utero and continuing throughout reproductive life, even during pregnancy and in the absence of ovulation, until approximately 1000 follicles/oocytes remain and menopause ensues.

ENDOCRINE SYSTEM CHANGES WITH AGING

The entire endocrine system changes with advancing age. The somatotrophic axis begins to decline in the fourth decade, prior to the decline in ovarian function. This decline is accelerated in the face of ovarian failure and may act to accelerate the decline in ovarian function. However, pituitary concentrations of GH as well as ACTH and TSH remain constant into the ninth decade. While the thyroid gland undergoes progressive fibrosis with age and concentrations of T_3 decline by 25% to 40%, elderly patients still remain euthyroid. Beta cell function also undergoes degeneration with aging such that by age 65 years, 50% of subjects have abnormal glucose tolerance tests. Frank diabetes is less frequent, however, occurring in approximately 7% of the population. The female reproductive system, on the other hand, undergoes complete failure at a relatively early age.

Secretion of reproductive hormones during the menopausal transition (MT) was previously thought to decline progressively in a linear fashion, but hormone levels have since been shown to fluctuate widely. Studies in large cohorts of women have demonstrated that circulating FSH concentrations rise progressively during the MT. The initial monotropic rise in FSH is attributed to a decrease in ovarian inhibin secretion rather than to a decrease in estradiol production.

Inhibin and activin are proteins produced by the granulosa cells and have been shown to play major roles during the MT. Inhibin consists of a covalently bound dimer with an α subunit and one of two different β subunits, designated as β_A and β_B; the resulting heterodimers are known as inhibin A and inhibin B. Inhibin A is secreted by the corpus luteum and inhibin B by antral and dominant follicles. Consequently, inhibin A levels increase during the luteal phase, and inhibin B concentrations rise during the follicular phase. Both inhibins inhibit pituitary FSH secretion. Activins are a related class of proteins that stimulate pituitary FSH release. The activin molecule is a homodimer composed of two covalently linked inhibin β subunits, designated as activin A ($\beta_A\beta_A$) and activin B ($\beta_B\beta_B$).

AMH is also secreted by the granulosa cells of secondary and preantral follicles. Circulating concentrations remain relatively stable across the menstrual cycle and correlate with the number of early antral follicles. Levels of AMH decrease markedly and progressively across the MT to a time point approximately 5 years prior to the final period when levels are below the limit of detection.

During the late reproductive stage (stage –3), follicular phase inhibin B levels decrease as FSH concentrations rise. As the MT progresses, luteal phase inhibin A levels also decline. Activin A concentrations also are elevated in perimenopausal women. Whereas activins clearly play a local role in regulating pituitary FSH secretion, their ability to act as endocrine factors to influence the production of FSH has not been established. Thus, a decrease in secretion of inhibin A and inhibin B, and a corresponding increase in activin production may favor increased FSH secretion in the absence of any decrease (and perhaps an increase) in estradiol production.

Estrogens/Progesterone

The main circulating estrogen during the premenopausal years is 17β-estradiol. Levels of this hormone are controlled by the developing follicle and resultant corpus luteum. The fact that oophorectomy reduces peripheral estradiol levels from 120 to 18 pg/mL confirms that over 85% of circulating estradiol is derived from the ovary. In perimenopausal women, estradiol production fluctuates with FSH levels and can reach higher concentrations than those observed in young women under age 35. Estradiol levels generally do not decrease significantly until late in the MT. Estradiol levels may be quite variable, with chaotic patterns and occasionally very high or very low levels. This dramatic variability may lead to an increase in symptomatology during the perimenopausal years (stages –2 to –1). As peripheral gonadotropins rise, LH pulsatile patterns become abnormal. There is an increase in pulse frequency, with a decrease in GnRH inhibition by opioids. Despite continuing regular cyclic menstruation, progesterone levels during the early MT are lower than in women of mid-reproductive-age and vary inversely with body mass index. Women in the late MT exhibit impaired folliculogenesis and an increasing incidence of anovulation, compared to mid-reproductive-aged women. Essentially all estradiol in postmenopausal women is derived from peripheral conversion from estrone.

The predominant estrogen in the postmenopausal woman is estrone, with a biologic potency approximately one-third that of estradiol. The circulating levels of estrone (and estrone sulfate) in older women are approximately one-third to one-half of the concentration observed in women of reproductive age (Table 13–7).

TABLE 13–7 Plasma concentrations of sex steroids in premenopausal and postmenopausal women.

Steroid (concentration)	Premenopausal	Postmenopausal
Estrone (pg/mL)	50->125[a]	30-35
Estrone sulfate (pg/mL)	1000-1800[a]	350
Estradiol (pg/mL)	50->250[a]	10-20
DHEAS (ng/mL)	1-3	0.1-2.7
Testosterone (ng/mL)	<1	<1

[a]Plasma concentration depends on the phase of menstrual cycle.
Abbreviation: DHEAS, dehydroepiandrosterone sulfate.

This is due to estrone production, resulting largely from peripheral aromatization of androstenedione (see earlier). This aromatase activity increases with aging by two- to fourfold and is further amplified by the increased adiposity that typically accompanies the aging process (see earlier). Estrone and estradiol production rates during the postmenopausal years are 40 and 6 μg/d, respectively. This compares with 80 to 500 μg/d for estradiol during the reproductive years.

Androgens

In contrast to estrogens, circulating androgens (DHEAS, androstenedione, and testosterone) decrease less dramatically after physiologic menopause (see Table 13–7). DHEAS undergoes a linear reduction with aging in both men and women (~2% per year starting at age 30), but there is no specific decline associated with menopause. Changes in DHEAS levels have been associated with alterations in body composition with aging. Androstenedione production similarly decreases with aging, but the circulating levels are affected less because ovarian secretion is maintained, albeit at a reduced rate. Testosterone levels do not vary appreciably during the MT. Testosterone levels decrease after menopause. Historically it was believed the postmenopausal ovary produced a larger percentage of testosterone (50%) than did the premenopausal ovary. However, the literature is conflicting on the origin of androgens in postmenopausal women. The conventional view was that the adrenals, ovaries, and periphery all contributed to circulating androgen levels in postmenopausal women. Contemporary data suggest that androgen production after menopause is largely derived from adrenal precursors. This is supported by studies that have shown that postmenopausal women receiving dexamethasone suppression, or who have endogenous adrenal insufficiency, have undetectable levels of circulating androgens. Investigators have also demonstrated that the postmenopausal ovary has no appreciable enzymatic activities capable of generating sex steroids. The fact that women of reproductive age who undergo a bilateral oophorectomy have less testosterone and androstenedione than menopausal women with intact ovaries challenges this concept. However, the conflict may be explained by the hypothesis that the postmenopausal ovary produces androgens for a limited time.

Hypothalamic/Pituitary

Significant additional information regarding the hormonal changes during the menopausal transition is being developed in the multiethnic, community-based, longitudinal study of perimenopausal women at seven sites throughout the United States, The Study of Women's Health Across the Nation (SWAN). While most attention has been devoted to the role of the ovarian and oocyte decline in the onset of menopause, new evidence suggests potential alterations in the hypothalamic-pituitary feedback system. In evaluating the ability of estradiol to stimulate an effective LH surge, data from SWAN suggest the MT is characterized by three distinct hormonal patterns: (1) estrogen rise with rise in LH

but anovulation; (2) estrogen rise without a concomitant rise in LH; or (3) failure of rise in either estradiol or FSH. Additionally, there may be ethnic differences in the sensitivity of the pituitary to negative feedback.

MENOPAUSAL CONSEQUENCES

Given the endocrinologic changes associated with aging, many symptoms appearing in the aging female may be due to estrogen deficiency or diminished androgen or GH secretion. Disorders that are definitely due to estrogen deprivation include vasomotor symptoms and urogenital atrophy. Osteoporosis is also thought to be due largely to estrogen deficiency, and it may be exacerbated by the relative decline in GH levels. The same may be said for the hormone-related increase in the prevalence of atherosclerotic cardiovascular disease and psychosocial symptoms, including insomnia, fatigue, short-term memory changes, and possibly depression. Both DHEAS and GH may impact these phenomena as well. Most women who are symptomatic during the MT present with frequent or excessive bleeding or with hot flashes and other symptoms of estrogen deficiency. Other common symptoms during the MT include decreased libido, forgetfulness, vaginal dryness, and urinary incontinence.

Mood disorders also are increased during the MT. Community-based surveys have shown that perimenopausal women report significantly more psychological distress and have an increased risk for significant depression, compared with premenopausal or postmenopausal women. In an 8-year longitudinal study of premenopausal women having no prior history of depression, a depressive disorder was more likely to be diagnosed during the MT than in the premenopausal years (OR, 2.5; 95% CI, 1.25-5.02, $p = 0.01$).

Vasomotor Symptoms

Vasomotor symptoms (hot flushes) are experienced with greatest frequency during stages −1 and +1, with about 75% to 85% of women complaining of this symptom. Although 80% of the US women have symptoms lasting for at least 1 year, only 25% of women are still symptomatic at 5 years after the final menstrual period. Studies of hot flushes with external monitoring of skin temperature and resistance have shown a frequency of approximately 54 ± 10 minutes. In sleep studies, hot flush frequency has been shown to interrupt rapid eye movement sleep and may contribute to some of the psychosocial complaints. Hot flushes are temporally correlated with pulses of LH, but exogenous LH does not induce a flush, suggesting that there is some central mediator leading to both the flush and the elevation in LH.

Sleep disturbances, most likely the result of vasomotor activity, also are very common during the MT. In longitudinal studies of perimenopausal women, the prevalence of sleep disturbances has ranged from 32% to 40% in the early MT and from 38% to 46% in the late MT.

Vasomotor symptoms during the MT can be treated with hormone therapy (HT) using estrogen or progestin alone or in combination, neuroactive agents, or other nonhormonal alternatives.

Estrogen therapy provides the best treatment for severe vasomotor symptoms, reducing their frequency and severity in 80% to 85% of women over 12 weeks compared with 30% of women receiving placebo. Hormone therapy also may help in the management of depression associated with the MT. In a randomized, placebo-controlled, 12-week trial involving perimenopausal women ages 40 to 55, symptoms of depression were improved in 68% of women receiving unopposed estrogen treatment (0.1 mg transdermal estradiol patch), compared with 20% of those receiving placebo ($p = 0.001$). In general, HT should be used at the lowest doses to manage menopausal symptoms. Testing estrogen levels is not necessary and should not guide treatment.

Other drugs have been tried in women for whom estrogen is contraindicated, although none have the efficacy of HT for the treatment of menopausal symptoms. These alternatives include transdermal clonidine, ergot alkaloids, and, more recently, selective serotonin reuptake inhibitors and gabapentin. High-dose progestins may also produce some relief.

Genital Atrophy

The vagina, vulva, urethra, and bladder trigone not only share embryonic proximity but all contain estrogen receptors. Atrophy begins in stage −2 to −1. The most common symptoms include itching and vaginal thinning, with decreased distensibility and reduced secretions, leading to vaginal dryness and pain with intercourse. This and the change in pH with resultant changes in vaginal flora increase the incidence of vaginal and urinary tract infections. Estrogen is the treatment of choice, and treatment must continue for at least 1 to 3 months for symptomatic improvement to be noted. The systemic dosage necessary for vaginal protection is somewhat higher than that needed for bone protection (see later), and local therapy by means of creams or vaginal rings may thus be advisable to limit systemic absorption. It should be noted, however, that vaginal absorption of steroids is quite efficient once estrogenization and revascularization have occurred. If the goal is to limit systemic absorption, slow-release rings may be superior to estrogen creams.

Vaginal estrogen frequently improves symptoms of urinary frequency, dysuria, urgency, and postvoid dribbling. Its direct effect to improve stress incontinence is less clear.

Osteoporosis

Osteoporosis is a condition in which bone loss is sufficient to allow fracture with minimal trauma. Major risk factors for the development of osteoporosis are the peak bone density attained in the late teens and early twenties (stressing the importance of bone building in the young) and the rate of loss (accelerated with estrogen deficiency). Primary or *senile* osteoporosis usually affects women between the ages of 55 and 70 years. The most common sites include the vertebrae and the long bones of the arms and legs. Secondary osteoporosis is caused by a specific disease (such as hyperparathyroidism) or medication usage (such as glucocorticoids) (see Chapter 8).

Menopausal bone loss begins before the final menstrual period during stage −1. Postmenopausal osteoporosis causes over 1.3 million

fractures annually in the United States. Most of the more than 250,000 hip fractures are due to primary osteoporosis, and—given that 15% of patients die within a year after a hip fracture and 75% of patients lose their independence—the social costs, not to mention the financial costs, are great.

Bone loss following natural menopause is approximately 1% to 2% per year compared with 3.9% per year following oophorectomy. A woman's genetic background, lifestyle, dietary habits, and coexisting disease also influence the development of osteoporosis. Cigarette smoking, caffeine usage, and alcohol consumption also negatively affect bone loss, whereas weight-bearing activity appears to have a positive influence. See Chapter 8 for a detailed discussion of bone and mineral metabolism and osteoporosis.

A. Osteoporosis treatment

1. **Estrogen therapy**—Estrogen therapy acts via the inhibition of bone resorption. Both BMD and fracture rate are improved with estrogen therapy. However, with cessation of estrogen therapy, there is a rapid and progressive loss of bone mineral content. By 4 years after therapy, bone density is no different from that of patients who were never treated with estrogen. Estrogen is approved for prevention of osteoporosis, and there is also some support for its usage as a treatment modality in established disease. Dosages of 0.625 mg of conjugated estrogens orally daily—and, more recently, as low as 0.3 mg—have been shown to slow bone loss and provide adequate protection against the development of osteoporosis. Higher dosages may be required to treat existing disease.

2. **Alternative therapies for osteoporosis**

    a. **Calcitonin**—Calcitonin is a hormone normally secreted by the thyroid gland. Calcitonin (salmon) is available as a nasal spray specifically developed to decrease local side effects caused by subcutaneous injection. Although few studies have been performed and no data are available regarding reduction in hip fracture, it does seem to be especially beneficial for women with a recent and still painful vertebral fracture. Intranasal calcitonin has also been shown to improve spinal bone density and decrease the vertebral fracture rate in established osteoporosis. The increase in bone density appears to peak in as little as 12 to 18 months. The waning effects of calcitonin therapy over time may be due to downregulation of calcitonin receptors on osteoclasts and/or the development of neutralizing antibodies.

    b. **Bisphosphonates**—These compounds are analogs of pyrophosphates and have a high affinity for hydroxyapatite in bone matrix. The basic structure of bisphosphonates allows a large number of manipulations of the basic molecule, producing different types of bisphosphonates that vary considerably in their potency on bone. In order of increasing potency are pamidronate, alendronate, risedronate, ibandronate, and zoledronic acid.

    Alendronate has been evaluated extensively in patients with osteoporosis. Alendronate has been shown to inhibit markers of bone remodeling and increase BMD at the lumbar spine, hip, and total body and reduces fracture risk. Alendronate is taken orally; the recommended doses are 70 mg once weekly or 10 mg daily; alendronate must be taken according to a strict dosing schedule (in the morning on an empty stomach, with the patient required to remain upright for 30 minutes thereafter). The medication has very poor bioavailability (approximately 1%), and for that reason these instructions must be meticulously obeyed. Alendronate also has a propensity for causing irritation of the esophagus and stomach, especially in women with preexisting esophageal reflux, gastric or duodenal disease. Risedronate is similarly effective in the dosage of 35 mg weekly or 5 mg once daily, and the same dosing regimen is recommended. Ibandronate has the easiest schedule for administration 150 mg once monthly.

    Increases in bone density with alendronate, risedronate, and ibandronate are greater than what is seen with calcitonin and similar to what is seen with HT. The escape phenomenon seen with calcitonin is not seen with these oral bisphosphonates.

    An important issue concerning long-term administration of bisphosphonates relates to their long half-lives in bone and their incorporation into the bone matrix and the potential for rare adverse events such as atypical fractures and osteonecrosis of the jaw.

    c. **SERMs**—Raloxifene is the first selective estrogen receptor modulator (SERM) approved for prevention and treatment of osteoporosis and for the prevention of breast cancer. SERMs act selectively as estrogen receptor agonists in some tissues (bone and heart) and antagonists in others (breast and uterus and possibly brain). Data with raloxifene show preservation of BMD, albeit less well than that seen with alendronate, risedronate, ibandronate, or HT, and spinal fracture data support a protective effect.

    It is believed that the differential effects of estrogens and antiestrogens are related to the transcriptional activation of specific estrogen response elements. Two different domains of the estrogen receptor (AF-1 and AF-2) are responsible for this transcriptional activation. Estrogens and antiestrogens appear to act via different domains, leading to their differential effects. Both act to maintain BMD—at least partially—via regulation of the gene for TGF-β.

    Recently a tissue selective estrogen complex (TSEC), a combination of conjugated estrogen plus the SERM bazodoxifene, was released for the prevention of osteoporosis. This agent is designed to preserve BMD while controlling the side effects commonly seen with SERM therapy (eg, hot flashes) by estrogen.

    d. **Calcium and vitamin D**—These are critical adjuvants for any type of antiresorptive therapy. Decreased ability to absorb calcium among older women is due in part to impaired vitamin D activation and effect. Older women may have limited exposure to sunlight, and their dietary vitamin D intake may be lower than that of younger women.

    Daily intakes of 1000 to 1200 mg of calcium and 800 to 1200 IU of vitamin D are probably sufficient to reduce the risk of fragility fractures very modestly (~10%).

    e. **Anabolic therapy**—The only anabolic therapy currently available for the treatment of severe osteoporosis parathyroid hormone (1-34) or teriparatide was approved for clinical use in 2001. Details about its efficacy and use are described in Chapter 8.

f. Antibody to receptor activator of nuclear factor kappa B ligand (RANK-L) therapy—This agent is a neutralizing monoclonal antibody to RANK-L that blocks osteoclastogenesis and is highly effective in reducing spine, hip, and nonvertebral fractures. Its mechanism of action and efficacy are discussed in Chapter 8.

Atherosclerotic Cardiovascular Disease

Cardiovascular disease is the number one cause of mortality in both men and women in Western society. This is largely attributed to age and lifestyle. Lifestyle modifications are known to decrease the incidence of atherosclerotic cardiovascular disease. For women, cardiovascular disease is largely a disease of the postmenopause. Women now spend more than a third of their lives in the postmenopausal years, and preventive measures are thus of paramount importance. Although a large body of observational evidence supported a protective effect of ET on cardiovascular disease, observational data are limited by the confounding variables of patient self-selection. Animal and *in vitro* studies, as well as assessment of surrogate markers in women, also showed a positive effect of ET and HT against cardiovascular disease development. However, several large randomized, controlled studies fail to support a protective role for HT in preventing cardiovascular events.

One of the first such trials was the Heart and Estrogen-Progestin Replacement Study (HERS), a secondary prevention trial that evaluated the use of daily HT (0.625 mg conjugated estrogens plus 2.5 mg medroxyprogesterone acetate [MPA]) in 2763 postmenopausal women with a mean age of 66.7 years and preexisting vascular disease. The study failed to demonstrate any overall difference in vascular events. This occurred despite improvements in lipid parameters in those patients receiving HT. The Estrogen Replacement and Atherosclerosis (ERA) Trial compared 3.2 years of treatment with estrogen, combined estrogen and progestin, and placebo in postmenopausal women aged 42 to 80 years. It also failed to demonstrate a significant difference in the rate of progression of coronary atherosclerosis between the three groups. The importance of this study was the inclusion of an estrogen-only arm.

The Women's Health Initiative (WHI) was the first large randomized study to look at primary prevention of cardiovascular disease. This study compared (1) the combination of conjugated equine estrogen (CEE) and MPA with placebo and (2) CEE to placebo. It was designed to assess the overall risks and benefits of HT in a prospective randomized fashion.

The WHI demonstrated that there was an unacceptable risk profile for the combination HT arm of the trial. There was an increase in the incidence in breast cancer (an increase of 8 cases per 10,000 women) with no cardiovascular protection (and potentially increased cardiovascular risk). There was, in fact, an increase in venous thromboembolism, strokes, and coronary heart disease. The risk of stroke and thromboembolism continued for the 5 years of study, whereas most of the coronary heart disease was limited to the first year of treatment. There were, however, documented decreases in the risk of fracture and colon cancer.

In the CEE-only arm, there was an increased risk of stroke and a decreased risk in hip fractures compared to placebo. This study showed that the use of ET had no protective effect on coronary heart disease. Interestingly, there appeared to be a trend toward a reduction in breast cancer (0.77, CI 0.59-1.01) with use of ET. More recent studies and reevaluation of large datasets have suggested that combined estrogen/progestin has a more profound increased risk on breast cancer, than estrogen alone or cyclic progestins, consistent with increase in mitogenic activity of the breast during the normal luteal phase when progesterone levels are high.

Treatment—Summary

As noted earlier, long-term use of HT in older menopausal women has been associated with increased risks for venous thromboembolism, coronary events, stroke, and breast cancer. Although short-term treatment of symptomatic women during the MT likely poses significantly fewer risks, HT generally should be used in the lowest effective dose and for the shortest time required. Testing estrogen levels is not necessary and should not guide treatment. Data suggest the use of HT does not increase the risk of breast cancer, on a yearly basis, more than would continuing spontaneous cycles for any given age. This suggests treatment of symptomatic women in their forties may not increase breast cancer risk over normal cycling. Low-dose estrogen regimens (conjugated equine estrogens, 0.3 mg daily, or its equivalent) can achieve as much as a 75% reduction in vasomotor symptoms over 12 weeks, approaching the efficacy of standard-dose HT regimens, and may be associated with fewer risks and side effects. The decision to use HT should be made only after first carefully reviewing its risks and benefits for the individual.

The relative safety of HT during the MT has not been thoroughly investigated. The results of one observational study have suggested that women who start HT near menopause had a decreased risk of coronary heart disease when taking estrogen alone (relative risk [RR] = 0.66; 95% CI, 0.54-0.80) or in combination with progestin (RR = 0.72; 95% CI, 0.56-0.92). A secondary analysis conducted by the investigators involved in the WHI revealed that risk for coronary heart disease was not significantly increased in women under age 60 years of age or within 10 years of menopause. Further studies to evaluate the safety and efficacy of HT during the MT and the early postmenopausal years are ongoing.

Concerns about the risks of HT have increased interest in nonhormonal alternatives for the treatment of symptoms in the MT. In some women, vasomotor symptoms during the MT can be reduced by wearing layered clothing, avoiding caffeine and alcohol, and by keeping the ambient temperature a few degrees cooler. Herbal treatments, such as black cohosh (Remifemin Menopause; Enzymatic Therapy, Green Bay, WI), have been shown to have marginal or no benefit in placebo-controlled trials. Neuroactive agents, including selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), alpha adrenergic agents, and others all have some efficacy in the treatment of vasomotor symptoms (Table 13–8). Both SSRIs and SNRIs may be effective because norepinephrine and serotonin appear to be involved in the hypothalamic regulation of temperature homeostasis and to play a role in the development of

TABLE 13–8 Treatment for hot flashes.

Drug	Name	Dose (mg/day)
SSRI	Citalopram	10-20
	Fluoxetine	10-20
	Sertraline	25-50
	Paroxetine	10-20
SNRI	Venlafaxine	37.5-150
	Desvenlafaxine	50-100
Alpha adrenergic agents	Clonidine	0.1
Gamma aminobutyric acid	Gabapentin	300-900

hot flashes. Randomized placebo-controlled trials have shown that SSRIs (citalopram, sertraline, paroxetine) and SNRIs (venlafaxine) can help to reduce the severity and frequency of hot flushes. Clonidine (an alpha adrenergic agonist) and gabapentin also have some efficacy. Gabapentin is the only agent compared head-to-head with estrogen suggesting equivalent efficacy when used in high doses.

The WHI study did not address the effect of hormone treatment on hot flushes and vaginal atrophy. Clearly, there are alternatives for the treatment of osteoporosis and cardiovascular disease that are superior if prevention of both conditions is the sole reason for HT. Every woman should discuss with her caregiver the optimal management for her as an individual. This should take into account medical and family history as well as symptomatology. It can be uniformly recommended, however, that menopausal women maintain appropriate nutrition, weight reduction, and exercise along with moderation in alcohol and caffeine intake and cessation of smoking.

INFERTILITY

Infertility is defined as the inability of a couple to conceive after 1 year of frequent unprotected intercourse without contraception. This definition is based on observational data showing that approximately 85% of couples achieve pregnancy after 1 year of unprotected coitus. Using this definition, approximately 15% of reproductive-age couples experience infertility. However, the diagnosis of infertility does not mean that they cannot conceive—a more precise diagnosis term would be **subfertility**, or a diminished capacity to conceive. The actual probability of the fertility potential of a population may be better assessed with variables that can quantify a monthly cycle rate. The concepts that have been used for quantitative analysis are **fecundability** and **fecundity**. Fecundability is defined as the probability of achieving a pregnancy within one menstrual cycle, and in normal couples the chance of conception after 1 month is approximately 25%. Fecundity is a related concept that is defined as the ability to achieve a live birth within one menstrual cycle.

In the United States, demands for infertility treatment have dramatically increased. The 1995 National Survey of Family Growth reported that 9.3 million women received infertility treatment in their lifetime compared with 6.8 million in 1988. This rise in treatment is due not only to increased public awareness—it also reflects the significant demographic, societal, and economic changes in our society. These include the aging of the baby boom generation, which has increased the size of the reproductive-age population. Perhaps more important is the increased use of contraception and postponement of childbearing until the last two decades of a woman's reproductive life. Approximately 20% of women in the United States now have their first child after 35 years of age.

Age alone has a significant impact on fertility and affects a woman many years before the onset of menopause. One factor is the age-dependent loss of ovarian follicles (see later). A 38-year-old woman has 25% of the fecundability of a woman under 30 years of age. Another age-related subfertility factor is that the spontaneous abortion rate increases with advancing age. The overall incidence of clinical abortion increases from 10% in women under age 30 to more than 40% in women over 40. The increased pregnancy loss can be largely attributed to abnormalities in the aging oocyte; older follicles have an increased rate of meiotic dysfunction, resulting in higher rates of chromosomal abnormalities.

The main causes of female subfertility can be classified in the following way: (1) ovulatory defects, (2) pelvic disorders, and (3) male factors. These factors account for 80% to 85% of couples diagnosed with infertility. They are not mutually exclusive—about 15% of couples have more than one cause of subfertility. In approximately 20% of couples, the cause remains unknown and is classified as unexplained infertility. This section will briefly discuss the causes of subfertility and review the diagnosis and management.

DIAGNOSIS OF INFERTILITY

Ovulatory Defects

Ovulatory disorders are responsible for 25% of cases of infertility. Ovulatory status can be obtained from the history. If a woman experiences cyclic, predictable menses at monthly intervals, ovulation can be predicted 98% of the time. This is not an invariable rule, however, and irregular menstrual cycles are not a sure sign of anovulation.

The only way to confirm ovulation is by achieving pregnancy. However, a variety of methods can indicate that ovulation has occurred. For example, a thermal shift occurs around the time of ovulation. Prior to ovulation, morning basal body temperature (BBT) is below 98°F (36.7°C), and after ovulation the temperature increases at least 0.4°F (0.2°C) for at least 1 to 3 days. This rise in temperature reflects the progesterone that is secreted from the corpus luteum, which consequently raises the hypothalamic set-point for BBT. The temperature rise occurs approximately 2 days after ovulation because of the time and dose required for the progesterone effect at the hypothalamus. BBT can, therefore, not be utilized to prospectively predict ovulation. Measurements of midluteal serum progesterone concentration can also be performed to document the occurrence of ovulation. If this level is

greater than 3 μg/L (9.5 nmol/L), it is a strong indication that ovulation has occurred. An endometrial biopsy can confirm ovulation. It is performed during the luteal phase and gives a qualitative assessment of ovulation, because the duration of progesterone exposure produces predictable endometrial histology. Lastly, a sonographic examination documenting a decrease in follicle size—or disappearance altogether of the previously developed follicle—is suggestive of ovulation. All of these methods indicate that ovulation has occurred.

There are only a few ways to predict that ovulation is going to occur. The most common way is to detect the LH surge. Ovulation typically occurs 34 to 36 hours after the onset of the LH surge.

Although ovulation may occur, some women may have a luteal-phase defect. This is characterized by an inadequate quantity or duration of progesterone secretion by the corpus luteum. There is a distinct window of time for implantation. The theory is that the progesterone deficiency desynchronizes ovulation (egg) and implantation (endometrium). However, the incidence of luteal phase defects is difficult to assess because the definition is not standardized. Typically, the diagnosis is established by luteal phase endometrial dating; if the histologic development of the endometrium lags more than 2 days beyond the day of the cycle, it is diagnostic of a luteal phase defect. However, up to 30% of women with normal cycles meet this criterion. Another method involves measuring midluteal progesterone levels. If progesterone is less than 10 ng/mL, it suggests a luteal phase defect. This is not reliable because progesterone is intermittently secreted, and the serum progesterone level can change from 1 hour to the next in the same individual. Furthermore, the lack of properly validated tests places the existence of luteal phase defects and their association with subfertility in question. Lastly, as empiric treatment for unexplained infertility has developed, delaying treatment (see later, superovulation with IUI) for exact diagnoses has less importance. More sophisticated testing of endometrial proteins required for implantation (eg, integrins, glycodelin) may revive enthusiasm for making a specific diagnosis in the future.

The cause of ovulatory dysfunction has been previously discussed. All anovulatory patients should have determination of PRL and TSH levels—and, if necessary, androgen levels—to identify the cause of the ovulatory disturbance. Treatment should be directed toward the cause, which is discussed in greater detail later. It could be argued that all patients should have evaluation of early follicular cycle (days 2-4) FSH, LH, and estradiol to assess ovarian reserve (age).

Pelvic Disorders

Pelvic disorders account for more than 30% of couples with the diagnosis of infertility. Uterine tube damage and adhesion formation are responsible for most pelvic pathologic processes causing infertility, whereas endometriosis is the primary pelvic disorder causing subfertility. The causes of tubal damage and adhesions include postinfectious state (pelvic inflammatory disease [PID]), endometriosis, and a history of pelvic surgery (especially surgery for ruptured appendicitis).

PID is defined as infection of upper genital tract structures and is usually caused by a sexually transmitted disease. The known initiating organisms are chlamydiae and *Neisseria gonorrhoeae*. The symptoms are variable but usually include lower abdominal pain, nausea, and vaginal discharge. However, in up to 30% of chlamydial infections, PID may be clinically inapparent and may remain undiagnosed until presenting with subfertility.

Endometriosis is the presence of endometrial glands and stroma outside of the uterus. There may be no manifestations other than infertility, or symptoms may progress to include severe pelvic pain, dysmenorrhea, and dyspareunia. The diagnosis is suspected if findings on surgical exploration show characteristic lesions. Lesions can be staged according to published criteria. Diagnosis is confirmed with biopsy of the peritoneal lesions. The disease occurs in approximately 3% to 10% of reproductive-age women and may be responsible for up to 25% to 35% of the female factors responsible for subfertility.

The pathogenesis of endometriosis is not completely known. A prominent theory (Sampson) involves retrograde menstruation. It is well established that menses can flow through the uterine tubes into the abdominal cavity. In fact, this phenomenon is thought to occur in almost all menstruating women. There is good evidence that the endometrial tissue subsequently invades and proliferates into the peritoneum. It is theorized that the immune system should normally dispose of the tissue and that altered immunity may result in implantation of this endometrial tissue outside the uterus in those women who subsequently develop endometriosis.

There is a strong association between adhesive disease and endometriosis. In these cases, the cause of subfertility is a result of distorted anatomy and consequently altered function. However, in mild cases of endometriosis, where only peritoneal lesions are identified and no anatomic distortion exists, the cause of infertility remains uncertain and controversial. There is evidence that the peritoneal fluid is altered in the presence of endometrial tissue with increased macrophages and inflammatory mediators. Several studies suggest that inflammatory changes result in adverse effects on folliculogenesis, ovum transport, fertilization, and implantation.

Tubal damage can be diagnosed with a hysterosalpingogram or surgical exploration. Hysterosalpingography involves the introduction of radiopaque contrast media into the pelvis through the cervix and then fluoroscopy, revealing an outline of contrast in the uterine cavity, uterine tubes, and peritoneal cavity. The diagnosis of pelvic endometriosis can only be made by surgery, and most often the surgical procedure is laparoscopy. Diagnostic laparoscopy is usually done when there is a high suspicion of endometriosis based on the clinical history or adhesive disease based on a history of PID or pelvic surgery. Laparoscopy may also be performed, if all other tests are normal and the couple continues not to achieve a pregnancy.

Male Factor Causes

The male factor contributes in 40% to 50% of cases of diagnosed infertility, and all evaluations should include the male partner. The diagnostic test for male factor infertility is the semen analysis.

Although this is a largely descriptive test (volume, sperm count, motility, and morphology), there is some correlation with pregnancy outcome. This should be used solely as a screening test. To understand the pathophysiology of male factors, it is important to review the physiology of spermatogenesis and the anatomy of the male reproductive tract as described in Chapter 12.

Unexplained Infertility

Approximately 15% to 20% of the couples diagnosed with infertility have no identifiable cause after a full investigation. The workup should include documentation of ovulation (regular menstrual cycles, progesterone levels, or LH testing), hysterosalpingography to verify patent fallopian tubes, and a semen analysis. The term *unexplained* implies that there is a potential explanation for the subfertility, but the cause has yet to be identified. The cause may be subtle abnormalities in folliculogenesis, sperm-ovum interactions, or defective implantation.

Several studies have evaluated the natural history of unexplained infertility. It is estimated that fecundity in younger couples (female partner under the age of 40) with unexplained infertility is 3% to 5% compared with 20% to 25% in the age-matched couples with normal fertility. Treatment involves methods that increase fecundability and are discussed later.

MANAGEMENT OF THE INFERTILE COUPLE

It is important to remember that in most couples, there is a chance for spontaneous conception. Recent studies estimate that the average probability for live birth without treatment is 25% to 40% during the 3 years after the first infertility consultation. This translates into a cycle fecundity rate of 0.7% to 1% per month. The presence of endometriosis, abnormal sperm, or tubal disease independently reduces the chance of spontaneous pregnancy and live birth by approximately 50% for each variable. Infertility for more than 3 years, female age over 30 years, and primary infertility were important negative prognostic factors.

Evaluation should focus on known causes of infertility or subfertility: ovulatory defects, pelvic disorders (tubal disease, endometriosis), and male factor issues.

Ovulatory Disorders

Treatment should be diagnosis-specific, if possible. For the female, this means that the cause of any ovulatory defect should be determined and specific treatment then instituted. This enhances outcome and decreases the risk of complications (spontaneous abortion and multiple gestation). This treatment may include the use of dopamine agonists (hyperprolactinemia), thyroid replacement (hypothyroidism), pulsatile GnRH (hypogonadotropic hypogonadism), or clomiphene citrate (for PCOS). The most common cause of anovulation is inappropriate feedback such as in PCOS. Ovulation in patients with PCOS can be induced with clomiphene citrate, a nonsteroidal agonist-antagonist of estrogen that blocks the hypothalamic-pituitary axis from feedback by circulating estrogens. As a result, there is increased gonadotropin release to stimulate follicular recruitment and ovulation. In addition, because PCOS is associated with insulin resistance, and elevated insulin directly has an impact on the ovary, insulin sensitizers such as metformin have been used to enhance ovulatory response in women with PCOS. However, a large multicenter randomized trial compared clomiphene to metformin and found clomiphene to be significantly more effective for ovulation induction and achieving a live birth Most recently, letrozole, when compared with clomiphene, was associated with higher live-birth and ovulation rates among infertile women with PCOS.

Pelvic Disorders

In general, adhesive tubal lesions should be treated surgically. The location and extent of disease should, however, be evaluated. Patients with distal tubal occlusion—unless it is very mild—are most often better served by assisted reproduction (*in vitro* fertilization [IVF]). Other possible causes of infertility should also be examined. If a patient has a history of documented tubal disease, in addition to other abnormalities (ovulatory dysfunction or male factor infertility), or if they are over 35, the likelihood for successful surgical management decreases by approximately 50%, and consideration for avoiding surgery and moving directly to assisted reproduction is paramount. The exception to this rule is the presence of hydrosalpinges on ultrasound. The presence of hydrosalpinges that retain fluid when nondistended (ie, not seen with hysterosalpingography) leads to a significant reduction in outcome with assisted reproductive therapy (ART). Prior removal or proximal occlusion of the tube to prevent contamination of the uterine cavity should be performed before ART is offered.

There are conflicting data in the literature concerning the appropriate treatment for mild endometriosis. A well-designed randomized trial from Canada evaluated the effect of surgical treatment on pregnancy outcome for patients diagnosed with mild endometriosis without anatomic distortion. It showed that pregnancy rates at 9 months post-laparoscopy were 27% in the surgically treated group compared with 18% in the untreated group. Severe endometriosis (disease that alters the pelvic anatomy or involves the ovary with endometriomas) should be surgically treated to restore normal pelvic anatomy. There appears to be no advantage to medical therapy for endometriosis in women seeking fertility.

Male Factor Infertility

Male factor infertility is discussed in Chapter 12. Like female partner treatment, therapy should be targeted, if possible, toward the cause of subfertility. Obstructive disease may be treated surgically. A prominent varicocele with a stress pattern on semen analysis (decreased motility with an increase in abnormal morphology) may suggest a need for surgical repair. Any endocrinologic abnormalities (while less common in the male) should be treated (eg, prolactinoma). Unfortunately, beyond this point, most treatments require a combined approach very similar to that discussed later for unexplained infertility.

Unexplained Infertility

The treatment of unexplained infertility can be frustrating for the physician and the patients because the recommendations for therapy are not targeted toward a specific diagnosis. Although there are very limited evidence-based data to guide treatment, therapy should be directed toward increasing the fecundability rate. The two main treatments are superovulation plus intrauterine insemination (IUI) and IVF.

Superovulation methods are designed to qualitatively improve the cycle and to hyperstimulate the ovary with rescue of more follicles (quantitative improvement). Administration of clomiphene citrate or of gonadotropins can be used for superovulation. However, success rates are only significantly higher than expectant management when combined with IUI of washed sperm. IVF provides a higher fecundability rate. However, these procedures are significantly more costly and more invasive, and they should be used after a trial (3 or 4 cycles) of superovulation and IUI has failed. Evidence suggests that persistent treatment with IUI is more expensive and time to live birth is increased, compared to treatment with IVF. With older patients, aggressive therapy should be considered earlier in the treatment effort.

CONTRACEPTION

Approximately 50% of all pregnancies in the United States are unplanned. In adolescents and in women of older reproductive age, the unplanned pregnancy rate is higher, approaching 82% and 77%, respectively. This equates to 3.5 million unplanned pregnancies in the United States per year. The advent of oral contraceptives has meant that women have been able to postpone childbearing. However, approximately 50% of unplanned pregnancies are due to contraceptive failures. Possible causes of failure include lack of education, poor compliance, and side-effect profiles. In this section, we discuss the different methods of hormonal contraception. We shall discuss also the target population for the various modalities of contraception and their mechanisms, side effects, and ways to decrease failure rates. At the end of the section, emergency contraception will be discussed briefly.

ORAL CONTRACEPTIVES

Combination Pills

In the United States, oral contraceptive pills are the most widely used method for contraception. There are two types of oral contraception: combination pills and progestin-only pills. The various hormones used in birth control pills are illustrated in Figure 13–19.

The development of oral contraceptive agents began with the isolation of progesterone. However, progesterone was very expensive and difficult to isolate. Ethisterone, a derivative of an androgen, was found to have progestin activity and was much easier to isolate than progesterone. With removal of carbon 19, the progestational activity was increased, and the new compound was termed norethindrone. When this hormone was administered to

women, ovulation was inhibited. During the process of norethindrone purification, an estrogen contaminant was found. When this contaminant was removed, women would experience breakthrough bleeding. The estrogen was added back, thereby creating the first-generation combination birth control pill, which was approved by the Food and Drug Administration (FDA) in 1960.

Oral contraceptives can be divided into generations based on dose and type of hormone. The first-generation birth control pills contained more than 50 μg of ethinyl estradiol or mestranol and a progestin. The adverse events associated with high-dose estrogen, such as coronary thrombosis, led to development of the second-generation pill, which contained less than 50 μg of ethinyl estradiol and progestins other than levonorgestrel derivatives. Next, attention was directed toward the progestin, which was thought to have adverse androgenic effects such as affecting lipid profiles and glucose tolerance. This led to the development of third-generation pills that contained both a lower dose of estrogen (20-30 μg of ethinyl estradiol) and newer progestins (gonanes: desogestrel or norgestimate). Indeed, studies have demonstrated a reduction in metabolic changes associated with these progestins, but limited data are available to show any actual reduction of cardiovascular events. Another recently developed progestin, drospirenone, has antimineralocorticoid and antiandrogenic activity in addition to its pharmacologic progestational effects. As an analog of spironolactone rather than androgen, it competitively binds to aldosterone receptors, and it may counteract the estrogen stimulation of the renin-angiotensin system, resulting in more weight stability and less water retention. A newer combination oral contraceptive, Yasmin, which contains 3 mg drospirenone and 30 μg ethinyl estradiol, has been approved by the FDA and is prescribed for women with hyperandrogenism or other side effects attributable to oral contraceptives. However, the relative antiandrogenic activity of drospirenone is small compared with cyproterone acetate or the therapeutic dose of spironolactone used for the treatment of hirsutism.

Contraceptives can be classified also based on formulas or schedules of administration. The theory behind phasic preparations was to further decrease the amount of total progestin administered in an attempt to reduce metabolic changes attributed to the progestin, thereby decreasing adverse effects. The traditional monophasic pill (eg, Loestrin) contains 30 μg of ethinyl estradiol and 1.5 mg of norethindrone. This dose is given every day for 3 weeks with a 1-week, hormone-free interval. The progestin dose remains constant throughout the cycle. The second type is the biphasic pill (eg, Ortho-Novum 10/11), which contains 35 μg of ethinyl estradiol and either 0.5 or 1 mg of norethindrone. The 0.5 mg of norethindrone is administered in the first 10 days of the month, and the 1 mg is administered for the following 11 days. The last 7 days of the cycle are free of hormone. With this combination, there was a theoretical increase in breakthrough bleeding and an increased pregnancy rate. A meta-analysis revealed no difference, but limited data were available.

Because of concerns that this regimen might result in both breakthrough bleeding and pregnancies, another phasic formulation was developed. The triphasic pills (eg, Triphasil, Ortho-Novum 7/7/7) contain 0.5, 0.75, and 1 mg norethindrone

combined with 35 μg ethinyl estradiol. Theoretically, this formulation improves cycle control. There are several other regimens, some of which alter estrogen doses to simulate the estrogen cyclic rhythm (Triphasil-30, Triphasil-40, Triphasil-30 μg ethinyl estradiol) and possibly decrease breakthrough bleeding. A meta-analysis comparing biphasic versus triphasic pills revealed that triphasic pills significantly improved cycle control. However, the progestins in each pill tested were different, and this could account for better cycle control rather than the phasic formulation. An additional meta-analysis was performed on triphasic versus monophasic pills to assess cycle control and metabolic effects. This analysis revealed no difference between the formulations. Therefore, there is little

scientific rationale for prescribing phasic preparations in preference to the monophasic pill.

The pharmacologic activity of progestins is based on the progestational activity and bioavailability of each progestin as well as the dose. The relative potencies of the different progestins are levonorgestrel greater than norgestrel greater than norethindrone. The active estrogen component of oral contraceptives is ethinyl estradiol (even if mestranol is administered).

When the hormones are administered for 21 days of the cycle, there is enough progestin to inhibit rapid follicle growth for about 7 more days. Figure 13–20 demonstrates that during the steroid-free interval there is no rise in estrogen, indicating no follicular

maturation. It is likely that pills missed after this time are responsible for some of the unintended pregnancies. Therefore, it is important that this interval not be extended.

Pharmacologic doses of progestin inhibit ovulation by suppressing GnRH pulsatility and possibly inhibiting release of pituitary LH. Progestins also impair implantation and produce thick, scanty cervical mucus that retards sperm penetration. These latter methods play a minor role in the mechanism of oral contraception.

Ethinyl estradiol helps prevent the selection of a dominant follicle by suppressing pituitary FSH. In addition to FSH suppression, ethinyl estradiol provides stability to the endometrium, decreasing breakthrough bleeding. It also upregulates the progesterone receptor and decreases clearance, thereby potentiating the activity of the progestin.

Traditionally, a pill is administered daily for 3 weeks out of 4, preferably at the same time each day (more critical with progestin-only pills). This regimen was designed to mimic the menstrual cycle with monthly withdrawal bleeding. The conventional start date is on the first Sunday after menses (first day of menses for triphasics). An alternative method is to start at the time of the clinic visit, regardless of the day of the menstrual cycle, with a backup method for 7 days (*Quick-Start*). This method has the advantage of immediate contraception without adverse bleeding events. In addition, with the Quick-Start method, women are more likely to start the second pack of oral contraceptives, suggesting increased compliance. During the 28-day regimen, there is a 1-week, steroid-free interval. If the steroid-free interval is prolonged beyond the 7-day window, ovulation is possible. Therefore,

this is a critical time not to neglect taking pills. On the other hand, a woman may continue to take the hormone pills and skip the steroid-free interval to avoid monthly bleeding. A randomized trial comparing continuous oral contraception with the traditional cyclic method revealed a significantly greater incidence of erratic bleeding with (overall) the same number of days of bleeding, albeit with a reduced volume of bleeding. New formulations have been developed for those who do not desire cyclic bleeding. This regimen involves 84 days of continuous hormone administration followed by a steroid-free interval of 1 week. This can easily be done with the traditionally packaged oral contraceptive pills.

A routine for daily administration improves compliance and contraceptive efficacy. Failure to take the pill at the same time every day and not understanding the package insert are associated with missing two or more pills during the cycle. To decrease failure rates, women should understand that if they forget to take the pill, they must use barrier prophylaxis.

Postpartum women who are not breastfeeding may begin combination oral contraceptives 3 weeks after delivery. For women who are breastfeeding, it is advised that institution of combination oral contraceptives be delayed until 3 months postpartum. The recommendation for this delay is due to decreased milk letdown secondary to estrogen but may be waived once lactation is well established.

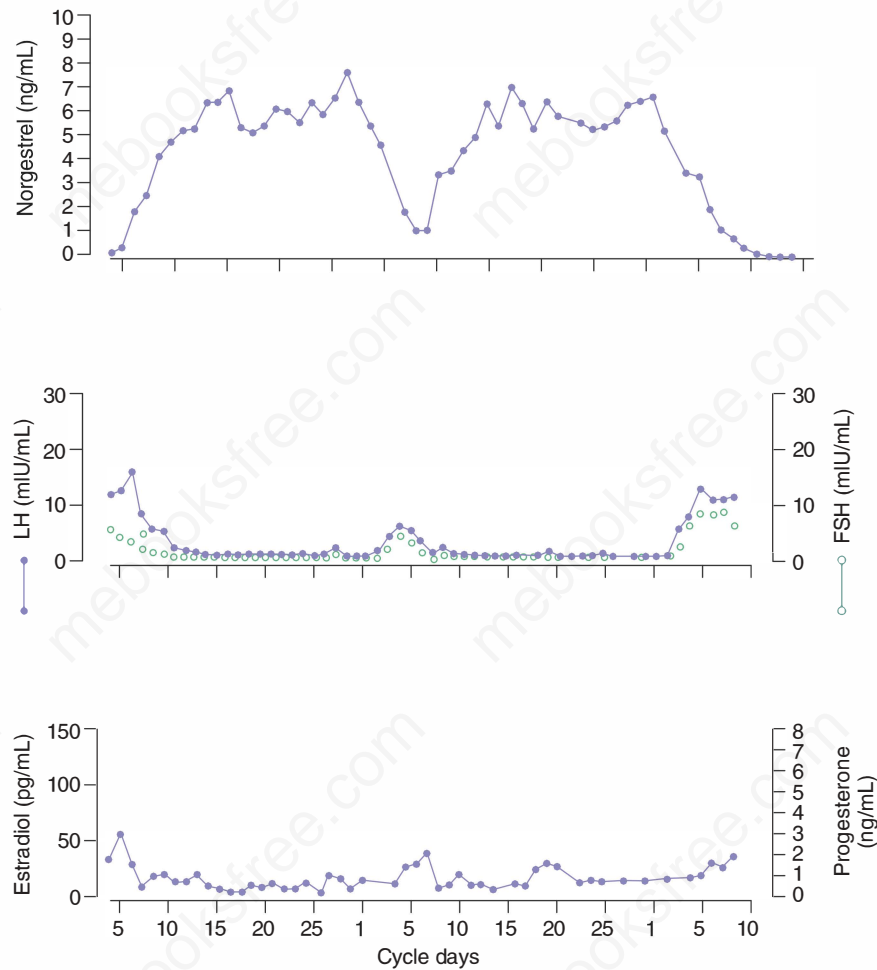
Noncompliance increases the incidence of unwanted pregnancies. Appropriate use of birth control is achieved 32% to 85% of the time in the general population. Teenagers have at most a 50% continuation rate, and 25% of pill users discontinue the practice in the first year. The efficacy of the oral contraceptive under


FIGURE 13–20 Progestin effects on steroidogenesis and ovulation. (Reproduced with permission from Brenner PF, Mishell DR Jr, Stanczyk FZ, et al. Serum levels of d-norgestrel, luteinizing hormone, follicle-stimulating hormone, estradiol, and progesterone in women during and following ingestion of combination oral contraceptives containing dl-norgestrel. *Am J Obstet Gynecol*. 1977 Sep 15;129(2):133-140.)

conditions of perfect use is 0.1 failures per 100 woman-years (0.1 per 100 users). With typical use, the failure rate is 3%, with first-year failure rates approaching 7.3% to 8.5%. Side effects contribute to noncompliance. The most common side effect is breakthrough bleeding. Other unwanted symptoms include bloating, breast tenderness, nausea, and possibly headaches, weight gain, and depression. Some studies suggest that altering estrogen doses may improve symptoms. Failure rates may also be associated with concomitant use of drugs (eg, rifampin, hydantoins) that accelerate hormone metabolism.

A. Other benefits There are noncontraceptive benefits to the pill. These include reduced monthly blood loss (less iron deficiency) and less dysmenorrhea as well as reduced benign breast disease and mastalgia. Oral contraceptives also reduce the incidence of PID and ectopic pregnancies. Other significant benefits include a reduction in risk of ovarian cancer, endometrial cancer, and colorectal cancer. Oral contraceptive use also has cosmetic benefits; it can improve excess hair growth and acne (see PCOS). It is not unusual for the pill to be administered for noncontraceptive problems.

B. Potential risks In general, oral contraceptives have proved to be safe for most women, but the possibility of adverse effects has received much attention. Unfortunately, the literature is full of conflicting reports. Data concerning controversial adverse effects will be discussed in the following section.

Although the estrogen in combination oral contraceptives tends to increase triglycerides and total cholesterol, these levels are still within the normal range, and the contraceptives appear to increase HDL and decrease LDL. Progestins attenuate these effects, which suggest an adverse metabolic milieu. Although it is known that low HDL-LDL ratios are associated with cardiovascular events, the importance of lipid changes associated with birth control pills is unknown. To date there is no strong evidence of an increased incidence of myocardial infarctions in healthy nonsmoking oral contraceptive users. In patients with other cardiovascular risk factors such as hypertension—at least in Europe—there is an up to 12-fold increased risk of cardiovascular events. Women who are over 35 years of age and who smoke are at increased risk of cardiovascular events. This risk is amplified with use of the birth control pills. If more than 15 cigarettes per day are smoked, there

is a relative risk (RR) of 3.3 for a cardiovascular event, compared with an RR of 20.8 with concomitant use of oral contraceptives. However, if a woman smokes fewer than 15 cigarettes per day, there is an RR of 2.0 for a cardiovascular event, compared with an RR of 3.5 with concomitant contraceptive use. Former smokers after 1 year have no significant increased risk. First-generation oral contraceptives (>50 μg ethinyl estradiol) imposed an RR for stroke (ischemic or hemorrhagic) of 5.8. With low-dose agents (<50 μg ethinyl estradiol), there appears to be no significant increased risk of stroke among healthy normotensive nonsmoking women. The RR associated with hemorrhagic stroke for hypertensive women is 10.2 to 14.2. Because the potential exists for adverse outcomes, women taking oral contraceptives should be screened regularly for cardiovascular risk factors to ensure safe administration.

The risk of deep vein thrombosis and pulmonary embolism is increased two- to threefold with administration of the pill. The mechanism by which oral contraceptives enhance venous thrombosis is unknown, but there may be estrogen-related changes in coagulation parameters. These include increased clotting factors and activation of platelets and a decrease in protein S and fibrinolytic activity. However, these changes in measured serum clotting factors do not predict the occurrence of deep vein thrombosis. Genetic thrombophilias increase the risk of venous thrombosis. The prevalence of factor V Leiden in the general population is 5%. The incidence of deep vein thrombosis among this population is 60 per 100,000 per year, and with use of oral contraceptives, the incidence approaches 280 to 300 per 100,000 per year. The baseline incidence of deep vein thrombosis in women is approximately 3 per 100,000 per year, and with current oral contraceptive uses it is 9.6 to 21.1 per 100,000 per year. For comparison, during pregnancy, the incidence of deep vein thrombosis is 60 per 100,000 per year. Older age (>40-44) increases the incidence two- to threefold but does not affect the RR. There is no evidence that smoking has an effect on the incidence of deep vein thrombosis with oral contraceptive use. At this time, universal screening for thrombophilias is not cost effective. However, any history of deep vein thrombosis warrants a workup for thrombophilia.

The association of oral contraceptives and cancer risk has been evaluated for breast, cervical, and liver cancer. Observational studies investigating a possible association between oral contraceptive use and breast cancer have reported conflicting results. The most recent information is that oral contraceptive usage (current or past use) has no impact on the incidence of breast cancer—RR 1.0 (CI 95% 0.8-1.3)—among women 35 to 64 years of age. Several observational studies have linked oral contraceptive use with invasive cervical cancer, although it is not clear if this association is causally related. A recent study investigating the association between oral contraception use and cervical cancer revealed a nearly threefold increased risk among human papillomavirus carriers with 5 to 9 years of oral contraceptive use (RR 2.82; 95% CI 1.46-5.42). This evidence suggests that women taking oral contraceptives should be screened yearly with Pap smears to prevent cervical cancer. In the 1980s, there was an association between hepatocellular carcinoma in women under 50 years of age and oral contraceptive use. With further investigation there appears to be

Breast cancer
Endometrial cancer
History of cerebrovascular or cardiovascular disease
Undiagnosed vaginal bleeding
Uncontrolled hypertension

no increased risk of hepatic cancer with the use of oral contraceptives.

After discontinuation of oral contraceptives, the activity of the HPO axis gradually returns to a precontraceptive state. After a 2- to 4-week prolongation of the follicular phase, the LH peak is observed, which suggests that the suppressive effects of the oral contraceptive have dissipated and that cyclic menses will resume.

Contraindications to oral contraceptive administration are summarized in Table 13–9.

Progestin Only

Progestin-only pills (Ortho Micronor, Nor-QD, 0.35 mg norethindrone; Ovrette, 0.075 mg levonorgestrel) are also available for contraception. The target population for administration of progestin-only contraception includes women with contraindications to estrogen, breastfeeding mothers, and older women.

The circulating levels of progestin following ingestion of progestin-only pills (minipill) are 25% to 50% of that following ingestion of estrogen-progestin oral contraceptive pills. Serum levels that peak 2 hours after administration are followed by rapid elimination (Figure 13–21). The peak levels of norethindrone and levonorgestrel vary (4-14 and 0.9-2 ng/mL, respectively), but 24 hours after pill ingestion, serum levels are 0.2 to 1.6 ng/mL and 0.2 to 0.5 ng/mL, respectively. Thus, there is no accumulation of progestin over time. Progestin-only administration results in lower steady state levels and a shorter half-life compared with concomitant administration with estrogen.

Owing to the lower levels of progestin in the progestin-only pill, there is less influence on the inhibition of ovulation and more impact of thickening cervical mucus (*hostile environment*) inhibiting sperm penetration. Sperm that are able to penetrate have decreased mobility. Progestins also alter the endometrial lining (inhibition of progesterone receptor synthesis and reduction in endometrial glandular development, preventing implantation) and perhaps inhibit the motility (number and motility of the cilia) of the uterine tube. LH peaks—as well as FSH peaks—are suppressed compared with pretreatment levels. The change in cervical mucus takes place 2 to 4 hours after the first dose. However, after 24 hours, thinning of the cervical mucus is evident, allowing unimpaired sperm penetration, which is why it is critical to take the progestin-only pills at the same time every day.

The progestin-only pill should be started on the first day of menses. This pill should be taken at the same time every day. If

A. Norethindrone

B. Levonorgestrel
FIGURE 13–21 Serum levels attained with progestin-only pills. [Reproduced with permission from McCann MF, Potter LS. Progestin-only oral contraception: a comprehensive review. *Contraception.* 1994 Dec;50(6 Suppl 1):S1-S195.]

administration is 3 hours late, a backup method should be used for 48 hours. If a pill is missed, a backup method should be used for 48 hours, and if two or more pills are missed, a backup method should be used for 48 hours due to rapid resumption of the cervical mucus effect. If no menses occur in 4 weeks, a pregnancy test is necessary. Progestin-only pills may be administered immediately postpartum.

The efficacy of progestin-only pills under conditions of perfect use is 0.3 to 3.1 failures per 100 woman-years (failure rates of 1.1%-9.6% in the first year) or 0.5 per 100 users. This efficacy rate is achieved only with careful compliance. The typical use is associated with a greater than 5% failure rate. Failure rates were lowest in women over 38½ years of age and those who were breastfeeding. The efficacy may also be influenced by body weight and by concomitant use of anticonvulsants. The major disadvantage is that the pill must be administered at the same time every day. As a result of even slight flexibility in the schedule, there is increased contraceptive failure.

The risks associated with progestin-only pills are minimal. Various studies have revealed no significant impact on lipids, carbohydrate metabolism, blood pressure, or the incidence

of myocardial infarction and stroke. Furthermore, no adverse coagulation parameters have been associated with its use. There are almost no data on the association of progestin-only pills and endometrial, ovarian, cervical, or breast cancer. The major side effect is breakthrough bleeding (40%-60%). Other side effects include acne and persistent ovarian cysts. With discontinuation of the pill, menses resume with no impact on subsequent pregnancy rates or future fertility.

CONTRACEPTION: LONG-ACTING CONTRACEPTIVES

The high rate of unintended pregnancies has led to the development of long-acting reversible contraceptive modalities. Interest in long-acting methods is increasing because they offer convenience, obviate problems of compliance, and thus offer higher efficacy. Most long-acting systems contain either combination or progestin-only hormones. The effectiveness of these hormones is prolonged, mostly due to the sustained system that results in a gradual release. The modes of administration include injectables,

transdermal patches, subdermal rods, vaginal rings, and intrauterine devices (IUDs). The various types of long-acting contraceptives are discussed later.

Injectable Contraceptives

A. Progestin only   Injectable progestins that contain MPA (Depo-Provera) are beneficial when women have contraindications to estrogen, use antiepileptics, are mentally handicapped, or have poor compliance. Furthermore, there is good evidence that its use is safe in the presence of coronary artery disease, congestive heart failure, diabetes, tobacco use, and a history of venous thromboembolism. Other uses of MPA include treatment of metastatic endometrial or renal carcinoma.

Although most other long-acting contraceptives are sustained-release formulations, Depo-Provera (150 mg MPA) is provided as an aqueous microcrystalline suspension that gradually declines throughout the cycle (Figure 13–22). Pharmacologic levels (>0.5 ng/mL) are achieved within the first 24 hours and peak (at 2 ng/mL) within the first week after the injection. Serum concentrations are maintained at 1 ng/mL for approximately 3 months. Interestingly, estrogen concentration is in the early to midfollicular

level (below 100 pg/mL) and persists for 4 months after the last injection. The serum concentration of MPA decreases to 0.2 ng/mL during the last 5 to 6 months (ovulation occurs when levels are <0.1 ng/mL). However, one study observed progesterone levels to rise after 3½ months.

The mechanism of action depends mainly on the ability of higher peaks of hormone to inhibit ovulation (LH surge). Like other progestins, MPA increases cervical mucus viscosity, alters the endometrium, and decreases the motility of the uterine tubes and uterus. FSH levels are minimally suppressed with Depo-Provera.

The manufacturer's recommendation is to administer the agent every 3 months, starting within 5 days of the onset of menses and not to exceed 1 erweek. The agent is injected deeply into the upper-outer quadrant of the buttock or deltoid without massage to ensure slow release. If the subject is postpartum and not breastfeeding, Depo-Provera should be given within 3 weeks after delivery and if lactating within 6 weeks (Table 13–10).

Because compliance is not an issue, the failure rate is minimal at 0 to 0.7 per 100 woman-years (0.3 per 100 users). Weight and use of concurrent medications do not affect the efficacy. However, continuation rates are poor at 50% to 60% because of the side-effect profile. The major dissatisfaction that leads to

FIGURE 13–22 Serum medroxyprogesterone acetate (MPA) levels following injection of Depo-Provera. Open bars represent serum estradiol; closed bars represent serum progesterone concentrations. (Reproduced with permission from Ortiz A, Hirol M, Stanczyk FZ, et al. Serum medroxyprogesterone acetate [MPA] and ovarian function following intramuscular injection of depo-MPA. *J Clin Endocrinol Metab*. 1977 Jan;44(1):32-38.)

TABLE 13–10 Scheduling for injectable contraceptives.

Method	DMPA	MPA/E$_2$C
First injection		
Spontaneous menstrual cycle	Within 5 d of menses onset	Within 5 d of menses onset
Spontaneous or elective first-trimester abortion	Within 7 d	Within 7 d
Term delivery	Within 3 wk postpartum if not lactating; within 6 wk postpartum if lactating	Between 21 and 28 d postpartum if not lactating
Switching from combination OCs	With administered active pills or within 7 d after administering the pill pack's last active tablet	With administered active pills or within 7 d after administering the pill pack's last active tablet
Switching from DMPA	—	Within 13 wk after last DMPA injection
Switching from MPA/E$_2$C	Within 33 d after previous injection	—
Switching from levonorgestrel implant	Any time within 5 y of implant insertion; use of a condom back-up is recommended for 1 wk	Any time within 5 y of implant insertion; use of a condom backup is recommended for 1 wk
Switching from Copper T 380A IUD	First injection should occur before IUD removal and within 10 y after IUD insertion; a condom should be used as a back-up if the first injection is not administered within 5 d of menses onset	First injection should occur before IUD removal and within 10 y after IUD insertion condom should be used as a back-up if the first injection is not administered within 5 d of menses onset
Subsequent injections		
Injection interval	Every 12 wk or 3 mo; earlier reinjections are acceptable	Every 28 d or 4 wk or monthly; reinjection earlier than 23 d may impair cycle
Grace period	2 wk (14 wk from last injection); after 1 wk manufacturer recommends pregnancy testing before repeat injection	Control ±5 d (23-33 d from last injection); thereafter, pregnancy testing needed before repeat injection

Abbreviations: DMPA, depot medroxyprogesterone acetate; IUD, intrauterine device; MPA/E$_2$C, medroxyprogesterone acetate and estradiol cypionate; OCs, oral contraceptives.

discontinuation is breakthrough bleeding, which approaches 50% to 70% in the first year of use. Other side effects include weight gain (2.1 kg/y), dizziness, abdominal pain, anxiety, and possibly depression. Another disadvantage with the use of Depo-Provera is a delay in fertility after discontinuation. Ovulation returns when serum levels are less than 0.1 ng/mL. The time from discontinuation to ovulation is prolonged. Only 50% of patients ovulate at 6 months after discontinuing the medication, and although the agent does not cause infertility, achieving pregnancy may be delayed for more than 1 year. (The length of time for release at the injection site is unpredictable.) After the first year, 60% of women become amenorrheic, and at 5 years, the incidence of amenorrhea approaches 80%, which can be considered a potential benefit. Other benefits with use of MPA include prevention of iron deficiency anemia, ectopic pregnancy, PID, and endometrial cancer. In addition, Depo-Provera is a recommended contraceptive for women with sickle cell disease (decreased crisis) and seizure disorders (raises seizure threshold). Other therapeutic uses include dysmenorrhea and endometrial hyperplasia or cancer.

One major concern with use of Depo-Provera is the development of osteopenia, with possible advancement to osteoporosis later in life. Several observational studies have evaluated the potential impact on bone. A prospective trial revealed that current users, after 12 months of use, experience a mean BMD loss of 2.74%. However, on examining former users 30 months later, it was found that mean BMD was similar to that of nonusers, indicating that the loss is reversible and of minimal clinical importance. An ongoing multicenter study assessing BMD in users versus nonusers should clarify the impact of Depo-Provera on bone. BMD in adolescents has also been investigated because adolescence is a critical time in bone mineralization. A small prospective study revealed that BMD was decreased by 1.5% to 3.1% after 1 and 2 years of use in Norplant users, compared to increases in BMD of 9.3% and 9.5% in controls. This is a potential concern and has also led to a prospective multicenter study investigating the use of Depo-Provera in adolescents. Although one possible cause is less exposure to estrogen, an alternative and perhaps not exclusive theory involves MPA-dependent glucocorticoid activity that impairs osteoblast differentiation. Other potential risks include an adverse lipid profile (increase in LDL, decrease in HDL) and a slightly increased risk of breast cancer. The association of breast cancer with use of Depo-Provera is minimal within the first 4 years of use, with no risk after 5 years of use. Paradoxically, MPA has been used for treatment of metastatic breast cancer.

B. Combination The development of monthly combination injectables (Lunelle) has responded to the erratic bleeding associated with Depo-Provera (Figure 13–23). The cycle control is similar to what is achieved with combined oral contraceptives. The monthly withdrawal bleeding occurs 2 weeks after the injection. The target populations are adolescents and women who have difficulty with compliance. Lunelle is an aqueous solution containing
FIGURE 13–23 Serum medroxyprogesterone acetate (MPA) and estradiol levels following Lunelle injection. (Reproduced with permission from Rahimy MH, Ryan KK, Hopkins NK. Lunelle monthly contraceptive injection (medroxyprogesterone acetate and estradiol cypionate injectable suspension): steady-state pharmacokinetics of MPA and E2 in surgically sterile women. *Contraception.* 1999 Oct;60(4): 209-214.)

25 mg of MPA and 5 mg of estradiol cypionate per 0.5 mL. In women who receive repeated administration of Lunelle, peak estradiol levels occur approximately 2 days after the third injection and are 247 pg/mL (similar to peak ovulatory levels). The estradiol level returns to baseline 14 days after the last injection (100 pg/mL); the drop in estradiol is associated with menstrual bleeding (2-3 weeks after the last injection). Peak MPA levels (2.17 ng/mL) occur 3½ days after the third monthly injection. The mean MPA level is 1.25 ng/mL. The level at day 28 of the cycle is 0.44 to 0.47 ng/mL (level needed for contraceptive effect is 0.1-0.2 ng/mL). The earliest return of ovulation seen in women with multiple injections has been 60 days after the last dose. The mechanism of action, risks, and contraindications are similar to those of combined oral contraceptives.

Lunelle is administered intramuscularly in the buttock or deltoid every month. The first injection should be given within the first 5 days of the menstrual cycle (see Table 13–10). Even though

pharmacokinetic analysis reveals a delay in ovulation, the manufacturer recommends a 5-day grace period. The failure rate is 0.1 per 100 woman-years. Neither body weight nor use of concomitant drugs appears to affect the efficacy. Although this contraceptive has the advantages of the oral contraceptives and is associated with better compliance, the continuation rate is only 55%. This may be due to its side-effect profile, which is similar to that of the combined oral contraceptives with the addition of monthly injections.

There are limited data on potential risks. The risk potential is probably similar to that of the combined oral contraceptives, with a potentially lower incidence of deep vein thrombosis secondary to the absence of the first-pass effect. On discontinuation of Lunelle, achieving pregnancy may be delayed for as long as to 3 to 10 months after the last injection.

Lunelle was approved for use in the United States in 2000. However, in October 2002, Lunelle was recalled from the market, due to plant manufacturing problems. Alternatives to Lunelle that are administered outside the United States are: Mesigyna, Perlutal, Yectames, and Chinese Injectable No 1.

Subdermal Implants

The Norplant package consists of six capsules (34 mm in length, 2.4 mm in diameter), with each capsule providing 36 mg of levonorgestrel (total 216 mg). The target population is women who have contraindications to or adverse side effects from estrogen, women who are postpartum or breastfeeding, and adolescent mothers. This method provides long-term continuous contraception (approved for 5 years) that is rapidly reversible. The advantages, side effects, risks, and contraindications are similar to those of oral progestins. The major disadvantage—not present with use of oral progestins—is the surgical insertion and removal of the rods. A newer system, Norplant II, contains two rods (4 cm in length, 3.4 cm in diameter) and releases 50 μg/d of norgestrel (approved for 3 years). The two-rod system has the same mechanism of action and side-effect profile as its predecessor. However, the rods are much easier and faster to insert and remove than the capsules.

Within the first 24 hours, serum concentrations of levonorgestrel are 0.4 to 0.5 ng/mL. The capsules release 85 μg of levonorgestrel per 24 hours for the first year (equivalent to the daily dose of progestin-only pills) and then 50 μg for the remaining 5 years. The mean serum levels of progestin after the first 6 months are 0.25 to 0.6 ng/mL, slightly decreased at 5 years to 0.17 to 0.35 ng/mL. A levonorgestrel concentration below 0.2 ng/mL is associated with increased pregnancy rates. The site of implantation (leg, forearm, and arm) does not affect circulating progestin levels. Even though progestin levels are sufficient to prevent ovulation within the first 24 hours, the manufacturer recommends use of a backup method for 3 days after insertion. On removal, the progestin levels rapidly decline and undetectable serum levels are achieved after 96 hours. As a result, most women ovulate within 1 month after removal of the implants.

Norplant provides contraception in several ways. In the first 2 years, the levonorgestrel concentration is high enough to suppress the LH surge—most likely at the hypothalamic level—and

thereby inhibits ovulation. However, given the low concentrations of progestin, there is no real effect on FSH. The estradiol levels approximate those in ovulatory women. In addition, there are irregular serum peaks (often prolonged) and declines in serum estrogen levels that may contribute to erratic bleeding. By 5 years, more than 50% of the cycles are ovulatory. However, ovulatory cycles while using Norplant have been associated with luteal phase insufficiency. Other mechanisms of contraception are similar to oral progestins and include thickening of the cervical mucus, alterations of the endometrium, and changes in tubal and uterine motility.

The failure rate is 0.2 to 2.1 failures per 100 woman-years (0.9 per 100 users). Like oral progestins, body weight affects circulating levels and may result in more failures in the fourth or fifth year of use. Similar to oral progestins, the incidence of ectopic pregnancy among failures is increased to 20% (overall incidence is 0.28-1.3 per 1000 woman-years). The continuation rate (discontinuation rate of 10%-15% per year) is age-dependent and ranges from 33% to 78%. Menstrual disturbances are the most frequent side effect; they approach 40% to 80%, especially in the first 2 years. Although the incidence of abnormal uterine bleeding is similar to that of Depo-Provera, a significant difference between these methods is that Norplant provides only a 10% amenorrhea rate at 5 years. Other reported side effects include headache (30% indication for removal) and possibly weight gain, mood changes, anxiety, and depression—as well as ovarian cyst formation (eightfold increase), breast tenderness, acne, galactorrhea (if insertion occurs on discontinuation of lactation), possible hair loss, and pain or other adverse reactions at the insertion site (0.8% of cases at discontinuation).

Transdermal Patch

The transdermal patch (Ortho Evra) is another approach to contraception. The thin 20-cm^2 patch is composed of a protective layer, a middle (medicated) layer, and a release liner that is removed prior to application. The system delivers 150 μg of norelgestromin (active metabolite of norgestimate) and 20 μg of ethinyl estradiol per day to the systemic circulation. The target population is similar to that described earlier for Lunelle. One advantage of this system over Lunelle is that there are no monthly injections, and as a result, there is greater autonomy for the patient. The patch is applied once a week for 3 consecutive weeks, followed by a patch-free week for monthly withdrawal bleeding. The patch should be changed on the same day each week. The mechanism of action, contraindications, and side effects are similar to what has been described in the section on oral contraceptives.

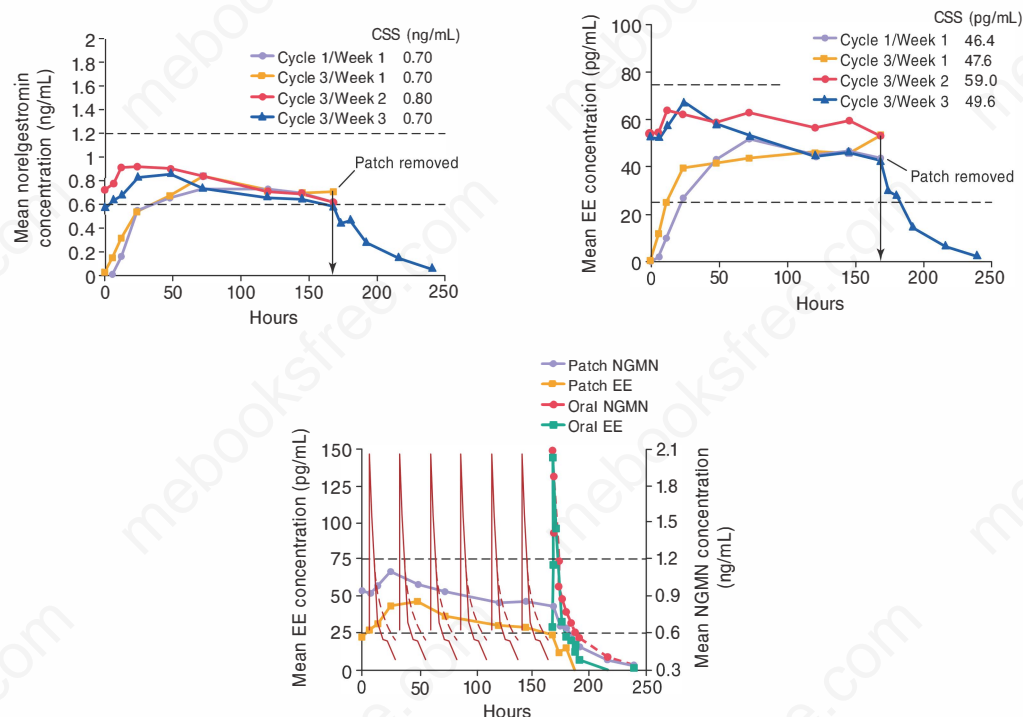
With use of the transdermal patch, the peak ethinyl estradiol and norelgestromin levels are 50 to 60 pg/mL and 0.7 to 0.8 ng/mL, respectively. Because of this unique delivery system, hormone levels achieve a steady state condition throughout the cycle (see later and Figure 13–24). After the seventh day of application, there are adequate hormone levels to inhibit ovulation for 2 more days. With each consecutive patch, there is minimal accumulation of norelgestromin or ethinyl estradiol. The amount of hormone delivered is not affected by the environment, activity, or site of


FIGURE 13–24 Comparative serum steroid (CSS) levels of norelgestromin (NGMN) and ethinyl estradiol (EE) following patch administration. (Reproduced with permission from Abrams LS et al. Multiple-dose pharmacokinetics of a contraceptive patch in healthy women participants. *Contraception*. 2001 Nov;64(5):287-294.)

application (abdomen, buttock, arm, torso). The adhesive is very reliable in a variety of conditions, including exercise, swimming, humidity, saunas, and bathing. Complete detachment occurs in 1.8% of cases and partial detachment in 2.9% of cases.

The failure rate is 0.7 per 100 woman-years under conditions of perfect use. Body weight has not been shown to affect the efficacy. The compliance with perfect use ranges from 88.1% to 91% among all age groups. This is significantly different from what is achieved with oral contraceptives (67%-85%), especially with women under 20 years of age. The side-effect profile is similar to that of oral contraceptives, except that there is slightly more breakthrough bleeding with the transdermal patch in the first 1 to 2 months (up to 12.2% vs 8.1%) and less breast tenderness (6.1% vs 18.8%). The incidence of skin reaction was 17.4%, characterized as mild in 92%, resulting in discontinuation in under 2%. The risks and contraindications are similar to that of combined oral contraceptives.

Vaginal Rings

Since the early 1900s, it has been recognized that the vagina is a place where steroids can be rapidly absorbed into the circulation. A study in the 1960s revealed that silicone rubber pessaries containing sex steroids would release the drug at a continuous rate. These studies led to the development of contraceptive vaginal rings.

As with oral contraceptives, there are combination and progestin-only formulations. Several progestin-only rings have been introduced since the 1970s. However, they were associated with significant menstrual disturbances. More recently, combination types have been developed. The most recent (2002) FDA-approved vaginal ring is a combination type called the NuvaRing.

The NuvaRing is made of ethylene vinyl acetate that provides 0.015 mg of ethinyl estradiol and 0.120 mg of etonogestrel per day. Maximum serum concentrations are achieved within 1 week after placement. The ring is designed to be used for 21 days and then removed for 1 full week to permit withdrawal bleeding. This device is capable of inhibiting ovulation within 3 days after insertion. After removal, the time to ovulation is 19 days. The mechanism of action, contraindications, and risks are similar to those of oral contraceptives. However, when assessing systemic exposure, use of the vaginal ring allows for 50% of the total exposure to ethinyl estradiol (15 μg in the ring compared with a 30-μg ethinyl estradiol-containing oral contraceptive).

The failure rate is similar to that reported with oral contraceptives. The continuation rate is 85.6% to 90%. Irregular bleeding is minimal (5.5%), and overall, the device is well tolerated, with an associated 2.5% discontinuation rate. Side effects are similar to those of oral contraceptives, but cycle control appears to be improved. The reported incidence of vaginal discharge is 23% versus 14.5% with oral contraceptives. The ring does not appear to interfere with intercourse (1%-2% of partners reported discomfort); however, the device can be removed for 2 to 3 hours during intercourse without changing efficacy.

Intrauterine Devices

IUDs are another modality of contraception that has been used clinically since the 1960s. Historically, these devices were made of plastic (polyethylene) impregnated with barium sulfate to make them radiopaque. Several other devices were subsequently developed, including the Dalkon Shield. After the introduction of the Dalkon Shield, an increase in pelvic infections was observed secondary to its multifilament tail. Furthermore, tubal infertility and septic abortions were increasing, and massive litigation occurred as a result. Consequently, even though the modern IUD has negligible associated risk, the use of IUDs in the United States is minimal—less than 1% of married women.

Currently, two types of IUDs are used in the United States: the copper- and the hormone-containing devices. The most recent FDA-approved intrauterine system contains levonorgestrel (Mirena) and is approved for 5 years of use. Several studies have demonstrated that these devices are unlike the Dalkon Shield and are very safe and efficacious. The target population is women who desire highly effective contraception that is long-term and rapidly reversible.

The copper (TCu-380A) IUD is a T-shaped device. The mechanism of action is mostly spermicidal due to the sterile inflammatory reaction that is created secondary to a foreign body in the uterus. The abundance of white blood cells that are present as a result kills the spermatozoa by phagocytosis. The amount of dissolution of copper is less than the daily amount ingested in the diet. However, with release of copper, salts are created that alter the endometrium and cervical mucus. Sperm transport is significantly impaired, limiting access to the oviducts.

There are two hormone-containing IUDs: the progesterone-releasing device (Progestasert) and the levonorgestrel-releasing device (Mirena). The Progestasert contains progesterone, which is released at a rate of 65 mg/d (approved for 1 year). This diffuses into the endometrial cavity, resulting in decidualization and atrophy of the endometrium. Serum progesterone levels do not change with the use of Progestasert. The main mechanism of action is to impair implantation. Mirena contains 52 mg of levonorgestrel, which is gradually released at a rate of 20 μg/d (approved for 5 years). Unlike Progestasert, systemic absorption of levonorgestrel inhibits ovulation about half the time. Although women may continue to have cyclic menses, over 40% have impaired follicular growth, with up to 23% developing luteinized unruptured follicles. Other mechanisms of action are similar to those described for Progestasert and the progestin-only pills. Mirena has the added advantage of significantly decreasing menstrual flow and has been used to treat menorrhagia.

The IUD should be placed within 7 days after onset of the menstrual cycle or at any time postpartum. Protection begins immediately after insertion. The failure rates after the first year of use are 0.5% to 0.8% for the TCu-380A, 1.3% to 1.6% for Progestasert, and 0.1% to 0.2% for Mirena. The expulsion rate is approximately 10%.

If a woman becomes pregnant with an IUD in place, the incidence of an ectopic pregnancy is 4.5% to 25%. The incidence of ectopic pregnancies with IUDs varies depending on the type of device. With Progestasert, the ectopic rate is slightly higher (6.80 per 1000 woman-years), most likely because its mechanism of action is limited to inhibiting implantation in the endometrium—in contrast to the copper or levonorgestrel IUD

(0.2-0.4 per 1000 woman-years), both of which also interfere with conception.

The continuation rate range for the current IUDs is 40% to 66.2% (Mirena). The side effects of the copper IUD include dysmenorrhea and menorrhagia. The most common adverse effect associated with the hormone-containing devices is erratic, albeit significantly less, bleeding. In fact, 40% of women experienced amenorrhea at 6 months and 50% at 12 months. The incidence of spotting in the first 6 months was 25% but decreased to 11% after 2 years. Other reported side effects of levonorgestrel include depression, headaches, and acne. There is a tendency to develop ovarian cysts early after insertion with the levonorgestrel-containing device that resolves after 4 months of use.

The nominal risks associated with IUD use include pelvic infection (within 1 month after insertion), lost IUD (ie, perforation into the abdominal cavity; 1:3000), and miscarriage. There is no association between IUD use and uterine or cervical cancer. Contraindications to IUD use are active genital infection and unexplained bleeding.

EMERGENCY CONTRACEPTION

Postcoital contraception is a method that may be used by a woman who believes her contraceptive method has failed or who has had unprotected intercourse and feels that she may be at risk for an unintended pregnancy. The first study to evaluate the efficacy of emergency contraception with hormones was in 1963. Subsequently, several studies have been performed with various contraceptives that paved the way for more widespread use. In 1997, the FDA approved the use of high-dose oral contraceptives for postcoital contraception. Since then, pharmaceutical companies have marketed specific packaging for the use of emergency contraception. Other methods, including mifepristone (RU-486) and the IUD have also been effective for postcoital contraception.

Similar to the formulas of oral contraception, there are both combination and progestin-only types of emergency contraception. The combination method (Yuzpe regimen) entails administration of two doses of two tablets (Ovral: 50 µg ethinyl estradiol, 0.5 mg norgestrel) 12 hours apart (total: 200 µg ethinyl estradiol, 2 mg norgestrel). Other oral contraceptives may be used with adjustment in the number of pills for equivalence (ie, two doses of four tablets: any second-generation oral contraceptive 12 hours apart). The specific medication (Preven) that is FDA-approved and marketed for postcoital contraception contains two doses of four tablets (ethinyl estradiol 50 µg, levonorgestrel 0.25 mg) 12 hours apart. The progestin-only method involves two doses of 10 pills (Ovrette 0.075 mg) 12 hours apart (Plan A). The marketed form (Plan B) contains two doses of one tablet (levonorgestrel 0.75 mg) 12 hours apart.

Following a single oral dose of 0.75 mg of levonorgestrel, the serum concentration peak (5-10 ng/mL) was at 2 hours with a rapid decline during the first 24 hours. The mechanism of action is uncertain, but levonorgestrel most likely inhibits ovulation and alters the endometrium to prevent implantation. Studies have shown decreased sperm recovery from the uterine cavity, possibly

due to thickened cervical mucus, or the alkalinization of the intrauterine environment. Others have shown that changes in other factors, such as integrins, can alter endometrial receptivity. The mode of action likely depends on the timing of intercourse relative to ovulation and to the administration of emergency contraception.

Maximum efficacy is achieved if the first dose is administered within 72 hours after intercourse and repeated in 12 hours. Combination formulas have a failure rate of 2% to 3%, and progestin-only preparations have a failure rate of 1%. Emergency contraception effectively reduces the rate of unintended pregnancies from 8% to 2%, a 75% reduction. However, with increasing time since unprotected intercourse, the efficacy changes from 0.4% to 1.2% to 2.7% for the first, second, or third 24-hour period after unprotected intercourse. For maximum efficacy, emergency contraception may be prescribed in advance so women will already have the correct dosing. No increase in risk-taking behavior has been noted with this strategy.

Significant nausea or emesis (51.7%) is associated with use of emergency contraception, although it is substantially less with progestin-only formulations. An antiemetic should be administered 1 hour before each treatment. If a patient vomits within 1 hour after ingestion, additional pills need to be administered.

Contraindications to emergency contraception with the combination regimen are possibly the same as those described for oral contraceptives; for progestin-only pills, there are no contraindications. Emergency contraception should be an optional function of the rape management protocol.

NORMAL FETAL SEX DIFFERENTIATION

Fetal sexual development consists of three sequential stages (Figure 14–1): (1) an undifferentiated stage, characterized by the formation of gonadal and genital primordia, which are identical in both XX and XY embryos; (2) gonadal differentiation, where the undifferentiated gonads develop into ovaries or testes; and (3) sexual differentiation of the internal and external genitalia, which depends on the existence or absence of male hormone action. Other organs, for example, the brain, liver, or kidney, also undergo sexual differentiation, although their dimorphism is less evident. The understanding of these normal processes set the basis for the comprehension of the etiologies, pathophysiology, clinical presentation, and management of disorders of sex development (DSD). We will focus on those pathways known to have clinical relevance in humans, even if the knowledge derives from observations in experimental models.

THE UNDIFFERENTIATED STAGE

Between the fourth and the sixth weeks of embryonic development, that is, the sixth and eighth weeks from the last menstrual cycle, the anlagen of the gonads and reproductive ducts develop from the intermediate and lateral mesoderm. Endodermic derivatives involved in the formation of the cloaca and ectodermic structures give rise to the anlagen of future internal reproductive structures and of the external genitalia.

INITIAL FORMATION OF THE UROGENITAL RIDGES

During the fourth and fifth weeks, the intermediate mesoderm consists of paired cylindrical masses at each side of the midline, arranged along the posterior aspect of the embryo, laterally to the paraxial mesoderm and medially to the lateral plate mesoderm. The intermediate mesoderm thickens and protrudes into the coelomic cavity—the future abdominal cavity—to form the urogenital ridges, covered by the coelomic epithelium, a derivative of lateral mesoderm. Each urogenital ridge progressively becomes separated in two portions: a medial gonadal ridge and a lateral urinary ridge.

The urinary ridge can be divided into three regions: (1) at the cephalic end, the pronephros that rapidly regresses in the human embryo; (2) at the caudal end near the cloaca, the metanephros that gives rise to most of the kidney; (3) between them lies the mesonephros, which provides mesenchymal components to the gonadal ridge and also gives rise to the mesonephric or Wolffian ducts. The normal development of the Wolffian ducts is essential not only for the reproductive system, but also for the development of the kidneys.

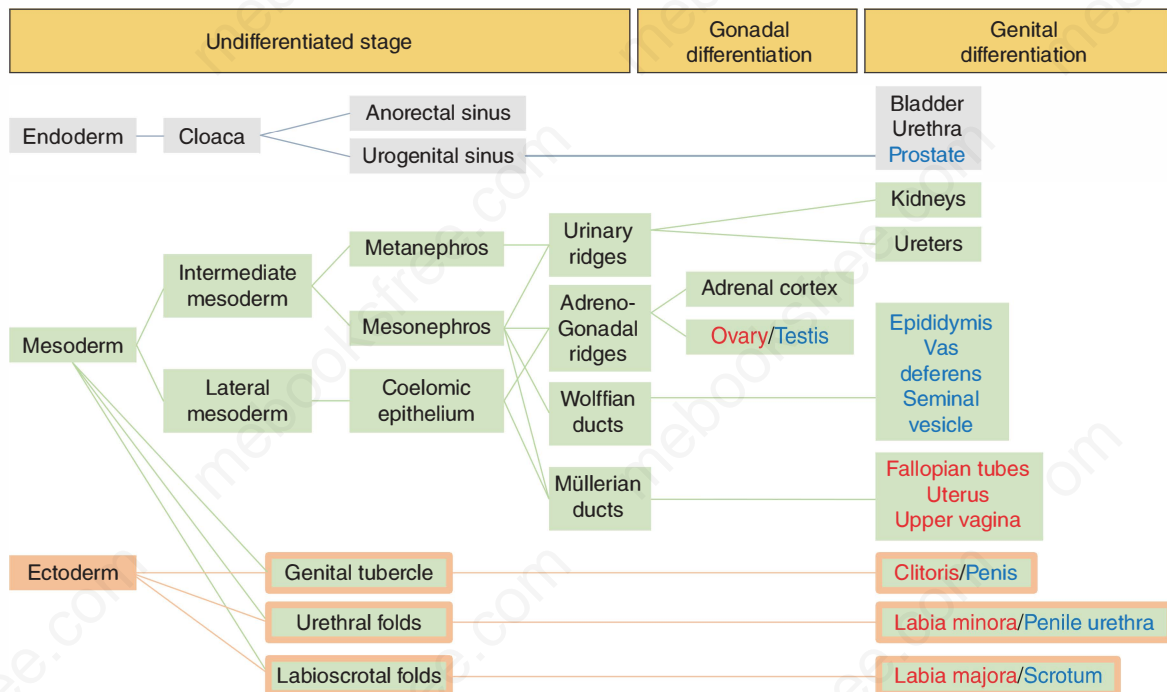
Early embryonic developmental processes are driven by regulatory pathways involving ubiquitously expressed factors whose deficiency may be lethal or result in multiple malformations. For instance, in mice homeobox transcription factors, like LHX1, EMX2 or PAX3, and others like WT1 play a role in the stabilization of the intermediate mesoderm leading to the development of the urogenital ridges. Knockout models show absence or defects of all urogenital derivatives, that is, kidneys and ureters, gonads and internal genital ducts.


FIGURE 14–1 The three stages in fetal sex differentiation. Gray boxes indicate endodermal derivatives; green boxes, mesodermal derivatives; and green/red boxes, structures with both mesodermal and ectodermal derivatives.

THE BIPOTENTIAL GONADS

The gonads and the adrenal cortex differentiate from the adreno-gonadal primordia, the medial portions of the former urogenital ridges. Factors like SF1 and DAX1, respectively encoded by genes *NR5A1* and *NR0B1*, CBX2, LHX9, GATA4, and SIX1/4 are essential for the development of the adreno-gonadal primordia. Cells from the coelomic epithelium and the mesonephric mesoderm contribute to their formation. Progressively, two distinct cell populations separate to originate the adrenal primordium and the gonadal blastema at the beginning of the fifth embryonic week. During the fifth week, the gonadal blastema is colonized by primordial germ cells, of extra-gonadal origin. Several factors have been identified to have a role in the differentiation, migrations, and proliferation/apoptosis of primordial germ cells. Primordial germ cells derive from epiblast; factors involved in the specification of primordial germ cells include BMP2, BMP4, BMP8B, OCT3/4 (encoded by *POU5F1*), NANOG, SOX2, PRDM1, and PRDM14. At a very early stage of embryonic life, primordial germ cells move through the extra-embryonic region at the base of the allantois. In the fourth week, they can be identified in the yolk sac by their expression of PRDM1, alkaline phosphatase, OCT3/4 and the tyrosine kinase receptor C-KIT. Later, primordial germ cells become embedded in the wall of the hindgut, and migrate through the dorsal mesentery to reach the gonadal ridges. Chromatin modifications occur at this stage: genome-wide demethylation leads to erasure of genomic imprints or epigenetic marks. Like somatic cells of the gonadal ridges, germ cells are bipotential. We shall see that germ cells are essential for the development of the ovaries, but not the testes.

Until the end of the fifth week, XX and XY gonads are indistinguishable and bipotential, in that they can develop into ovaries or testes. Interestingly, not only are the optic and electron microscopic aspects identical but also the transcriptomes of the prospective XX and XY gonads are indistinguishable: factors that are later associated with testis fate, like SOX9 and FGF9, or with ovary fate, like DAX1, WNT4, and RSPO1, are expressed at similar levels in the bipotential XX and XY mouse gonads.

THE UNIPOTENTIAL INTERNAL DUCTS

The undifferentiated internal reproductive tract is similar in the XX and the XY embryo until the end of the sixth week and consists on each side of a set of two unipotential ducts: the Wolffian (mesonephric) giving rise to the male internal tract, and the Müllerian (paramesonephric) ducts, that are the anlagen of the female internal tract (Figure 14–2).
FIGURE 14–2 Jost's experiments revealing the determining role of the testes in fetal sex differentiation. In the male fetus, Wolffian ducts develop whereas Müllerian ducts regress. In the female fetus, the opposite occurs. Fetal castration, irrespective of genetic sex, results in female differentiation of the reproductive tract. (Reproduced with permission from Rey R, Josso N. Sexual differentiation. In: De Groot LJ, Beck-Peccoz P, Chrousos G, et al: Endotext [WWW.ENDOTEXT.ORG]. Published by MDTEXT.COM,INC, 2016. South DARTMOUTH,MA 02748.)

Wolffian Ducts

The Wolffian ducts originate in the intermediate mesoderm, dorsolaterally to the pronephros and laterally to somites 8 to 13, and grow caudally to end in the cloaca during the fifth embryonic week. A single ureteric bud evaginates from the Wolffian duct and grows dorsally, in response to inductive signals from metanephric mesenchyme. Interactions between the ureteric bud and the metanephros are essential for kidney development. Several factors have been identified as important for Wolffian duct formation. As already mentioned, members of the PAX family, WT1, EMX2, LIM1, and SIX1 are involved in early intermediate mesoderm stabilization. VANGL2, WNT5A, and PKD1 are necessary to Wolffian duct elongation, and PTEN, LGR4, and DICER, amongst others, play a role in Wolffian duct cell differentiation. Although the pathogenic mechanism is not fully understood, defects in the gene encoding the cystic fibrosis transmembrane conductance regulator (CFTR) are associated with congenital bilateral absence of Wolffian duct derivatives.

Müllerian Ducts

Müllerian ducts arise in the fifth embryonic week, as an invagination of the coelomic epithelium, laterally to the gonadal ridge. Their development can be divided into three phases: initiation, invagination and elongation. First, cells of the coelomic epithelium are specified to a Müllerian duct fate, they form placode-like thickening expressing LHX1, other members of the LIM family, DACH1 and DACH2, and anti-Müllerian hormone receptor type 2 (AMHR2), induced by WNT7A. In the second phase, Müllerian duct-specified cells extend caudally toward the Wolffian ducts. WNT4 expression in the mesonephric mesenchyme is necessary to begin invagination. Upon contact with the Wolffian duct, the elongation phase begins, consisting in proliferation and caudal migration of a group of cells at the caudal tip. Close contact with the Wolffian duct is necessary to Müllerian growth; indeed, the lack of Wolffian development leads to Müllerian truncation. Wolffian ducts do not contribute cells to the elongating Müllerian tip, but supply factors like WNT9B. In the eighth week, the growing tip of the Müllerian duct crosses the Wolffian duct ventrally and run in intimate contact with the contralateral Müllerian duct. These ducts fuse and give rise to the uterovaginal canal, which makes contact with the posterior wall of the urogenital sinus, causing an elevation, the Müllerian tubercle, flanked on both sides by the opening of the Wolffian ducts.

THE BIPOTENTIAL UROGENITAL SINUS AND EXTERNAL GENITALIA

The cloaca is the terminal portion of the hindgut, limited by the cloacal membrane. The epithelium of the cloaca is of endodermal origin, whereas the surrounding mesenchyme is mesodermal. In the fifth embryonic week (seventh week of amenorrhea), the urorectal septum divides the cloaca into the rectum dorsally and the urogenital sinus ventrally. The ventral portion of the cloacal

membrane becomes the urogenital membrane. Two mesodermal swellings develop laterally under the ectoderm of the genital membrane, the urethral folds and the labioscrotal swellings, while the genital tubercle emerges as a ventral and medial swelling. In the sixth week (8-15 mm embryo), the ostium of the urogenital sinus is surrounded by the labioscrotal swellings. Endodermal epithelial cells from the urogenital sinus invade the genital tubercle and form the urethral plate. After the corpora cavernosa and glans have differentiated, the ventral surface of the genital tubercle is depressed by a deep furrow, the urethral groove. The external genitalia remain undifferentiated up to approximately 9 weeks.

Early patterning of external genitalia is under the control of factors regulating the interactions between mesenchymal and epithelial tissues. As in the development of other body appendages, *BMP*, *FGF*, and *HOX* family genes play a predominant role during genital tubercle formation. SHH and β-catenin as well are key regulators of the mesenchymal genes involved in the patterning of the bipotential genital primordia.

At 10 weeks in both XX and XY fetuses, there is a vaginal primordium formed by the caudal tips of the Müllerian ducts, and medial and lateral outgrowths of the urogenital sinus, the sinovaginal bulbs, which fuse to form the vaginal cord or plate. When the vaginal plate regresses, the vaginal lumen is formed.

GONADAL DIFFERENTIATION

The differentiation of the gonadal ridge into a testis or an ovary is of paramount importance in the process of fetal sex differentiation. The pioneering experiments performed by Alfred Jost and colleagues more than 60 years ago clearly showed that, irrespective of their chromosomal constitution, when the gonads differentiate into testes, hormones produced drive internal and external genitalia along the male pathway. Conversely, when no testes are present, the genitalia follow the female pathway (see Figure 14–2). The ovaries have no influence on genital differentiation during intrauterine life. Recent progress in the understanding of molecular mechanisms indicates that the development of the undifferentiated gonadal ridge into a testis or an ovary requires a delicate dosage balance in the timing and levels of expression of several genes (Figure 14–3).

TESTICULAR DIFFERENTIATION

Testicular differentiation occurs by the end of the sixth embryonic week. Experimental evidence in mice indicates that the earliest hallmark of fetal testis development is the formation of the coelomic vessel in the XY gonadal ridge at its antimesonephric margin, that is, below the coelomic epithelium. A close spatial relationship exists between the gonadal ridge vascularization and testicular cord formation: endothelial cells migrating from the mesonephros to the coelomic zone of the differentiating gonad are essential for cord formation. Subsequently, somatic cells from the coelomic epithelium differentiate into Sertoli cells, aggregate within the
FIGURE 14–3 Gonadal and genital tract differentiation. Factors in black are involved in the development of the undifferentiated gonad; those in blue are essentially pro-testicular genes, whereas those in pink are mainly pro-ovarian or anti-testicular when overexpressed. When pro-testicular genes prevail, the coelomic vessel differentiates followed by testicular cord and Leydig cell development. Conversely, when no coelomic vessel develops, the gonad undergoes ovarian differentiation. The testes secrete two hormones involved in the virilization of the internal and external genitalia: anti-Müllerian hormone (AMH) by Sertoli cells, and testosterone by Leydig cells. In their absence, the genitalia follow the female pathway. 5α-red, 5α-reductase; AMH, anti-Müllerian hormone; AMHR2, AMH receptor type 2; AR, androgen receptor.

developing gonad and enclose germ cells to form the testicular cords, the precursors of the seminiferous tubules. Sertoli cells begin secreting anti-Müllerian hormone (AMH) as soon as they differentiate, that is, at the beginning of the seventh embryonic week. The primordial germ cells differentiate to gonocytes, which proliferate by mitosis but do not enter meiosis. Extracellular matrix components and mesenchymal cells of mesonephric origin fill the interstitial space between seminiferous cords and give rise to further blood vessels and differentiating Leydig cells, which begin secreting testosterone by the beginning of the eighth week.

OVARIAN DIFFERENTIATION

In the XX fetus, the gonad remains undifferentiated longer than in the XY fetus. Primordial germ cells differentiate to oogonia, which can be seen sparsely in the cortical zone during

the eighth week. The first unequivocal morphological sign of ovarian differentiation is meiotic entry of germ cells occurring in the tenth fetal week. Oocytes become surrounded by a single layer of follicular (or granulosa) cells to form primordial follicles. The earliest primary follicles appear at 15 weeks and the first Graafian follicles at 23 to 24 weeks. By the end of the seventh month of gestation, almost all germ cells have entered meiosis, proceeding to the diplotene stage, where they remain until gametogenesis is completed in adult life. Not all oocytes complete meiosis: from the 6 to 7 million ovarian follicles present at 25 fetal weeks, only 2 million persist at term. Most follicles undergo atresia.

The presence of germ cells is critical for the stabilization of the ovary, which is a major difference, as compared with testicular differentiation. While the somatic components of the fetal testis progress normally and produce testicular hormones in the absence of germ cells, ovarian follicles degenerate if germ cells are lost, and

the gonads acquire a fibrous aspect and are unable to synthesize ovarian hormones.

Granulosa cells, the female equivalent of Sertoli cells, enclose germ cells to form primordial follicles and regulate oocyte maturation. The source of granulosa cells is still debated: the coelomic epithelium, mesenchymal cells of the gonadal ridge and mesonephric cells form the adjacent rete ovarii. Theca cells surround the granulosa cells from the stage of primordial follicles onward; their origin is also unclear with two possible sources, which are the adjacent mesonephros and the ovarian stroma.

GENETIC MECHANISMS

The Importance of the Y Chromosome and the SRY Gene

Compelling evidence for the importance of the Y chromosome in testicular differentiation, irrespective of the number of X chromosomes present, has existed since 1959 when the 47,XXY karyotype for Klinefelter syndrome and the 45,X karyotype for Turner syndrome were first reported. Nonetheless, the testis-determining region on the Y chromosome was not identified until 1990, when *SRY* (Sex-determining region on the Y) was cloned in man and mouse.

SRY belongs to a family of DNA-binding proteins bearing a high mobility group (HMG) box and its gene maps to Yp11.2, very close to the **pseudoautosomal region 1 (PAR1)** (Figure 14–4), one of the only two regions of the Y chromosome that undergo meiotic recombination with homologous sequences (also known as crossing over) of the X chromosome during male spermatogenesis. The proximity of *SRY* to PAR1 makes it susceptible to aberrant translocation to the X chromosome, providing an explanation for XX maleness owing to SRY translocation.

The transient expression of *SRY* during embryogenesis triggers a cascade of gene interactions that leads to testicular development from the undifferentiated and bipotential gonadal ridge (see Figure 14–3). *SRY* expression initiates between days 41 and 44 post-fertilization in humans in the middle of the gonad and expands toward the poles. The timing and level of *SRY* expression are critical for normal testis differentiation; in fact, decreased or delayed expression results in testicular dysgenesis or the formation of ovotestes in mice. The factors regulating *SRY* expression are being elucidated: SF1, SP1, and the +KTS splice variant of WT1 activate *SRY* transcription. The cofactor CITED2 acts with WT1 and SF1 to increase SRY levels to the critical threshold for triggering testis development. Interaction between GATA4 and its cofactor FOG2 are also required for normal SRY expression and testicular differentiation in mice, possibly through its interaction with the +KTS isoform of WT1. Alternatively, GATA4 could act directly on the *SRY* promoter, after a series of phosphorylation reactions involving GADD45G and MAP3K4.

Other Pathways in Testicular versus Ovarian Differentiation

Considerable progress has been made since SRY was identified, and it has become clear that sex determination is a far more complex process than initially thought, regulated by competing molecular pathways in the somatic cells of the bipotential gonad.

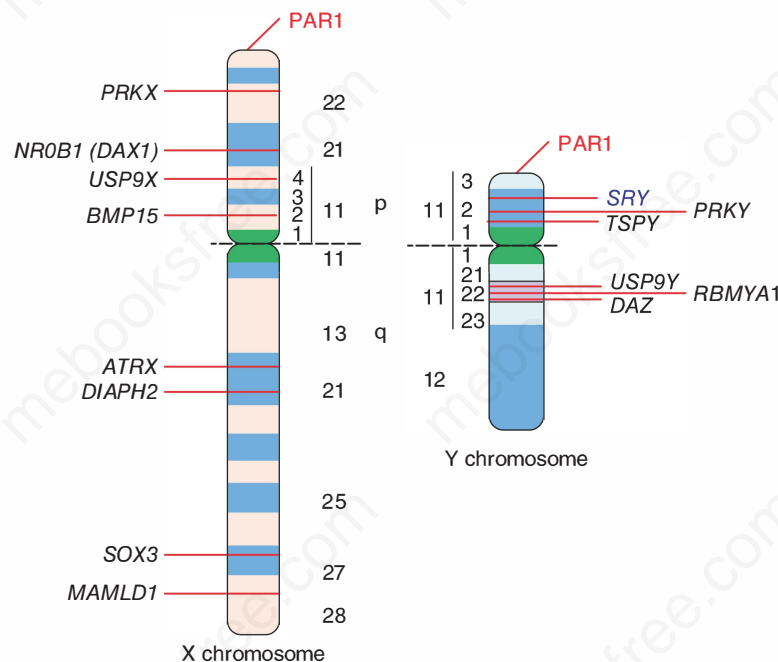
SOX family genes   The SRY-box gene *SOX9* is the earliest upregulated gene in the testis pathway downstream of SRY, followed by CITED4 and other members of the SOX family,


FIGURE 14–4 Sex chromosomes and genes involved in gonadal development and/or function. PAR, pseudoautosomal region.

including *SOX3*, *SOX10*, and *SOX13*, and many other genes that are critical for testicular differentiation. SOX9 is located on chromosome 17q, is an autosomal member of the HMG-box protein superfamily, and is the master regulator of testis differentiation, once SRY has upregulated its expression during a narrow critical time window. SRY and SF1 regulate SOX9 expression by directly binding to several sites within a 3.2-kb testis-specific enhancer (TES) or 1.4-kb of its core element (TESCO), present in its distal promoter. SOX9 is able to maintain its own expression via two different mechanisms: by interacting with SF1 to activate TES and with the help of feed-forward enhancing pathways involving FGF9 and PGD2. These mechanisms succeed in triggering Sertoli cell differentiation. FGF9 and SOX9 also up-regulate AXIN1 and GSK3β, which promote the destabilization of β-catenin and, thus, serve to block ovarian development (see Figure 14–3).

SOX9 mimics SRY independently of SRY expression: for instance, SOX9 overexpression during early embryogenesis induces testicular differentiation in XX humans and mice. SOX9 also affects the differentiation of the reproductive tract by upregulating AMH expression. SOX9 is not testis-specific: it is also expressed in chondrocytes, bile duct, CNS, hair follicles, heart, lung, pancreas and retina, which explains the several malformations observed in patients with SOX9 deficiency. Duplication of SOX9 is a cause of 46,XX sex reversal and SOX9 deletion causes campomelic dysplasia—a severe type of skeletal dysplasia associated with 46,XY sex reversal.

SOX3, encoded by a single-exon, X-linked gene, is involved in brain, pituitary and craniofacial development. Although SOX3 is not required for normal testicular differentiation, its ectopic overexpression in XX gonadal ridges induces testicular differentiation, probably by acting synergistically with SF1 to upregulate SOX9 expression.

SOX8 and **SOX10** are two autosomal SOX family members expressed in the gonads and in several other tissues. During mouse embryo development, the expression of SOX8 and SOX10 is triggered shortly after that of SOX9, but at lower level. Like SOX9 itself, SOX8 and SOX10 can synergize with SF1 and up-regulate SOX9 (see Figure 14–3) upon binding to TESCO. SOX8 can bind the canonical target DNA sequences and activate AMH transcription acting synergistically with SF1, but with less efficiency than SOX9. Later during fetal development, an interaction between SOX9 and SOX8 is required for basal lamina integrity of testis cords and for suppression of FOXL2, two events essential events to the normal development of testis cords.

Other testicular morphogens   The signaling cascade initiated by SRY and SOX family factors counteract the WNT4/FST/β-catenin pathway. When the former prevails, activin B, VEGF, PDGF, and other unidentified factors facilitate endothelial migration and formation of coelomic vessel and the testis-specific vasculature.

The formation of the seminiferous cords, which enclose the germ cells finally giving rise to the gametes, requires the formation of a basal lamina around Sertoli and germ cells. The presence of peritubular cells is essential. The differentiation of these cells

seems to be triggered by Sertoli cell-secreted factors, like DHH. Peritubular cells assemble around the cords and interact with Sertoli cells to produce the proteins of the extracellular matrix, like collagen, fibronectin and laminin, the components of the basal lamina.

First genetic theories about ovary differentiation   Molecular pathways underlying fetal ovarian differentiation remain largely unexplored. Most of the present knowledge relies on observations concerning the absence of testicular differentiation. However, the "default pathway theory" proposing that the sole absence of *SRY* results in ovarian differentiation seems to apply to specific experimental conditions in rodents. In humans, *SRY* mutations or deletions result in gonadal dysgenesis, but not in ovarian differentiation as no oocyte meiotic progression or follicle development has been described in these conditions, even during fetal life. Recent findings indicate that the coordinated action of several factors is needed for the differentiation and stabilization of the ovaries.

WNT/RSPO1/β-catenin and FST signaling pathways   Ovary-specific gene expression is triggered somewhat later than testis-specific genes. Despite similar expression in the XX and XY gonadal ridges, some factors, such as WNT4, R-Spondin 1 (encoded by *RSPO1*), β-catenin (encoded by *CTNNB1*) and follistatin (encoded by *FST*), increase their expression in the XX gonad. RSPO1 upregulates the expression of WNT4 and both factors work synergistically to counteract SOX family proteins, and to stabilize β-catenin, which accumulates in the nucleus and interacts with LEF1 leading to the activation of downstream genes and further inhibition of SOX9. *FST*, one of the genes up-regulated by the WNT4-triggered pathway, antagonizes activin B, thereby blocking the formation of the testis-specific vasculature (see Figure 14–3), an essential early step for testicular differentiation. Apart from this anti-testis action, WNT4 also has a pro-ovarian effect by supporting germ cell survival. The expression of all these factors is not limited to the developing ovary; for instance, WNT4 is expressed in the brain, lung, and mesonephros; RSPO1, in the CNS, lung and skin; and β-catenin, and follistatin are ubiquitous.

FOXL2 and follicular morphogenesis   The forkhead transcription factor FOXL2 is one of the earliest markers of ovarian differentiation and is essential for follicle formation: it can be detected in pregranulosa cells, and female mice lacking *Foxl2* have follicles whose maturation is arrested between the primordial and primary stages, with subsequent atresia. FOXL2 is also involved in the development of the eyelids.

MAP3K1 modulates the balance between female and male pathways   As explained, SOX9 and FGF9 upregulate AXIN1 and GSK3β, which promote the destabilization of β-catenin and block ovarian development. MAP3K1 sequestrates AXIN1, thus promoting the stabilization of β-catenin and favoring the ovarian pathway.

DMRT1 and DAX1: their precise roles remain elusive   The DM domain transcription factor family member DMRT1 appears

to play a conserved role in male gonad development among verte-brates. In mice, DMRT1 is required for normal testicular mor-phogenesis; loss of DMRT1 expression activates FOXL2 and reprograms Sertoli cells into granulosa cells, even in postnatal life, suggesting that DMRT1 is essential to maintain mammalian testis differentiation throughout life. In humans, the role of DMRT1, which maps to 9p24.3, is less clear although it seems to play a role in testicular differentiation, as suggested by observations in patients with 9p deletions. DAX1, encoded by *NR0B1*, is an orphan nuclear receptor mapping to the DSS (Dosage Sensitive Sex-reversal) region on Xp21. DAX1 was the first putative testis repressor and/or ovarian determining gene, as suggested by the observation that a duplication of DSS results in sex-reversal in 46,XY patients, and DAX1 overexpression in transgenic XY mice impairs testis differentiation by antagonizing the ability of SF1 to synergize with SRY action on SOX9. However, a *Dax1* gene knockout did not prevent ovarian differentiation in XX. Both low and high DAX1 expression results in abnormal gonadal differen-tiation. DAX1 is also involved in the development of the adrenal cortex. Losses of function DAX1 mutations are associated with congenital adrenal hypoplasia and hypogonadism in males.

DIFFERENCES IN TESTICULAR AND OVARIAN GERM CELL DEVELOPMENT

As mentioned, primordial germ cells are bipotential. Interest-ingly, their commitment to a spermatogenic or an oogenic fate does not depend on their XY or XX karyotype. Rather, the functional characteristics of the surrounding somatic cells of the gonads regulate germ cell sexual differentiation. In the female embryo, germ cells are exposed to high levels of **retinoic acid** secreted by cells from the mesonephros and the ovary expressing retinaldehyde dehydrogenases (ALDHs, also known as RALDHs). Exposure to retinoic acid induces the expression of **STRA8**, which triggers germ cell meiosis. Thus, oogonia give rise to primary oocytes, which become surrounded by a single layer of flat granulosa cells to form primordial follicles. Granulosa cells become cuboid and proliferate, giving rise to primary and small growing follicles. During fetal life meiosis progresses but is arrested at the diplotene stage of the first mei-otic prophase until puberty.

In male embryos, primordial germ cells colonizing the testis become clustered in the testis cords, surrounded by Sertoli cells; while Leydig cells are present in the interstitial tissue between cords. Germ cells proliferate by mitosis but do not enter meiosis because the cytochrome P450 enzyme CYP26B1 expressed by Sertoli and Leydig cells mediates the degradation of retinoic acid and hampers the expression of STRA8. In Ser-toli cells, CYP26B1 expression is activated by SOX9 and SF1. FGF9, another factor upregulated in Sertoli cells in response to SOX9, also prevents germ cells from entering meiosis. Thus, germ cells give rise to gonocytes that differentiate to spermato-gonia and proliferate by mitosis, but meiosis only starts at puberty in the male gonad.

HORMONE-DEPENDENT DIFFERENTIATION OF THE GENITALIA

ONE GONAD, TWO CELLS, TWO HORMONES

As already mentioned, Jost's experiments on fetal endocrinology provide the basis for the comprehension of sexual differentiation: only the testis—not the ovary—plays a role in sexual differentia-tion of the internal and external genitalia during fetal life. He went further to show that the testicular hormone secretion had a dual nature, since androgens alone were not capable of fulfilling all features of sex differentiation. We now know that androgens, secreted by Leydig cells, are responsible for the development of the unipotential Wolffian ducts into the male internal reproductive ducts and also for the virilization of the bipotential urogenital sinus and external genitalia, and that AMH, secreted by Sertoli cells, drives the regression of the unipotential Müllerian ducts (see Figure 14–3). In the absence of testes and, therefore, of androgen and AMH action, Wolffian ducts regress, Müllerian ducts develop into the internal female ducts and external genitalia follow the female pathway. In Jost's experiments with early castration of rab-bit embryos, all fetuses developed female internal and external genital structures indicating that ovarian hormones play no role in normal fetal sex differentiation. Other experimental models and human disorders have confirmed this observation.

AMH AND THE FATE OF MÜLLERIAN DUCTS

Anti-Müllerian hormone (AMH), a member of the TGF-β fam-ily, is responsible for the regression of Müllerian ducts in the male fetus. AMH is expressed at high levels by Sertoli cells as soon as they differentiate. Although Müllerian duct regression takes place in the eighth and ninth weeks of fetal life, Sertoli cells continue to produce high amounts of AMH until puberty. In the female, AMH is produced at lower levels by granulosa cells of growing follicles from the twenty-third fetal week, a stage where Müllerian ducts are no longer responsive to it.

Regulation of AMH Expression

AMH transcription in fetal Sertoli cells is triggered by SOX9. SF1, GATA4, and WT1 synergize to increase SOX9-activated AMH transcription, a synergy antagonized by DAX1. This initial stage of AMH production is independent of gonadotropins. Subse-quently, during the second and third trimesters of fetal life and in the neonate, FSH increases testicular AMH production by induc-ing Sertoli cell proliferation and by upregulating AMH transcrip-tion in each Sertoli cell. AMH declines at puberty, when Sertoli cells mature; this is an androgen-mediated effect. Remarkably, AMH expression is not inhibited in fetal and neonatal periods in

spite of high androgen production by the testes; this is due to the fact that Sertoli cells do not express the androgen receptor in those periods of life.

AMH Action

AMH signals through two distinct membrane receptors present in the mesenchymal cells that surround the Müllerian duct. Following proteolytic cleavage into its N and C terminal fragments, AMH binds specifically to the AMH receptor type 2, which subsequently activates a non-specific type 1 receptor. AMH action on Müllerian ducts provokes apoptosis in some epithelial cells whereas others undertake epithelial-to-mesenchymal transformation. Consequently, the epithelial Müllerian ducts disappear beginning days 55 to 60 of fetal life. By the end of the ninth week, Müllerian ducts are no longer responsive to AMH; therefore, any delay in AMH expression may result in the persistence of Müllerian derivatives.

Müllerian Derivatives in the Female

In the absence of AMH action, Müllerian ducts persist and develop into an epithelial tube that gives rise to the endometrium, while the surrounding mesenchyme differentiates into the myometrium of the uterus and Fallopian tubes. Müllerian derivatives also contribute to the upper portion of the vagina (see Figure 14–3).

ANDROGENS AND THE FATE OF THE WOLFFIAN DUCTS, UROGENITAL SINUS, AND EXTERNAL GENITALIA

The interstitial compartment of the testis contains developing Leydig cells, the most important androgen-producing cells in the male, from the beginning of the ninth week in the human embryo. The origin of Leydig cells is still a matter of debate: the precursors have been proposed to be either migrating cells from the coelomic epithelium, the mesonephros or the neural crest, or resident cells present in the adreno-gonadal primordium. Leydig cells also produce insulin-like factor 3 (INSL3), involved in the transabdominal phase of testicular descent. The initial differentiation of fetal Leydig cells depends on Sertoli cell-secreted PDGFs, but further Leydig cell differentiation, proliferation, and steroidogenic capacity depend on placental hCG in the first and second trimesters of gestational life, and on fetal pituitary LH thereafter. Both hCG and LH act on the same LH/CG receptor, a G protein-coupled receptor present in testicular Leydig cells. Testosterone levels peak between 11 and 14 weeks in the male fetus.

Steroidogenesis

Testosterone production
Testosterone is the most abundant androgen produced by the testis. Steroidogenesis is a long process starting from cholesterol through the coordinated action of steroidogenic enzymes (Figure 14–5), most of which are also expressed in the adrenal gland, explaining why many steroidogenic disorders are common to the testis and adrenal. The initial step in steroidogenesis is the conversion of cholesterol to pregnenolone, mediated by the P450 side-chain cleavage enzyme (P450scc) in the inner mitochondrial membrane. The transfer of cholesterol into the mitochondria is dependent on steroidogenic acute regulatory protein (StAR) and TSPO. Pregnenolone is subsequently metabolized by P450c17 that has two distinct activities: a 17α-hydroxylase activity responsible for the conversion of pregnenolone to 17α-hydroxypregnenolone and a 17,20 lyase activity, capable of converting 17α-hydroxypregnenolone to dehydroepiandrosterone (DHEA). The flavoprotein P450 oxidoreductase (POR) and the cytochrome b5 are required for optimal 17,20 lyase activity. P450c17 and its partner proteins also convert the Δ4 compound progesterone into 17α-hydroxyprogesterone and Δ4-androstenedione. The final testicular enzyme in testosterone biosynthesis is 17β-hydroxysteroid dehydrogenase type 3 (17β-HSD-3), which converts Δ4-androstenedione to testosterone and the Δ5 steroid DHEA to androstenediol. Several 17β-HSD isoforms have been identified, but only the type 3 is expressed in the testis. Another hydroxysteroid dehydrogenase, 3β-HSD type 2, is responsible for the conversion of Δ5 to Δ4 steroids. All these enzymes, except 17β-HSD-3, are present in both the testis and the adrenal cortex.

Dihydrotestosterone (DHT) production
Testosterone is less potent than its metabolite DHT, which binds the androgen receptor with higher affinity than testosterone, and also cannot be aromatized to estrogen, thus its effects are purely androgenic. In the classic pathway, testosterone is converted to DHT in target tissues by the enzyme 5α-reductase type 2 expressed in the urogenital sinus, including the prostate primordium, and in the fetal genital skin. Another isoenzyme, 5α-reductase type 1, is expressed in the adrenal cortex, in liver after birth and in skin from the time of puberty. An alternative, also called "backdoor," pathway exists for DHT production which does not involve testosterone as a precursor (see Figure 14–5). Progesterone and 17-hydroxyprogesterone are respectively converted to dihydroprogesterone and 17-hydroxydihydroprogesterone by 5α-reductase type 1, and to allopregnanolone and 17-hydroxyallopregnanolone by 3αHSD. P450c17 convert them to androsterone. The latter is subsequently finally metabolized to DHT via androstanediol or androstenedione by 17β-HSD types 3 or 5, and 17β-HSD type 6 together with 3αHSD.

Estrogen production
Estrogens are synthesized from androgens by the action of the P450 aromatase, which is expressed in the granulosa cells of the ovary, the placenta and also in muscle, liver, hair follicles, adipose tissue, and brain.

Adrenal cortex steroids
The adrenal cortex comprises the zona glomerulosa, which synthesizes mineralocorticoids (aldosterone) essentially under the regulation of the renin/angiotensin system and serum potassium concentration, the zona fasciculata, responsible for glucocorticoid (cortisol) secretion primarily under the stimulation of ACTH, and the zona reticularis, where adrenal androgens (DHEA sulphate and Δ4-androstenedione) are

FIGURE 14–5 This diagram illustrates adrenal, ovarian, and testicular steroidogenic pathways. Under the usual circumstances in humans, 17-OHP is a poor substrate for CYP17A1 (dotted line). In CAH due to 21-OHD, the defect leads to accumulation of progesterone and 17-OHP, which are diverted not only to AD and T but also to additional metabolites such as 16α-hydroxyprogesterone and 21-deoxycortisol. The adrenal cortex also secretes 11β-hydroxyandrostenedione (11OHAD), and 11-ketotestosterone (11KT). In green, steps that are common to adrenals and gonads; in red, those related to gonadal steroids, in dark gray, those related to adrenal steroids, and in blue those involved in the "backdoor pathway." Δ5 pathway involving pregnenolone through DHEA, and Δ4 pathway involving progesterone through testosterone are indicated. Δ5 steroids are converted to Δ4 steroids by 3β-HSD. 3β-HSD, 3β-hydroxysteroid dehydrogenase; 5α-red, 5α-reductase; 17-HSD, 17β-hydroxysteroid dehydrogenase; P450aldo, Cytochrome P450 aldosterone synthase; P450aro, Cytochrome P450 aromatase; P450c11, Cytochrome P450 11β-hydroxylase; P450c17, Cytochrome P450 17α-hydroxylase/17,20-lyase; P450c21, Cytochrome P450 21-hydroxylase; P450scc, Cytochrome P450 steroid sidechain cleavage; AKR, Aldo-keto reductase; DHEA, Dehydroepiandrosterone; DHT, Dihydrotestosterone; DOC, Desoxycorticosterone; POR, Cytochrome P450 oxidoreductase; SF1, Steroidogenic factor 1; StAR, Steroidogenic acute regulatory protein. (Reproduced with permission from Rey RA, Grinspon RP. Normal male sexual differentiation and aetiology of disorders of sex development. *Best Pract Res Clin Endocrinol Metab*. 2011 Apr;25(2):221-238.)

produced under ACTH control. The initial steps are shared with gonadal steroidogenesis (see Figure 14–5). The existence of the cytochrome P450 with 21-hydroxylase activity converts progesterone to deoxycorticosterone in the zona glomerulosa and 17-hydroxyprogesterone to deoxycortisol in the zona fasciculata. Subsequently, another cytochrome P450, aldosterone synthase, converts deoxycorticosterone to corticosterone and aldosterone in two successive steps, whereas 11β-hydroxylase converts deoxycortisol to cortisol. In the fetus, the zona reticularis makes little Δ4-androstenedione and massive amounts of DHEAS, because expression of 3β-HSD type 2 is low as compared to that of DHEA-sulfotransferase. With adrenarche, the zona reticularis secretes increased amounts of DHEAS, DHEA, and androstenedione. Testosterone production is also low because 17β-HSD type 3 is not expressed. Alternative enzymes of the AKR1C family, including 17β-HSD type 5 (encoded by *AKR1C3*) are probably responsible for the small amounts of testosterone production.

Androgen Action in Target Tissues

All androgens act through binding with the same androgen receptor, a zinc-finger transcription factor encoded by the *AR* gene mapping to Xq12. Like other nuclear receptors, the androgen receptor is composed of three major functional domains: a large N-terminal domain that precedes the DNA-binding domain, which is connected to the C-terminal ligand-binding domain by a short-hinge region. Unlike other members of the steroid receptor family, the androgen receptor resides mainly in the cytoplasm and translocates into the nucleus in the presence of its ligand. The androgen receptor binds to specific DNA motifs, the androgen response elements (ARE), present in the promoter regions of target genes. Interestingly, the *SRD5A2* gene encoding 5α-reductase type 2 has ARE sequences in its promoter and is regulated by testosterone. The androgen receptor activity is modulated by coregulators, partner

Wolffian Duct Derivatives

The Wolffian ducts are exposed to very high local concentrations of testosterone, unlike more distant organs receiving testosterone only via the peripheral circulation. Therefore, conversion to DHT does not seem essential for their stabilization and differentiation (see Figure 14–3). Between weeks 9 and 13, the upper part of the Wolffian duct differentiates into the epididymis. Below, it becomes the vas deferens, which opens into the urogenital sinus at the level of Müllerian tubercle. The seminal vesicle originates from a dilatation of the terminal portion of the vas deferens in 12-week-old fetuses. In the absence of androgen action, for example, in the normal XX fetus or in cases of androgen synthesis or androgen receptor defects, the Wolffian ducts degenerate by weeks 10 to 12.

The Bipotential Urogenital Sinus

The urogenital sinus originates the bladder of both sexes, the prostate and the prostatic and membranous portions of the urethra in the male, and the whole urethra and the lower portion of the vagina in the female. Male differentiation is dependent on testosterone conversion to DHT.

Prostatic buds appear at approximately 10 weeks at the site of the Müllerian tubercle and grow into solid branching cords. Maturation of the prostatic gland is accompanied by development of the prostatic utricle. Two buds of epithelial cells, called the sinoutricular bulbs in the male, develop from the urogenital sinus close to the opening of the Wolffian ducts and grow inward, fusing with the medial Müllerian tubercle, to form the sinoutricular cord, enclosed within the prostate gland, which canalizes at 18 weeks to form the prostatic utricle, the male equivalent of the vagina.

Female differentiation of the urogenital sinus is characterized by the acquisition of a separate vaginal opening on the surface of the perineum (Figure 14–6). At the end of the ambisexual stage, the vaginal anlage is located just underneath the bladder neck. In females, the lower end of the vagina slides down along the urethra until the vaginal rudiment opens directly on the surface of the perineum at 22 weeks. The hymen marks the separation between the vagina and the diminutive urogenital sinus, which becomes the vestibule.
FIGURE 14–6 Sex differentiation of urogenital sinus (left) and external genitalia (right). See text for details. (Reproduced with permission from Rey R, Josso N. Sexual differentiation. In: De Groot LJ, Beck-Peccoz P, Chrousos G, et al. Endotext [WWW.ENDOTEXT.ORG]. Published by MDTEXT.COM,INC, 2016. South DARTMOUTH,MA 02748.)

The embryology of the vagina is still matter of debate. The most accepted view proposes that the upper part of the vagina derives from the Müllerian ducts and the lower part from the sinovaginal bulbs, which by fusion form the vaginal plate, derived from the urogenital sinus. The Wolffian ducts do not seem to contribute cells to the sinovaginal bulbs but they may have a helper function during downward movement of the vaginal bud in the female.

The Bipotential External Genitalia

Masculinization of the external genitalia begins during the ninth fetal week in response to DHT, and is characterized by lengthening of the anogenital distance. Subsequently labioscrotal folds fuse in a dorsal to ventral fashion (see Figure 14–6). The embryological development of the penile urethra is controversial. Some authors describe it as a two-step process, with the proximal urethra forming by fusion of the urethral folds around the urethral plate and the distal urethra arising from an invagination of the apical ectoderm. Others propose that the entire male urethra is of endodermal origin, formed by the urethral plate dorsally and the fused urethral folds ventrally.

The genital tubercle gives rise to the glans penis and the corpora cavernosa. Surprisingly, there is no size difference between penile or clitoral size until 14 weeks despite the fact that serum testosterone levels peak between 11 and 14 weeks in males. Urethral organogenesis is complete at 14 weeks, apart from a physiological ventral curvature, which can persist up to 6 months of gestation. Maximal fetal penile growth occurs during the third trimester, at a time when male testosterone levels, now under fetal LH control, are declining.

In the female fetus, the anogenital distance does not increase; the urethral folds do not fuse and form the labia minora, while the labioscrotal swellings give rise to the labia majora. The dorsal commissure forms at their junction. When the vagina acquires a separate perineal opening, the diminutive pars pelvina and the pars phallica of the urogenital sinus become the vestibule. The genital tubercle emerges as a ventral and medial swelling and becomes the origin of the clitoris.

Testicular Descent

During fetal life, the testis migrates from its initial pararenal location to its final position in the scrotum. Testicular descent can be divided into two phases. Initially, the upper pole of the testis is connected to the posterior abdominal wall by the cranial suspensory ligament while a primitive gubernaculum extends from the caudal pole to the inner inguinal ring. During the transabdominal phase, between fetal weeks 10 and 15, the cranial suspensory ligament dissolves and the gubernaculum testis swells and pulls the testis down to the inguinal ring. This phase is dependent on androgens and INSL3. The inguinoscrotal phase occurs between 27 and 35 weeks, and is mainly dependent on androgen action. The clinical relevance of the involvement of other factors, like homeobox A10 (HOXA10), calcitonin gene-related peptide (CGPR), and AMH, still needs to be fully elucidated. Physiological cryptorchidism is frequent in premature infants. In the female, the cranial ligament holds the ovary in a high position, and the gubernaculum, giving rise to the round ligament, remains long and thin.

DISORDERS OF SEX DIFFERENTIATION (DSD)

DEFINITIONS AND HISTORICAL PERSPECTIVES

Terms that have been used to describe these conditions include the following:

1. **Ambiguous genitalia**—the condition in which an infant's external genitals do not appear clearly male or female.
2. **Pseudo-hermaphroditism**—the condition in which external genitalia are not consistent with gonadal development (ovaries or testes) and karyotype. These were formerly classified based on karyotype in which the pronoun used (female or male) described the karyotype.
   a. Female pseudo-hermaphroditism—indicating masculinized external genitalia in an individual with ovaries, 46,XX karyotype and female internal genitalia.
   b. Male pseudo-hermaphroditism—indicating incompletely virilized genitalia in an individual with testes and 46,XY karyotype.
3. **True hermaphroditism**—an individual with both ovarian and testicular tissue.
4. **Intersex**—a condition of incomplete or disordered genital or gonadal development leading to a discordance between genetic sex, gonadal sex, and genital sex.
   a. This definition preceded the terminology: DSD, first proposed in 2006.
   b. Examples vary from ambiguous genitalia, to male genitalia with 46,XX karyotype or female genitalia with 46,XY karyotype, to male genitalia and internal ovaries or female genitalia and testes.
5. **Disorders of sex development**—these are congenital conditions in which development of chromosomal, gonadal and genital sex is atypical.
   a. This newly created broad category was suggested to replace the term intersex.
   b. Categories included the following plus other rare classifications (Table 14–1):
      i. 46,XY DSD replaced the male pseudo-hermaphrodite category and includes undervirilized and under-masculinized XY male.
      ii. 46,XX DSD replaced the female pseudo-hermaphrodite category: masculinized and over-virilized 46,XX female.
      iii. Sex chromosome DSD as an inclusive category including the former true hermaphrodite and mixed gonadal dysgenesis or asymmetric gonadal differentiation categories (45,X/46,XY), 46,XX/46,XY chimeric, ovotesticular DSD and also Turner syndrome and Klinefelter syndrome and its variants.
      iv. To accommodate the rare conditions such as XY female, XX sex reversal, and XY sex reversal, the terms 46,XX testicular DSD, and 46,XY complete gonadal dysgenesis were proposed.
   c. This broad DSD definition has been interpreted to include conditions such as cryptorchidism and isolated hypospadias, sex chromosome aneuploidies such as Turner and

TABLE 14–1 Karyotype-based classification of DSD.

DSD Type	Pathogenic Classification	Etiology
46,XY DSD	Malformative DSD	Defective morphogenesis of the genital primordia
	Dysgenetic DSD	Complete, partial, or asymmetric gonadal dysgenesis
		Ovotesticular DSD
	Non-dysgenetic DSD	Disorders of androgens synthesis
		Disorders of androgen action (AIS)
		Disorders of AMH synthesis or action
46,XX DSD	Malformative DSD	Defective morphogenesis of the genital primordia
	Dysgenetic DSD	Ovotesticular DSD
		Testicular DSD
		Ovarian dysgenesis
	Non-dysgenetic DSD	Excessive adrenal androgen synthesis (CAH)
		Decreased placental androgen aromatization (aromatase deficiency)
		Androgen-secreting tumors
		Androgenic drugs
Sex chromosome DSD	Dysgenetic DSD	Ovotesticular DSD (46,XX/46,XY, mosaicisms with 46,XX and 46,XY lineages)
		Asymmetric gonadal dysgenesis (45,X/46,XY, other mosaicisms with a 45,X lineage)
		Turner syndrome (45,X and variants)
		Klinefelter syndrome (47,XXY and variants)
		Triple X syndrome (47,XXX and variants)

Klinefelter syndromes, as well as adrenal enzyme deficiencies to include 46,XY individual having appropriate internal and external genital differentiation, such as congenital adrenal hyperplasia (CAH), 21-hydroxylase deficiency.

  i. This new terminology has been criticized for carrying a stigma and for unnecessarily medicalizing those with intersex traits.

  ii. The breadth of the new terminology requires further definition to clarify what category is being discussed and also obscures the incidence of subcategories, for example, the incidence of DSD individuals with external genitalia so ambiguous that it is necessary to determine sex of rearing.

6. **Sex and gender** (definitions may differ or overlap)

  a. Sex—defined traditionally as either male or female based on their reproductive functions. To differentiate from gender, sex refers to biology including appearance of external genitalia, traditionally considered a binary classification.

  b. Gender—the behavioral, cultural, or psychological traits typically associated with male or female sex; classified as feminine, masculine or neuter.

  c. Gender identity—an individual's self-designation as male or female (or uncommonly a non-binary definition). Gender identity develops over time.

  d. Gender role—sex-typical behaviors are impacted by hormonal exposure, particularly androgens and additionally defined by societies.

  e. Sexual orientation—the erotic interest as heterosexual, homosexual, bisexual, or fluid.

  f. Sexual identity—may be considered a composite of gender identity, gender role, and sexual orientation.

Since ancient times, society has been challenged with how to respond to individuals with anatomic differences of genital development. The anatomic variations influenced the characters of ancient mythology, that is, hermaphrodites. Responses to genital atypia continue to evolve, involving changes in perceptions, recommendations, and guidelines for male or female assignment for the infant born with ambiguous genitalia.

Historically, the approach to the individual with ambiguous genitalia has been based upon then current understanding of both the pathophysiology, the determinants of gender and the cultural background of the time. In spite of the advancement, major gaps in knowledge persist, particularly regarding the determinants, hence predictors, of gender development. When considering progression of the medical approach to sex assignment as "generations," the first generation, used prior to the mid-20th century, was based on the perception that "true sex" was ascertained by gonadal differentiation and that "true gender" would follow "true sex." Hence, gonadal histology became the basis for sex assignment or reassignment. Thus, if ovarian development was documented, sex assignment was female, regardless of the extent of

masculinization of the reproductive system, and the converse was true for those with testicular histology, who received a male assignment. This paradigm was modified during the 1950s after chromosomal sex could be determined. The perception of sex chromosomes, before appreciation of the role of genes on both autosomes and sex chromosomes on sex differentiation, was that a Y chromosome meant a male sex, while two Xs meant female. Chromosomal and gonadal sex together determined "true sex" for assignment or reassignment. Tragic outcomes of the practice of recommending a female reassignment for a child with ovaries who essentially fully developed male genitalia and was being raised as male illustrate the fallacy of this approach.

In the 1960s, the next or "second generation" perspective developed in response to the realization that gender development was a complex, multifactorial, although incompletely understood, process. This "Optimal Gender" approach, recognized gender development as a multifactorial process involving both pre- and postnatal variables, heavily influenced by psychosocial factors. Both heredity and environment were felt to be involved. This concept led to the hypothesis that gender was malleable at birth, was significantly influenced by postnatal inputs, and could be imposed by aligning social inputs with sex assignment. Assignment was based upon perceived potential for fertility and capacity for penetrative intercourse, which, together with external genitalia consistent with the sex of rearing, were considered the key determinants for a good adult Quality of Life (QoL). For 46,XX patients, primarily those with 21-hydroxylase deficiency CAH, a female assignment was based on the conviction that suppression of adrenal androgen excess would allow an excellent potential for fertility, and that feminizing genital surgery would provide the capacity for traditional intercourse, and together these factors would form the basis for success in adult life. The availability of cortisone therapy to suppress excessive adrenal androgen secretion supported the assumption that such therapy would be followed by complete feminine development and fertility.

For 46,XY patients with incomplete masculinization, the optimal gender approach criteria included the expectation of poor potential for both fertility and testosterone secretion, so expected adequacy of penis development for penetrative intercourse in adulthood was considered the primary key factor for sex assignment. When an anatomically correct but very small penis was felt to have insufficient growth potential or when surgery for phallus with hypospadias could not be expected to result in an adequately sized and configured penis, a female assignment was considered. The basis of this perspective was apparently the crippling psychological outcome of a few adult males with a very diminutive penis size and the perspective that it would be inappropriate to raise a child as a male who would be incapable of traditional sexual intercourse.

Sex assignment for patients with true hermaphroditism and mixed gonadal dysgenesis (or asymmetric gonadal differentiation) was based upon external and internal reproductive system development and gonadal differentiation. For both diagnoses, if a single testosterone-producing testis was present alongside a phallic structure that could be repaired into a reasonable penis, male assignment was recommended even though fertility was not expected.

Since MGD does not involve functional ovarian tissue, even though fertility was highly unlikely, male assignment was usual because of masculinization. For ovotesticular DSD, if an ovary was present with follicles, a Fallopian tube on that same side and a uterus differentiated to potentially accommodate a fetus, a female assignment was considered. For both diagnoses, gonadectomy was considered because of risk of malignancy.

Influences that impacted this second generation approach included case reports and patient outcome series, including the dissatisfaction and non-acceptance of sex assignment when sex reassignment was attempted following in response to a missed diagnosis, particularly among those who had been exposed to significant androgen during fetal and post-natal life. There was little appreciation of the trauma inflicted when an individual was told that they were actually the opposite sex from what they presumed. The practice of incomplete disclosure of medical information, also a tenet of the second generation approach, was intended to shelter patients from information that was felt to impede adjustment with the sex assigned but in hindsight was clearly unethical, risked the trauma of late disclosure, and underestimated the resilience of human nature.

Although practice shifts had already begun, the "third generation" version of sex assignment guidelines was defined at the 2005 international consensus conference. Recommendations for sex assignment, based upon the data available at that time, were consistent with the principle that each generation applies current scientific knowledge, using the cultural understanding of the time. A female assignment was considered to be appropriate for all 46,XX CAH patients based upon the evidence that 95% of such patients develop a female gender identity, although the lack of adequate data regarding that subgroup of patients with markedly virilized genitalia (Prader stage 4 and 5) was apparent. Female assignment was also recommended for 46,XY patients having CAIS and an LH receptor defect. Male assignment was recommended for patients with 5α-reductase deficiency and 17-hydroxysteroid dehydrogenase deficiency based upon outcome data indicating that the majority of patients identify as males in adult life. Those in the new Gonadal DSD category diagnosed with ovotesticular DSD and MGD, the recommendation remained as previously, assignment being based upon the composite anatomy judged to be more consistent with the better QoL.

A shift toward a male sex assignment had already begun before 2005 for many 46,XY DSD patients, particularly those without a defined etiologic diagnosis. This was influenced by the outcome among 46,XY individuals with cloacal exstrophy, a model of genital ambiguity in which fetal testicular testosterone secretion is normal. The finding that an impressive portion of the 46,XY infants with cloacal extrophy who were reassigned female and orchiectomized during the early neonatal period later expressed a male gender identity suggested an indelible impact of fetal testosterone on gender development outside of any postnatal testosterone exposure.

It is apparent that the perception that karyotype, rather than specific genes on both sex chromosomes and autosomes, persists and may be detrimental to best judgment regarding sex assignment. Also, as with gender dysphoria among those with normal

biologic development, a broader gender model that goes beyond a simple binary system is more likely to be considered.

There was also a shift in surgery over the last half of the previous century for females with clitoromegaly, likely related to increased appreciation of the female sexual responsiveness. Gradually surgery became reserved for those with more extreme degrees of enlargement using refined techniques that preserve innervation. Also, during the 1990s, there was dissatisfaction by former patients with both non-disclosure of their medical history expressed and genital surgery that had been performed when they were young. While it is unclear what portion of former patients were dissatisfied with their treatment, especially surgery during infancy and childhood, these complaints demanded attention of those caring for these patients. This, plus the recognition of the need to reassess care of DSD patients was the motivation for the meeting of the Consensus Group. These caretakers were confronted with accusations, largely focused against Dr. John Money—the researcher who developed the optimal gender strategy in response to a non-intersex case—regarding the negative impact his approach had on their gender development. When no one else provided counseling to the family of a patient who had a traumatic penile amputation during circumcision (not an intersex condition and not presenting in the neonatal period), Dr. Money suggested a female assignment consistent with the perspective at that time that sex of rearing was a major determinant for gender development, if reassignment occurred before 18 months of age. Ultimately, it became clear that this child developed a **male** gender identity, in contrast to another patient with a similar history of accidental penis amputation who developed a female gender identity. This highly publicized case, together with concerns about female assignment for other 46,XY DSD patients, was likely a major factor in the shift away from female assignment.

There is a contingent of concerned individuals who hold the perspective that genital surgery during infancy is simply cosmetic surgery unless some physically life-threatening condition exists. This position does not take into account the unknown role that external genital anatomy plays in gender identity development. Allowing a child to grow up with genitalia that do not fit sex assignment has been considered as social experimentation in some settings (http://www.isna.org/colombia, accessed 2 Nov 2015). The position that surgery should wait until the patient is old enough to decide could be considered to preclude the parents' rights and responsibilities. Further, there is no good guidance to determine when a person has established a permanent gender or when one is old or mature enough to make a decision of this magnitude. There are examples of those who have decided and had surgery and later regretted it and examples of those who asked for surgery but later decided they no longer wanted surgery.

Currently, with the understanding of how complex gender development is, it is realized that it remains unpredictable in many settings. In the past, the approach to sex assignment may have been overly simplistic and too dogmatic. The challenge for the current approach is to consider the multiple facets involved and to arrive at an individualized care plan that is most likely to succeed. Male or female assignment should be approached from the perspective that it should be consistent with the most probable gender identity development and need not align with a potential surgical outcome or the capacity for traditional sexuality. An overarching goal of DSD management is to promote sex assignment that leads to positive self-esteem and sense of fulfillment.

PATHOGENIC CLASSIFICATION

The characteristics of the sex chromosomes, the gonads and/or the genitalia may be atypical or inconsistent for various reasons. In this section, the pathogenic mechanisms underlying the different conditions included under the definition of DSD will be discussed. For this, we shall refer to the embryologic and fetal processes described in the section "Normal fetal sex differentiation" that did not follow a typical development (Table 14–2).

Malformative DSD: Defects in the Morphogenesis of the Urogenital Primordia

Malformative, non-endocrine-related DSD, are due to defects in the early morphogenesis of the anlagen of the reproductive tract in individuals with normal gonadal differentiation. These disorders are suspected when the genital abnormalities are inconsistent with defective sex hormone secretion or action. For instance, isolated aphallia in a patient with a normally developed scrotum and descended testes is inconsistent with a defect in androgen secretion or action. The normal embryologic process underlying the formation of the genital primordia in early embryogenesis is impaired due to genetic or environmental causes. In these patients, serum levels of gonadal hormones are usually within the normal range.

A. Defective morphogenesis of the Müllerian or Wolffian ducts   Malformations of the vagina and uterus occur in females with hand-foot-genital syndrome due to *HOXA13* mutations and in patients with Mayer-Rokitansky-Küster-Hauser syndrome (MRKH, OMIM 277000), a heterogeneous disorder with abnormalities that may range from upper vaginal atresia to total Müllerian agenesis associated with urinary tract abnormalities, and even cervicothoracic somite dysplasia (known as MURCS association, OMIM 601076). Mutations in the *WNT4* gene have been identified in a small subset of MRKH patients, but do not seem to be the main etiology of MRKH syndrome. Vaginal atresia has been described in McKusick-Kaufman syndrome (OMIM 236700), probably caused by mutations in the *MKKS* gene.

Congenital bilateral absence of the vas deferens is found in 95% of males with cystic fibrosis (OMIM 277180), and accounts for 1% to 2% of cases of male infertility.

B. Defective morphogenesis of the urogenital sinus and the *primordia* of the external genital   Early morphogenetic defects of the cloaca or the genital primordia, occurring independently of hormone action, may be responsible for isolated aphallia or isolated hypospadias in patients with normal gonadal function (Figure 14–7).

TABLE 14–2 Pathogenic classification of disorders of sex development (DSD).

DSD Type	Pathogenic Mechanism	Examples	Implicated Gene	OMIM
Malformative DSD	Defective morphogenesis of the Müllerian ducts or Wolffian ducts	Hand-foot-genital syndrome	HOXA13	140000
		MRKH syndrome	WNT4	277000
		MURCS association		601076
		McKusick-Kaufman syndrome	MKKS	236700
		Absence of the vas deferens	CFTR	277180
	Defective morphogenesis of the urogenital sinus and the primordia of the external genitalia	Isolated aphallia	ROR2	268310
		Isolated hypospadias	GLI3	146510
			SPECC1L	145410
			PITX2	180500
Dysgenetic DSD	Complete or partial gonadal dysgenesis (46,XY)	Swyer syndrome/Partial testicular dysgenesis	SRY	480000
			MAP3K1	613762

Congenital isolated aphallia has been described in patients with Robinow syndrome (OMIM 268310). **Isolated hypospadias** may be present in the Pallister-Hall syndrome (OMIM 146510), in the X-linked Opitz G/BBB syndrome (OMIM 145410), and in Axenfeld-Rieger syndrome type 1 (OMIM 180500).

Dysgenetic DSD: Abnormal Gonadal Differentiation

Gonadal dysgenesis represents the most conspicuous form of **fetal-onset primary hypogonadism** in which all cell lineages—Leydig/theca, Sertoli/granulosa, and germ cells—are affected. Gonadal dysgenesis may be associated with a diversity of karyotypes: 46,XY, 46,XX, sex chromosome aneuploidies like 45,X and mosaicisms including XY, XX, and/or sex chromosome monosomies or polysomies (see Table 14–2). As suggested by Jost's experiments, defective ovarian development resulting in primary ovarian failure does not affect fetal genital development, so these conditions will not be dealt with in this chapter. Conversely, any disorder affecting the normal process and/or timing of testicular development results in dysgenetic DSD. The severity of the condition may range from complete to very mild, and it may affect the right and left gonads equally, or may be asymmetrical. Finally, a peculiar form of gonadal dysgenesis consists in the development of both ovarian and testicular tissue. The degree of Müllerian duct regression, Wolffian duct development and virilization of the external genitalia depends on the amount of functional testicular tissue secreting androgens (Leydig cells) and AMH (Sertoli cells).

Some sex chromosome aneuploidies, like those observed in Klinefelter syndrome (47,XXY) and Turner syndrome (45,X), will be briefly described by reason of their high prevalence even though they rarely present with malformations of the external or internal genitalia in the newborn.

A. Dysgenetic DSD in 46,XY patients   Gonadal dysgenesis may occur in individuals with a Y chromosome as a consequence of defects in the testis determination pathway explained earlier (Figure 14–8). *SRY* seems to be the only testis-specific gene of the whole pathway, and thus, its mutations result in isolated gonadal dysgenesis, whereas mutations in other genes also result in malformations of non-reproductive organs (see Table 14–2).

Clinical features   Dysgenesis may be **complete**, usually called "pure gonadal dysgenesis" or "agenesis," represented by a streak of fibrous tissue, or **partial**, resulting in a wide spectrum of "testicular dysgenesis." In the latter case, gonads are small, the albuginea is thin, and the seminiferous tubules usually have annular aspect and are separated by wide intertubular spaces. Germ cells are the most affected population, followed by Sertoli cells. These gonads are at a higher risk of development of gonadal tumors, like gonadoblastoma from childhood and seminoma usually after puberty.

In complete or pure gonadal dysgenesis, the fetus is completely feminized, owing to the lack of the two testicular hormones involved in fetal sex differentiation. The diagnosis is usually not suspected until the age of puberty, when these girls present with

46,XY dysgenetic DSD
female/ambiguous genitalia with uterus
low/undetectable T and AMH

absence of thelarche and menarche. Sex steroids are extremely low or undetectable, and AMH is undetectable. Gonadotropins are elevated in the newborn and infant, but may decrease to almost normal levels by the age of 6 to 9 years, and increase again to extremely high levels thereafter. In some cases, gonadoblastoma can secrete steroids and result in some breast development.

SRY mutations   (OMIM 480000) Inactivating mutations or deletions of SRY are present in approximately 15% of 46,XY females with complete gonadal dysgenesis (Swyer syndrome). Nonreproductive organs are not affected, so these individuals may seek medical attention only at the age of puberty for the lack of pubertal signs.

SOX9 haploinsufficiency   (OMIM 608160) It, due to heterozygous mutations or deletions, leads to gonadal dysgenesis and campomelic dysplasia (congenital bowing and angulation of long bones), which can also be associated with macrocephaly, micrognathia, low-set ears, flat nasal bridge, congenital dislocation of hips, hypoplastic scapula, small thoracic cage, and cardiac and renal defects. Most patients die during the neonatal period as the result of respiratory distress, although occasionally long-term survival has been reported.

SF1 mutations   Mutations of *NR5A1*, encoding SF1 (OMIM 612965), have been identified in a wide spectrum of disorders of gonadal and adrenal function. However, adrenal function may be normal, and patients present with ambiguous genitalia, regressed Müllerian ducts and biological signs of partial gonadal dysgenesis. Severe cases with complete sex reversal or the opposite, mild forms limited to hypospadias or male factor infertility, have also been described. In mild cases, patients may be transiently fertile and pass the mutation on to the next generation.

WT1 mutations and deletions   (OMIM 607102) In patients with chromosomal aberrations or mutations affecting WT1 expression, gonadal dysgenesis is usually associated with progressive renal disease such as diffuse mesangial sclerosis. Three distinct clinical presentations are recognized. (a) Denys-Drash syndrome is characterized by the clinical triad of gonadal dysgenesis, nephropathy (proteinuria at an early age, evolving into nephrotic syndrome and renal failure owing to focal or diffuse mesangial sclerosis), and Wilms tumor. (b) Frasier syndrome is defined by the coexistence of gonadal dysgenesis, progressive nephropathy and gonadoblastoma, caused by mutations in the donor splice site in intron 9 that results in the +KTS isoform of *WT1*, named after the insertion of the amino acids lysine (K), threonine (T), and serine (S) in the protein. (c) WAGR syndrome is characterized by the association of Wilms tumor, aniridia, genitourinary abnormalities (ambiguous genitalia and/or gonadoblastoma), and mental retardation.

Chromosome 9p deletions   (OMIM 602424) These deletions have been described in patients with gonadal dysgenesis of variable severity in association with mental retardation, microcephaly, facial malformations, short stature, and/or digestive or bronchial malformations. *DMRT1* and *DMRT2* have been identified in the critical 9p24 region.

ATRX mutations or deletions   (OMIM 301040) These mutations or deletions are characterized by the coexistence of α-thalassemia, mental retardation with facial dysmorphism (telecanthus, epicanthus, midface hypoplasia, and small triangular nose with flat nasal bridge and anteverted nares), and ambiguous genitalia.

DHH mutations   These mutations result in 46,XY partial or complete gonadal dysgenesis associated with minifascicular neuropathy (OMIM 605423).

MAP3K1 mutations   (OMIM 600982) These mutations resulting in increased binding to AXIN1 enhance β-catenin expression and reduce SOX9/FGF9 expression. This shifts the balance between the testicular and ovarian pathways, resulting gonadal dysgenesis in 46,XY patients.

DSS duplications   In 46,XY patients with a partial duplication of Xp21.3-p21.2, complete or partial gonadal dysgenesis results in female or ambiguous genitalia, respectively. The locus was named DSS, for dosage-sensitive sex-reversal (OMIM 300018), because a double active dose (ie, escaping X inactivation) is likely the underlying cause of gonadal dysgenesis. This is not observed in patients with a complete X polysomy (eg, Klinefelter syndrome) because one of the X chromosomes undergoes inactivation. The smallest duplication includes *NR0B1*, which encodes **DAX1**, suspected to be the underlying cause; however, other contiguous genes also exist in the duplicated region and their implication cannot be excluded.

Environmental causes may underlie the increase in the incidence of hypospadias, cryptorchidism, low sperm count, and testicular cancer. It has been proposed that these signs are all part of the same underlying entity, named testicular dysgenesis syndrome. Cryptorchidism and other genital malformations have been observed with increased incidence in areas of intensive agriculture and in children of workers exposed to pesticides with estrogen-like action.

B. Dysgenetic DSD in patients with mosaicisms carrying a Y chromosome, including ovotesticular DSD and asymmetric gonadal differentiation   In patients with mosaicisms including a Y chromosome, testicular tissue usually develops in a dysgenetic context. When an XX cell lineage is also present, ovarian tissue may develop as well (see Table 14–2).

Ovotesticular DSD is reserved for the existence of both testicular tissue, including seminiferous tubules, and ovarian tissue, where the presence of follicular structures containing oocytes is mandatory; the sole existence of an "ovarian-like" stroma is insufficient. Ovotesticular DSD may present with bilateral ovotestes—gonads carrying both testicular and ovarian tissue—one testis and one ovary or one ovotestis and one testis or ovary. The testicular tissue is usually dysgenetic, whereas the ovarian tissue is most frequently of normal appearance. The occurrence of a 46,XX/46,XY karyotype or mosaicisms carrying both an XX and an XY lineage explains the existence of ovarian and testicular tissues. Ovotesticular DSD can also present in 46,XX individuals (see later) but is extremely rare in 46,XY patients.

The overall incidence of ovotesticular DSD is reported at 3% to 10% of cases of DSD. Ovotesticular disorder shows the highest prevalence among South African blacks with the number of published cases being 17 per 100 million people, followed by Europe at 15.3, and Asia at 1.2 cases per 100 million. The age and clinical features at presentation vary according to the amount of functional testicular and ovarian tissues. Patients may be almost completely virilized, with mild signs of androgen insufficiency like hypospadias and undescended testes. Serum androgen and AMH levels are usually within the male range, and gonadotropins are not elevated. At the age of puberty, exaggerated follicular development may provoke abdominal pain; estradiol may increase and result in breast development, and in extreme cases cyclic urethral bleeding may indicate the existence of Müllerian remnants. When the ovarian tissue predominates, and there is scarce testicular tissue, the newborn is feminized, with clitoromegaly and labial fusion. Androgens and AMH are elevated for a girl but low for a boy, and gonadotropins are usually within the normal female range.

Müllerian derivatives are usually present in less virilized patients; however, ultrasonographic assessment may be deceiving as a diagnostic tool in these newborns or infants due to difficulties in imaging resolution. The risk of gonadal malignancy is low, roughly between 2% and 5%, although it may vary according to the presence or absence of a Y chromosome.

Asymmetric gonadal differentiation, also known as **mixed gonadal dysgenesis**, is characterized by the presence of a more or less dysgenetic testis on one side and a streak on the other. The most frequent karyotype is 45,X/46,XY, where the predominance of the 45,X on one side explains the development of the streak and the predominance of the 46,XY lineage underlies the development of the testis on the other. However, a 45,X/46,XY karyotype should not be equated to asymmetric gonadal differentiation (see Table 14–2). Indeed, this karyotype can be an incidental finding in a normally virilized boy, and also asymmetric gonadal differentiation may occur in a 46,XY patient. The diagnosis is histological.

Clinically, the patient usually presents with asymmetric development of the scrotum, with the testis usually being in scrotal position. The internal ducts, as expected, are typically male on the side of the testis and female (hemi-uterus and Fallopian tube) on the side of the streak. Some patients may also have features typical of Turner Syndrome. Serum levels of androgens and AMH correlate with the amount of functional testicular tissue. The risk of gonadal tumor development is high.

C. Dysgenetic DSD in 46,XX patients, including ovotesticular DSD and testicular DSD

Testicular tissue can differentiate in the gonadal primordium of 46,XX fetuses, either as the only gonadal tissue in a condition called **46,XX Testicular DSD**, or together with ovarian tissue in **46,XX Ovotesticular DSD**. Both DSD forms can be further categorized as SRY-positive and SRY-negative groups (see Table 14–2). The existence of the SRY sequence explains the development of testicular tissue. In most instances, the *SRY* gene has been translocated to an X chromosome, due to recombination between the pseudoautosomal regions of the X and Y chromosomes. However, translocation to an autosome can occur. One example was the incidental finding of small testes, azoospermia, and translocation of *SRY* onto the terminal end of chromosome 16q in a 61-year-old 46,XX man. Indeed, *SRY*-positive 46,XX individuals most frequently have testes with only mild dysgenetic features (eg, scarce germ cells) and present as 46,XX males. Conversely, *SRY*-negative patients most frequently have dysgenetic testes or ovotestes and are diagnosed at birth because of ambiguous genitalia.

Molecular etiologies have been identified for some *SRY*-negative 46,XX individuals with testicular or ovotesticular DSD. They are associated with overexpression of "pro-testicular" genes, like *SOX9*, *SOX10*, and *SOX3*, or defects of "pro-ovarian" genes, like *RSPO1* and *WNT4* (see Figure 14–3).

SOX9, SOX10, and SOX3
Overexpression due to duplications of the *SOX9* gene or of non-coding regulatory elements upstream of *SOX9* have been reported in SRY-negative sex-reversed 46,XX individuals. These regulatory elements appear to include 40.7-41.9 kb sequences located approximately 600 kb upstream of *SOX9*.

Another association reported in 46,XX *SRY*-negative male is overexpression of the *SOX10* gene, which is located at 22q13. Gain of function *SOX3* mutations, located at Xq27, has also been associated with XX male sex reversal.

RSPO1
Inactivating mutations in *RSPO1* gene, located at chromosome 1p34, are associated with 46,XX sex reversal. In addition, affected individuals have palmoplantar hyperkeratosis with squamous cell carcinoma of skin and lack Müllerian structures.

WNT4
In a consanguineous family, fetuses and infants homozygous for a loss-of-function mutation in *WNT4*, located at chromosome 1p36.2, showed sex reversal and aberrant development of kidneys, adrenal and lungs. This compilation of features has been labeled as SERKAL syndrome. Heterozygous mutations in *WNT4* have been detected in 46,XX women with primary amenorrhea associated with Müllerian duct abnormalities and androgen excess but no existence of testicular tissue.

Clinical features
Patients with testicular DSD that are completely virilized correspond to the original description of "XX male," as defined by de la Chapelle. That definition was an individual of *"a male phenotype, male psychosexual identification, testes without macroscopic or microscopic evidence of ovarian tissue, and absence of female genital organs."* Approximately 90% of these XX males are *SRY*-positive. In these typical cases, diagnosis is usually delayed until adult life when the patient seeks medical care for infertility. Less frequently, boys may be studied for short stature or small testes at the age of puberty. In fact, XX boys are shorter than age-matched XY pairs, in spite of similar circulating levels of hormone of the growth axis, including IGF1 and IGFBP3. The existence of Y-specific growth genes may be the explanation. Testicular volume does not differ from that of control boys during childhood. The underlying reason is that testicular volume depends mainly on Sertoli cells before puberty. Sertoli and Leydig cell function is normal in childhood and in the early stages of puberty, as revealed by normal AMH, inhibin B, testosterone and gonadotropin levels. Like in Klinefelter syndrome, testicular volume increases progressively to 4 mL, and even to 6 to 8 mL mainly due to Sertoli cell proliferation, but then remains smaller due to germ cell depletion. The existence of two X chromosome and the absence of a Y chromosome results in meiotic failure, azoospermia and low semen volume. Seminiferous tubule dysfunction in the advanced stages of puberty and adulthood is reflected in low inhibin B and increasing FSH, whereas a mild Leydig cell dysfunction may exist in some cases leading to low normal testosterone and increased LH. A typical feature is the elevation of estrogen levels responsible for gynecomastia.

Testicular DSD with more severe dysgenetic features, usually associated with SRY-negative cases, present with a similar clinical spectrum to that described earlier for dysgenetic DSD in 46,XY patients. Clinical features of patients with 46,XX ovotesticular

DSD is similar to that described in the previous section; indeed, the presentation does not depend on the karyotype.

D. Gonadal dysgenesis in sex chromosome aneuploidies

Atypical sex chromosome constitution includes polysomies of the X chromosome in males (Klinefelter syndrome) and females (Triple X syndrome) and monosomy of the sex chromosome pair (45,X), with their mosaic variants. Usually, these disorders do not represent a differential diagnosis in patients with ambiguous genitalia. In the case of X chromosome polysomies, the gonadal dysgenesis is mild and of late onset, thus explaining why fetal development is not affected. However, they will be briefly described here because they conform to the classification of Sex-Chromosome DSD.

Klinefelter syndrome is the most common cause of male hypogonadism, with a prevalence of approximately 1.5 in 1000 males. Its first description in 1942 was clinical, and included eunuchoidism, gynecomastia, small testes, azoospermia, and elevated FSH. In 1959, the condition was associated to a 47,XXY karyotype. Over the past decades, the clinical spectrum of the syndrome has expanded to include patients with pure cell lines or mosaicisms with two or more X chromosomes and a Y chromosome. However, some authors warn that patients with 48,XXYY, 48,XXXY, and 49,XXXXY polysomies present more complex physical, medical, and psychological phenotypes and should not be considered as Klinefelter syndrome even though they share features of primary hypogonadism.

Gonadal dysgenesis is extremely mild during fetal life, only characterized by a decrease in germ cell numbers, but with no impairment of Leydig and Sertoli cell function until midpuberty. Therefore, internal and external genitalia are normally virilized in Klinefelter patients. Generally, at birth, no particular stigmata occur in Klinefelter syndrome. During childhood, no specific signs or symptoms are noted, except for an increased risk of cryptorchidism, learning disabilities, or behavior disorders. Gonadotropins, testosterone, AMH and inhibin B are within the normal range. Klinefelter boys are long-legged, most probably as the result of an overdose of the X-chromosome *SHOX* gene.

Pubertal development is usually spontaneous, but characterized by the lack of progression of testicular size beyond 6 to 8 mL and the development of gynecomastia. Due to meiotic failure associated with X chromosome polysomy, the seminiferous tubules do not enlarge, but rather undergo fibrosis and hyalinization, which results in small firm testes and azoospermia. Nonetheless, microscopic areas of the testes may be normal, and spermatozoa can be recovered by testicular puncture. The marked reduction of tubular volume accounts for the apparent hyperplasia of the interstitial tissue. Leydig cell function becomes progressively deficient, resulting in a reduced testosterone production rate with compensatory LH hypersecretion. Because of the high LH levels, estradiol secretion is stimulated, with an increased estradiol/testosterone ratio, which probably accounts for the development of gynecomastia.

47,XYY males and 47,XXX females are almost as frequent as Klinefelter syndrome, with a rough prevalence of 1 in 1000 live births. However, they are rarely diagnosed because they are usually oligo- or asymptomatic. Gonadal development and function does not show major impairment, except for premature ovarian failure described in XXX women. Like Klinefelter patients, these children are long-legged and might show behavior disturbances.

Turner syndrome was also initially a clinical description of a distinct entity associating sexual infantilism, webbed neck, and cubitus valgus in females. Definitive evidence for a 45,X karyotype was provided several decades later. Turner syndrome occurs in approximately 1 in 2500 live female births, but the number of unborn affected fetuses is much larger, since spontaneous abortion occurs in approximately 98% of pregnancies.

The syndrome spans a wide spectrum of clinical presentations. The main features include gonadal dysgenesis; short stature; a short, thick, and webbed neck; hypertelorism; epicanthus and ptosis of the eyelids; low posterior hairline; congenital lymphedema; broad child-like chest; cubitus valgus and short fourth metacarpals; multiple pigmented nevi; intestinal telangiectasia; recurrent otitis media; and a tendency to keloid formation. There is an increased risk of celiac disease, autoimmune thyroiditis, diabetes mellitus, rheumatoid arthritis, inflammatory bowel disease, cardiovascular defects—especially coarctation of the aorta and nonstenotic bicuspid aorta—and kidney anomalies. Bone age is delayed, and bone mineral density may be affected. Newborns are smaller than average both in length and in weight. Usually, postnatal growth lies in the normal range for the first 2 to 3 years, but then decreases, and height deviates progressively from the norm.

Ovarian follicles undergo premature apoptosis resulting in fibrous streaks as typical histologic findings. Gonadotropin levels are high during infancy, but may decrease to normal levels between 6 and 9 years of age, whereas undetectable AMH throughout childhood is indicative of the absence of ovarian tissue and predicts the likely absence of spontaneous pubertal development.

Turner syndrome variants with partial gonadal dysgenesis may occur in patients with mosaicisms (eg, 45,X/46,XX or other variants) or in cases of partial X chromosome losses (eg, isochromosomes of the long or the short arms, ring chromosomes). The normal X chromosome comes from the mother in most patients with a 45,X karyotype, but only in about half of those with isochromosomes or ring chromosomes. Turner syndrome variants with partial gonadal dysgenesis may present with less anatomic stigmata and spontaneous pubertal onset; however, primary or secondary amenorrhea, due to premature ovarian failure is the rule. Detectable, or even normal serum AMH, indicating the existence of ovarian follicles, may be predictive of spontaneous puberty. In these patients, gonadotropin levels may be only moderately elevated. Spontaneous pregnancy has been described but is an exceptional event.

Non-dysgenetic DSD with Testicular Differentiation

Even if testicular differentiation occurs following the expected early pathway in the 46,XY fetus, insufficient virilization or feminization of the genitalia may result when one of the two hormone-driven processes of genital development—the androgen-dependent or the AMH-dependent—are defective (see Table 14–2). As can be
FIGURE 14–9 Pathogenesis of non-dysgenetic DSD in 46,XY patients. **(A)** Defects in the production of androgens. **(B)** Androgen insensitivity syndrome (AIS). 3β-HSD-2, 3β-hydroxysteroid dehydrogenase type 2; 17β-HSD-3, 17β-hydroxysteroid dehydrogenase type 3; AMH, Anti-Müllerian hormone; AMHR2, AMH receptor type 2; AR, Androgen receptor; DSD, Disorder of sex development; LH/CG-R, Luteinizing hormone/Chorionic gonadotropin receptor; P450c17, Cytochrome P450 17-hydroxylase/17,20-lyase; P450scc, Cytochrome P450 side-chain cleavage; POR, Cytochrome P450 oxidoreductase; StAR, Steroidogenic Acute Regulatory protein; T, Testosterone.

expected, the phenotypes are entirely opposed according to which is the deficient pathway: whereas defects in androgen synthesis or action drive to a female without a uterus (Figure 14–9), defects in the AMH pathway lead to a male with a uterus.

A. Disorders of androgen synthesis In contrast to testicular dysgenesis, characterized by an early onset fetal hypogonadism, with whole testicular dysfunction, defects of androgen synthesis represent one form of "dissociated" or "cell-specific" fetal onset primary hypogonadism, in which Leydig cells, but not Sertoli cells, are primarily affected.

Defects in LHCG Receptor **Leydig Cell Aplasia or Hypoplasia** (OMIM 238320) is a rare autosomal recessive form of DSD due to inactivating mutations of the LH/chorionic gonadotropin (CG) receptor (LH/CGR). Leydig cell differentiation and function are impaired or completely abolished, thus resulting in a partial or total deficiency of androgen production by the testes. The phenotypic spectrum ranges from female external

genitalia to mild undervirilization. The karyotype is 46,XY, serum AMH is within the normal male range, and Müllerian derivatives are absent. Basal and human (h) CG-stimulated testosterone is low or undetectable, plasma LH is elevated, and FSH is normal. Testes are inguinal or intraabdominal and contain seminiferous tubules with Sertoli and germ cells but no Leydig cells. Most of the mutations found in the *LH/CGR* gene, located at chromosome 2p16.3, are in exon 11, encoding the seven transmembrane domains.

Defect of Cholesterol Biosynthesis **Smith-Lemli-Opitz Syndrome** (SLOS, OMIM 270400) is due to a dehydrocholesterol reductase (DHCR) defect that blocks the last step of cholesterol synthesis. Since cholesterol is also required for signal transduction of SHH in the development of the nervous system, face and limbs, undervirilization in 46,XY patients with SLOS is associated with microcephaly, low set ears, short and broad nose, cleft palate, broad gingival ridges, growth retardation, toe syndactyly, pyloric stenosis and congenital heart defects.

communities to change their social sex from female to male. At variance with the other androgen synthesis defects, sperm production is feasible when testes are brought to scrotal position. Serum hormone levels are characterized by a high T/DHT ratio (usually above 18-20) after hCG stimulation. However, the diagnosis is more accurate when an elevated $5\beta/5\alpha$ urinary metabolite ratio is found. Over 50 different mutations have been recorded in *SRD5A2*, which maps to chromosome 2p23.1. The genotype/phenotype correlation is poor.

Recently defects in the **"backdoor" pathway** have been identified in patients with deficient DHT production. Inheritance is also autosomal recessive, due to mutations in *AKR1C2* (OMIM 600450), encoding 3α-HSD type 3, and in *AKR1C4* (OMIM 600451), encoding 3α-HSD type 1. Both genes map to mapping to 10p15.1 (see Figure 14–5).

Other Defects of Androgen Biosynthesis   Mutations in *MAMLD1* (OMIM 300120) are associated with hypospadias and other defects of genital virilization, probably due to defects in testosterone production. The precise mechanisms by which MAMLD1 regulates steroid synthesis needs to be fully clarified.

B. Disorders of androgen action: The Androgen Insensitivity Syndrome (AIS)
More than 800 mutations have been recorded in the *AR* gene, mapping to Xq12, in patients with AIS (http://androgendb.mcgill.ca).

Complete Androgen Insensitivity Syndrome (CAIS)   Mutations that completely abolish the AR activity by affecting the formation of the steroid receptor-coregulator complex, its nuclear transport, its binding to DNA, or its transcriptional activation ability, underlie CAIS. It is the most frequent cause of DSD in completely feminized 46,XY subjects. Patients appear as normal females at birth and come to medical attention at puberty because of primary amenorrhea, after normal breast development due to estrogen synthesis from testicular testosterone production. Alternatively, the diagnosis may be made in girls because of an inguinal hernia containing a palpable gonad that turns out to be a testis, or prenatally because of discordance between genotype and phenotype. Pubic and axillary hair is absent, the vagina is short with a blind ending, and the uterus is absent, as a consequence of normal AMH action in fetal life (see Figure 14–9). The testes appear quite normal at birth, but germ cell number rapidly declines; due to androgen insensitivity, meiosis cannot proceed and spermatozoa are not produced. The risk of germ cell malignant degeneration is low, but benign tumors such as Sertoli cell adenomas or hamartomas are more frequent. Laboratory findings are characterized in non-gonadectomized patients by serum testosterone in the male range with elevated gonadotropins at pubertal age, but they can be low in the neonatal period. AMH levels are in the male range.

Partial Androgen Insensitivity Syndrome (PAIS)   is defined by some degree of virilization, which may range from predominantly female genitalia to phenotypic males with hypospadias and micropenis. The diagnosis is difficult in the absence of family history and cannot easily be distinguished from that of DHT synthesis defects. Hormone levels are usually in the male range, including testosterone, gonadotropins, and AMH, which distinguishes PAIS from gonadal dysgenesis in 46,XY DSD. Response to hCG stimulation is good in terms of testosterone production; this feature helps eliminate androgen synthetic defects from the differential diagnosis. At puberty, scanty pubic and axillary hair develop; gynecomastia is frequent; testosterone increases; and AMH may decrease in correlation with the degree of retained androgen action. There is poor genotype/phenotype correlation, and the same mutation can result in widely different phenotypes, even within the same family.

C. Disorders of AMH synthesis or action
The **persistent Müllerian duct syndrome (PMDS)** (OMIM 261550) is a rare, autosomal recessive form of DSD characterized by persistence of the uterus and Fallopian tubes in a boy otherwise normally virilized (Figure 14–10). The existence of other signs of undervirilization, like hypospadias, should be ruled out in order to distinguish this condition from gonadal dysgenesis. The presence of Müllerian derivatives is usually discovered at surgery for cryptorchidism or inguinal hernia. Two anatomical forms of PMDS have been described: in 1/5 of cases, the patient presents with bilateral cryptorchidism, and both testes are embedded in the broad ligament in an "ovarian" position, whereas in the more frequent presentation one testis has descended into the scrotum, dragging the Fallopian tube and the contralateral testis. Mutations in the AMH or the AMH receptor type 2 (AMHR2) receptor genes are found in approximately 85% of PMDS patients. Transmission is autosomal recessive. Idiopathic PMDS, not due to gene mutations, is frequently associated with associated abnormalities. Serum testosterone and gonadotropins are in the male range. AMH is undetectable in patients with *AMH* mutations, but within the male range in patients with *AMHR2* mutations. The risk of testicular tumors is not higher than in other patients with longstanding cryptorchidism. The main goal of treatment is to place the testes in the scrotum when necessary. If the uterus and Fallopian tubes limit mobility, proximal salpingectomy and excision of the uterine fundus may be performed after meticulous dissection of the vasa deferentia, leaving the cervix and pedicles of the myometrium in place to preserve vascularization.

Non-dysgenetic DSD with Ovarian Differentiation

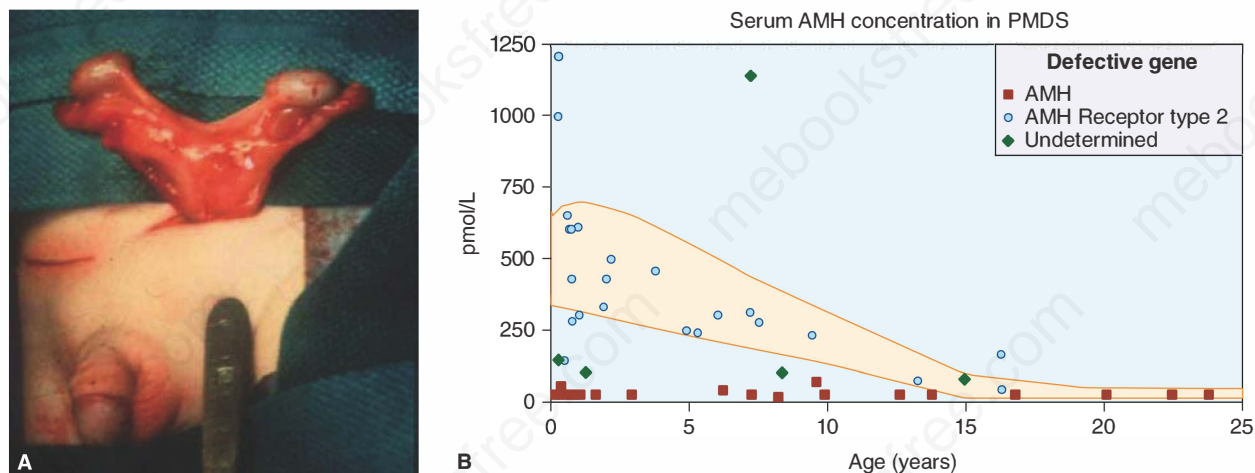
Exposure to elevated androgen levels during intrauterine life underlies virilization of the 46,XX fetuses in whom ovarian differentiation occurred (see Table 14–1). Individuals with 46,XX DSD and bilateral ovaries come to medical attention because of genital ambiguity at birth or postnatal virilization during childhood or at the time of expected puberty. As noted previously, the external genital development of 46,XY and 46,XX fetuses is similar until 6 to 7 weeks of gestation. The typical female fetus does not secrete androgens during gestation. Exposure of female fetuses to androgens during gestation alters the developmental


FIGURE 14–10 **(A)** Persistent Müllerian duct syndrome (PMDS) characterized by the persistence of uterus and Fallopian tubes in an otherwise normally virilized boy. **(B)** Patients with undetectable AMH have AMH gene mutations (red); those with normal or high AMH usually have AMH receptor type 2 mutations (blue), but in a few cases no mutation has been detected (undetermined, green). (Reproduced with permission from Jameson JL, De Groot LJ, de Kretser D, et al. *Endocrinology: Adult and Pediatric*, 7th ed. Philadelphia, PA: Elsevier Saunders; 2015.)

programming and can lead to masculinization of the external genitalia. However, since AMH is not produced during the period of Müllerian duct sensitivity, the uterus and Fallopian tubes develop. Excessive androgen sources can be fetal (eg, the virilizing form of CAH, which is the most common cause of genital ambiguity in a 46,XX infant), but also maternal (eg, steroid secreting tumors) or placental (eg, aromatase deficiency).

A. Disorders of adrenal steroidogenesis   Inheritance of these disorders of steroidogenesis is autosomal recessive. In **CAH**, cortisol biosynthesis is impaired due to mutations in genes encoding specific steroidogenic enzymes. Insufficient cortisol production leads to loss of negative feedback inhibition at the pituitary, increased ACTH secretion, and buildup of adrenal steroid hormones proximal to the deficient enzyme. Clinical features and laboratory data vary depending on which enzyme gene is involved. The most common type of CAH is 21-hydroxylase deficiency (21-OHD, OMIM 613815). The specific mutations and residual enzyme activity influence the extent of glucocorticoid and mineralocorticoid hormone deficiencies.

Accumulation of steroid hormone intermediates such as 17-hydroxyprogesterone (17-OHP) can drive adrenal steroid hormone metabolism toward the so-called alternate or "backdoor" steroid pathway (see Figure 14–5). In this pathway, excessive 17-OHP undergoes 5α and 3α-reduction to 5α-pregnane-3α,17α-diol-20-one (pdiol), ultimately generating androstanediol which is the substrate for 3α-oxidation and subsequent conversion to DHT bypassing testosterone synthesis. Mutations in 21-hydroxylase (*CYP21A2*), 11β-hydroxylase (*CYP11B1*), or P450-oxidoreductase (*POR*) increase flux through this pathway leading to elevated DHT concentrations and prenatal virilization of 46,XX fetuses. The relevance of other intra-adrenal C19 steroidogenic pathways is becoming apparent. For example, androstenedione

can be converted to 11β-hydroxy-androstenedione, which can be converted to more potent C19 androgens.

Determination of hormone concentrations is essential for the diagnosis of disorders affecting steroidogenesis. Traditionally, hormone concentrations have been measured using radioimmunoassays. However, radioimmunoassays can be problematic due to cross-reactivity with similar steroid compounds and limited sensitivity. The newer commercial direct platform immunoassays have introduced additional disadvantages including greater interference with steroid binding proteins and increased non-specific competition with the antibodies used in the assay. The use of liquid chromatography-tandem mass spectrometry (LC-MS/MS) enables simultaneous measurement of multiple steroids and can improve diagnostic testing for disorders of steroidogenesis. Urinary GC-MS avoids the trauma of collecting blood. Another advantage offered by urinary GC-MS is urinary steroid profiling which can lead to better characterization of disorders of steroidogenesis.

21-Hydroxylase Deficiency (21-OHD)   The most common type of CAH (accounting for 90%-95% of cases) is 21-OHD, due to mutations in the 21-hydroxylase (*CYP21A2*) gene located at chromosome 6p21.3 in the HLA class III region. This enzyme converts 17-OHP to 11-deoxycortisol (S) (see Figure 14–5). The reported incidence of 21-OHD ranges from 1 in 9000 to 1 in 15,000 for the **classic form** and 1 in 1000 for the **nonclassic form (NCAH)**. The classic form is categorized into **salt-losing** and **non-salting losing** forms. Estimates of *in vitro* 21-hydroxylase activity are less than 1% for mutations associated with salt-losing CAH, 2% to 10% for simple virilizing CAH, and 30% to 50% for NCAH. This classification system is somewhat contrived because disease severity is better depicted as a continuum based on residual enzyme activity. Most affected individuals are compound heterozygotes with different mutations on each allele. An affected

individual's phenotype is usually defined by their milder mutation. The frequency of CAH varies among ethnic/racial backgrounds.

The spectrum of impaired 21-hydroxylase activity ranges from complete glucocorticoid and mineralocorticoid deficiencies to mild deficiencies manifested principally by compensatory excessive adrenal androgen secretion. Ages at presentation range from infancy to adulthood depending on the clinical manifestations and severity of the mutations. Affected 46,XX infants with severe complete loss of function mutations typically present in the neonatal period with genital ambiguity. They can develop dehydration, hypoglycemia, hyponatremia, and hyperkalemia when the diagnosis is delayed or missed. If not identified by a newborn screening program, infant boys typically present at 2 to 3 weeks of age with failure to thrive, poor feeding, lethargy, dehydration, hypotension, hyponatremia, hyperkalemia, and hyperpigmentation of the scrotum. Missed or delayed diagnosis can lead to a fatal outcome. In addition to being life threatening, salt-losing crises have been associated with reduced cognitive function. In the absence of prenatal cortisol exposure, adrenomedullary development is aberrant in classic CAH and is often associated with epinephrine deficiency and hypoglycemia.

For affected 46,XX fetuses, the spectrum of prenatal external genital virilization ranges from clitoromegaly to perineal hypospadias to complete fusion of urethral and labioscrotal folds giving rise to a phallus with chordee and urethral meatus at the tip of phallus and a fused empty scrotum. External genital virilization may be so extensive that affected female infants appear to be males with bilateral undescended testes (Figures 14–11 and 14–12). Even in the absence of overt salt loss due to mineralocorticoid deficiency, there may be sufficient prenatal androgen exposure to virilize the external genitalia. Typically, the urethra and vagina open into the urogenital sinus with a single perineal orifice. For some girls, the urogenital confluence is high in the pelvis with the vagina opening into the urethra just below the bladder. Despite the excessive prenatal androgen exposure, ovarian position and uterine development are normal in affected females. Thus, physical examination showing bilateral undescended testes with a phallus and perineoscrotal hypospadias should prompt an evaluation for a virilizing CAH.

CAH due to 21-OHD is an autosomal recessive disorder characterized by *CYP21A2* mutations on both the maternal and paternal alleles. The gene is located within a complex genomic region at chromosome 6p21.3 and is approximately 30 kb from a highly homologous pseudogene, *CYP21A1P*. These genes are arranged in tandem repeats with the C4A and C4B genes and lie in close proximity to the tenascin (TNX) and serine threonine nuclear protein kinase (RP) genes. The tenascin-XB (*TNXB*) gene codes for an extracellular matrix protein. These four genes, *RP*, *C4*, *CYP21*, and *TNX*, form a unit known as RCCX. Most alleles carry two RCCX units in which one has *CYP21A2* and the other has *CYP21A1P*.

To date, over 150 *CYP21A2* mutations have been reported (www.cypalleles.ki.se and www.hgmd.cf.ac.uk). Most affected individuals are compound heterozygotes. Some alleles carry multiple mutations. In general, phenotype correlates with genotype such that the phenotype reflects the less severe mutation and residual 21-hydroxylase enzyme activity. Nevertheless, a small number of mutations account for the majority of affected alleles. The *de novo* mutation rate is reported to be less than 1%. The most frequently identified mutations represent gene conversion events in which *CYP21A2* has acquired deleterious *CYP21A1P* sequences. Misalignment during meiosis followed by genetic recombination can cause deletions and duplications giving rise to duplications or deletions of the RCCX unit. Haplotypes with 3 or 4 RCCX units have been described. Another example of misalignment is the *CYP21A1P/CYP21A2* chimera. Rarely, uniparental disomy can lead to CAH.

Following a pilot newborn screening program in 1977, most countries have implemented newborn screening programs using filter-paper whole blood 17-OHP levels. The blood sample should be collected after 48 hours of life. Automated time-resolved-dissociation-enhanced lanthanide fluoroimmunoassay (DELFIA) is often used for 17-OHP determinations. The goal of newborn screening has been to identify infants with salt-losing CAH and prevent mis-identification of affected females. Newborn screening

programs have decreased the morbidity and mortality associated with acute adrenal insufficiency. However, preterm and stressed infants can have elevated screening values leading to false positive results. In addition, cross-reactivity with sulfated steroids and 16α-hydroxyprogesterone contributes to false positive results. Decreased 11β-hydroxylase activity in the neonate may be another factor contributing to false positive testing. To avoid excessive recalls for false positive tests, birthweight and gestational age cut-points have been developed. False negative 17-OHP results leading to delayed diagnoses have been reported for both newborn girls and boys.

Discriminating individuals with NCAH from carriers may be challenging. The complexity of the *CYP21A2* locus complicates molecular diagnosis and precludes its use as the first line diagnostic test. At the present time, functional testing such as hormone determinations and/or ACTH stimulation tests may be necessary to confirm decreased 21-hydroxylase activity. Multiple genetic testing strategies such as PCR-based mutation detection methods, sequencing, and multiplex ligation-dependent probe amplification may be needed to accurately ascertain the mutations in an affected individual. Genotyping of parents to assign the affected maternal and paternal mutations and confirm that mutations are on opposite alleles may be essential. Genetic analysis can be a useful adjunct to newborn screening. It is important to acknowledge that this is a complex genetic locus, multiple mutations can occur

on a single allele and that different *CYP21A2* mutations can occur in one family.

Postnatal virilization continues in individuals with simple virilizing CAH who were not identified by newborn screening. Affected children present with premature development of pubic hair, tall stature, accelerated linear growth velocity, acne, and advanced skeletal maturation. Affected prepubertal boys may present with premature pubic hair, phallic enlargement, and bilateral small testes. The missense mutation, I172N, is associated with simple virilizing CAH.

NCAH is the most common form with increased prevalence in Ashkenazi Jews and Hispanics. Individuals with NCAH secrete sufficient cortisol and aldosterone to prevent symptoms of glucocorticoid and mineralocorticoid deficiency in association with excessive C19 adrenal androgen secretion. Clinical features range from premature pubarche to an asymptomatic state. The hyperandrogenic symptoms lead to an ascertainment bias such that more affected women are identified. Premature pubarche is the most common presenting feature in prepubertal children. Hirsutism is the most common presenting feature in post-pubertal women. The clinical features of NCAH and PCOS overlap. These features include hirsutism, irregular menses, chronic anovulation, infertility, acne, and polycystic ovary morphology. Women with NCAH have normal female external genitalia at birth, but may develop clitoromegaly. Affected men are generally identified through family studies or by infertility due to oligospermia.

Individuals with NCAH can carry mutations typically associated with NCAH on both alleles or a mutation associated with NCAH on one allele and a more severe mutation on the other allele. The frequency of genotype with nonclassic mutations on both alleles has been reported to range from 25% to 50%. Mutations associated with NCAH include V281L, P453S, and R339H. The P30L mutation is often detected in patients with NCAH, but is typically associated with more severe androgen excess.

Diagnosis   An elevated 17-OHP concentration is the hallmark of 21-OHD. For newborns, random 17-OHP concentrations are greater than 5000 ng/dL (150 nmol/L) after 48 hours of life. Since CAH is an autosomal recessive disorder, confirmatory 17-OHP concentrations need to be associated with mutations on both alleles. Beyond infancy, the blood sample for 17-OHP is best obtained in the early morning because of the circadian rhythm of ACTH and cortisol. In menstruating women, the sample should be obtained in the follicular phase. Morning 17-OHP concentrations greater than 200 ng/dL are not diagnostic, but warrant further evaluation.

When random 17-OHP concentrations are equivocal, an ACTH stimulation test should be performed. Following collection of a baseline blood sample, synthetic ACTH, 250 μg is administered. A second blood sample is obtained at 30 or 60 minutes for progesterone, 17-hydroxypregnenolone, 17-OHP, DHEA, androstenedione, and cortisol determinations. Since 17-OHP concentrations may be elevated in other disorders of steroidogenesis such as 11β-hydroxylase deficiency, determinations of deoxycorticosterone and 11-deoxycortisol concentrations may be warranted. In general, ACTH-stimulated 17-OHP concentrations

greater than 1500 ng/dL (45 nmol/L) are associated with *CYP21A2* mutations on both alleles. However, there are reports of individuals with diagnostic genotypes and ACTH-stimulated 17-OHP values between 1000 and 1400 ng/dL (30-45 nmol/L). Individuals with CAH have elevated 21-deoxycortisol concentrations. Indeed, screening by 21-deoxycortisol would improve the diagnostic evaluation for 21-OHD, but commercial availability of this hormone assay is limited. Steroid quantification, by LC-MS/MS has demonstrated elevated 17-OHP, 21-deoxycortisol, 16α-hydroxyprogesterone, and progesterone; these steroids comprise sensitive and specific biomarkers to accurately identify patients with CAH due to 21-OHD.

Mineralocorticoid deficiency is characterized by hyponatremia, hyperkalemia, and elevated plasma renin activity (PRA). In the affected newborn, the low dietary salt intake unmasks the mineralocorticoid deficiency within 7 to 14 days of life. Infants also tend to have a relative decreased sensitivity to aldosterone. Hyperkalemia typically occurs first with subsequent fall in sodium and bicarbonate. Individuals with simple virilizing CAH may have elevated PRA without overt salt loss. Individuals with NCAH generally have normal electrolytes and PRA values.

Additional helpful studies in the infant with ambiguous genitalia include karyotype and pelvic ultrasound to assess for Müllerian-duct derived structures. The apparent non-visualization of ovaries on ultrasound can be misleading because ovaries may be too small to be reliably detected by ultrasound.

Outcomes   The tremendous improvement in treatment means that almost all children with CAH thrive and are transitioned to adult care. To date, however, outcome reports are disappointing because many affected adults are lost to medical follow-up. In general, adults with CAH are shorter than expected for mid-parental height predictions. Both women and men can experience infertility. Increased incidences of obesity, dyslipidemia, osteoporosis, cardiovascular risk factors, and insulin resistance have been reported. Although various aspects of QoL are negatively impacted, some individuals appear to do relatively well. A study from a single medical center reported that adverse health outcomes, with the exception of testicular adrenal rest tumors (TARTs), were largely related to long-term disease control.

Factors contributing to the lack of fecundity include vaginal stenosis with dyspareunia, impaired sensation, poor self-esteem, and disinterest in having children. Reproductive outcome for women with CAH can be greatly improved by adequate suppression of progesterone and 17-OHP to promote ovulation and implantation of the fertilized ovum; this may require optimizing both glucocorticoid and mineralocorticoid therapies. In one series, women with CAH reported later sexual debut, fewer pregnancies and children, and increased incidence of homosexuality, which were related to type of surgical correction and the severity of their mutations. Another series utilizing a questionnaire provides more optimistic data regarding outcome for adult women with virilizing CAH. The consequences of prenatal androgen exposure on the developing female brain are being explored.

In addition to gonadal adrenal rest tumors, the elevated adrenal C19 steroid secretion can suppress gonadotropin secretion

resulting in hypogonadotropic hypogonadism and subsequent oligospermia. Gonadal adrenal rest tumors, predominantly TARTs occur in up to half of men. These tumors arise from adrenal cells that descend with the testes during testicular development. TARTs are not malignant, but can compress the rete testis and seminiferous tubules culminating in testicular atrophy and obstructive azoospermia. Ultrasound and MRI are helpful to detect TARTs less than 2 cm because small lesions are generally not palpable. TARTs may be present in childhood and adolescence and have rarely been described in men with nonclassic CAH. Although TARTs have been attributed to poor adherence, pathogenesis of TARTS may be more complicated. Ovarian adrenal rest tumors (OARTs) have been infrequently reported in affected women.

11β-Hydroxylase Deficiency

CAH due to 11β-hydroxylase deficiency (OMIM 202010) is characterized by glucocorticoid deficiency, excessive androgen secretion, and hypertension. This form of CAH is associated with mutations in the 11β-hydroxylase (*CYP11B1*) gene. The *CYP11B1* gene is located at chromosome 8q22 in close proximity to a highly homologous gene *CYP11B2*, which codes for aldosterone synthase. *CYP11B1* is primarily expressed in the zona fasciculata, whereas *CYP11B2* is expressed primarily in the zona glomerulosa.

This form of CAH accounts for 3% to 8% of cases with incidence of 1 in 100,000 in European populations. The highest incidence is reported among Moroccan Jews. The enzyme converts 11-deoxycortisol to cortisol primarily in the zona fasciculata (see Figure 14–5). Loss of function mutations leads to the accumulation of 11-deoxycortisol (compound S) and deoxycorticosterone (DOC). Low renin hypokalemic hypertension is an inconsistent finding. Individuals with 11β-hydroxylase deficiency present similar clinical features as patients with 21-OHD. Affected females may present with ambiguous genitalia. Similar to 21-OHD, a continuum of clinical manifestations occurs, including milder or nonclassic forms. Curiously, infants may experience transient salt loss, presumably due to limited salt intake, and transient mineralocorticoid resistance in the newborn period or during illnesses, while on hormone replacement therapy.

Typical laboratory findings are elevated compound S and DOC concentrations. Serum concentrations of 17-OHP, androstenedione, and testosterone may be mildly elevated. ACTH stimulation testing, which includes measurement of compound S and DOC, may be helpful to assess for this disorder. PRA concentrations are low or suppressed. Using urinary GC-MS, an increase of tetrahydro-11-deoxycortisol (THS) and the precursor to metabolite ratio {THS to [tetrahydrocortisone + tetrahydrocortisol (THF)+5αTHF)]} can be used as disease-specific diagnostic markers.

3β-Hydroxysteroid Dehydrogenase Deficiency

CAH due to 3β-hydroxysteroid dehydrogenase type 2 deficiency (OMIM 201810) is associated with mutations in the *HSD3B2* gene. This gene is mapped to chromosome 1p13.1 where it is located in close proximity to the highly homologous *HSD3B1* gene. The *HSD3B1* gene is expressed primarily in skin, placenta, prostate, and other peripheral tissues. The *HSD3B2* gene is primarily expressed in the adrenal cortex and gonads. Mutations in *HSD3B2*, but not *HSD3B1*, have been detected in patients with 3β-hydroxysteroid dehydrogenase deficiency.

The NAD$^+$-dependent enzyme 3β-hydroxysteroid dehydrogenase/Δ^5-Δ^4-isomerase is a bifunctional enzyme that catalyzes the conversion of the Δ^5 steroid precursors, pregnenolone, 17-hydroxypregnenolone, and DHEA into the respective Δ^4-ketosteroids, progesterone, 17-OHP, and androstenedione (see Figure 14–5). It is, therefore, essential for biosynthesis of mineralocorticoids, glucocorticoids, and sex steroids. Mutations are associated with virilization of the external genitalia of 46,XX fetuses due to increased DHEA synthesis. Affected 46,XY fetuses may have undervirilization of the external genitalia secondary to testosterone deficiency. Despite decreased testosterone synthesis, affected 46,XY fetuses usually have intact Wolffian duct structures (including vas deferens).

Infants with complete loss of function mutations may present in the neonatal period with acute adrenal insufficiency. Typical presentations for the non-salt-losing forms include premature pubarche and perineal hypospadias in affected XY infants. Confirmatory laboratory findings include elevated pregnenolone, 17-hydroxypregnenolone, and DHEA concentrations with elevated ratios of Δ^5 to Δ^4 steroids. Because enzymatic activity of the type 1 isozyme is unimpaired, elevated 17-OHP and androstenedione concentrations may be found.

Treatment

The goals of treatment for the CAHs include provision of adequate glucocorticoid and mineralocorticoid replacement to achieve normalization of adrenal C19 steroids. Finding the balance between overtreatment and undertreatment is often challenging. Titration of hydrocortisone dosing needs to be individualized based on clinical features, linear growth velocity, skeletal maturation, and steroid hormone concentrations in plasma and urine. The dose of mineralocorticoid should be adjusted so that the electrolytes and blood pressure, as well as the PRA, are in the normal range. An *in vitro* study confirmed the clinical observation that 17-OHP and progesterone have anti-mineralocorticoid effects; these steroid hormones interfere with aldosterone-mediated mineralocorticoid receptor transactivation.

Most of this section refers to 21-OHD because it is the most common form of CAH. Treatment of patients with salt-losing adrenal hyperplasia may be separated into chronic and acute phases. The neonate identified by newborn screening should be started on glucocorticoid and mineralocorticoid replacement therapy once confirmatory blood samples have been obtained. Typical hydrocortisone dosage is 25 to 30 mg/m^2/d in the newborn period that is subsequently weaned to approximately 8 to 15 mg/m^2/d. For infants and children diagnosed with simple virilizing CAH, typical hydrocortisone dosage is also approximately 8 to 15 mg/m^2/d. For most patients, the hydrocortisone dose is divided into three doses administered every 8 hours. Reverse circadian dosing with the highest hydrocortisone dose in the evening may benefit some individuals.

Oral fludrocortisone is utilized for mineralocorticoid replacement at 0.05 to 0.3 mg in the newborn. Fludrocortisone is also weaned to doses of approximately 0.05 to 0.2 mg daily. Some infants require added dietary salt (1-3 g daily) using a salt solution prepared by a pharmacist to avoid dose errors.

Treatment of individuals affected with NCAH is somewhat controversial. When diagnosed in children with advanced skeletal maturation, daily glucocorticoid treatment is generally prescribed to decrease adrenal C19 steroids and slow the rate of bone maturation. Since the major symptoms in adolescent girls include irregular menses, hirsutism, and acne, the use of oral contraceptives may be sufficient to control the symptoms. Most adolescent men are asymptomatic and identified through family screening studies. If the ACTH-stimulated peak cortisol response is less than 500 mmol/L (18 µg/dL), consideration should be given to stress dosing during acute illnesses. Women with NCAH who are actively trying to conceive may benefit from glucocorticoid treatment to promote ovulation, implantation, and decrease risk for miscarriages.

In acute adrenal crises, patients can present with hyponatremia, hyperkalemia, hypovolemia, hypoglycemia, acidosis, hypotension, and shock. Normal saline (10 cc/kg in two consecutive boluses) should be administered to patients. Glucose should be administered if the patient is hypoglycemic. Subsequent replacement of glucose, fluid, and electrolytes is calculated on the basis of deficits and standard maintenance requirements. Hydrocortisone sodium succinate (50 mg/m^2) should be given as a bolus followed by stress dosing.

Patients with physiologic stress such as fever, severe vomiting and diarrhea, severe injury, or elective surgery require additional glucocorticoid treatment. If the patient can take oral hydrocortisone, the usual dose is generally tripled during the acute illness, decreased to double dosage as the patient recovers, and eventually to their usual replacement dose. If unable to tolerate oral medications, intramuscular hydrocortisone sodium succinate should be administered as follows: 25 mg, for infants less than 12 months, 50 mg for children ages 1 to 4 years, and 100 mg for all over age 4 years. Parenteral hydrocortisone, at dose of approximately 30 to 50 mg/m^2/d, should be given every 6 hours if the patient is still unable to tolerate oral medications. In this situation, the patient may benefit from evaluation by a physician and intravenous fluids. All caregivers should be prepared to administer intramuscular hydrocortisone injections in emergencies. All patients should wear medical alert notification badges.

Prenatal dexamethasone therapy of pregnant women who are at risk of carrying a female fetus with atypical genitalia has been utilized to decrease the virilization of the external genitalia of affected female infants. To be effective, this therapy must be initiated at 6 to 7 weeks of gestation. However, human outcome studies have reported that prenatal dexamethasone is associated with orofacial clefts, decreased birth weight, poorer verbal working memory, and poorer self-perception of scholastic and social competence. Using an animal model, prenatal dexamethasone exposure has been shown to alter the neurodevelopmental program of CNS development. At the present time, long-term outcome studies for prenatal dexamethasone treatment are not available. Another option for couples at risk for a child with CAH is preimplantation genetic testing. Non-invasive early prenatal diagnosis using cell-free fetal DNA found in the maternal circulation has been reported.

Girls with genital ambiguity due to CAH may benefit from feminizing genitoplasty. The aims of surgery and the potential risks and benefits need to be thoroughly reviewed with the parents. Most importantly, each patient deserves individualized management. The goals of this surgery include an adequate vaginal introitus, separation of urethra from the vaginal introitus, and minimizing erectile tissue while simultaneously preserving glanular innervation and blood supply.

B. Glucocorticoid receptor gene mutation Primary generalized glucocorticoid resistance is characterized by target tissue insensitivity to glucocorticoids. This disorder can be associated with heterozygous loss of function mutations in the glucocorticoid receptor (*NR3C1*) gene (OMIM 615962). Some mutations act through a dominant negative mechanism to interfere with glucocorticoid signal transduction. Glucocorticoid resistance is characterized by high circulating cortisol concentrations without signs and symptoms of Cushing syndrome. The resistance of the hypothalamic-pituitary axis to suppression leads to increased ACTH secretion with increased secretion of adrenal hormones with salt-retaining and androgenic activities. The normal circadian rhythm is maintained, albeit with a higher set-point for ACTH and cortisol concentrations. The spectrum of clinical manifestations ranges from virilization of female fetuses, premature pubarche, hypertension, hypokalemia, and, in females, hirsutism and infertility. Tests useful to confirm the diagnosis include 24-hour urinary-free cortisol determinations and genetic analysis of the *NR3C1* gene. Treatment involves the judicious use of a synthetic glucocorticoid (eg, dexamethasone) to decrease the excessive ACTH, mineralocorticoid, and adrenal androgen concentrations.

C. Placental aromatase deficiency Aromatase is a cytochrome P450 enzyme that converts C19 androgens to C18 estrogens. The aromatase (*CYP19A1*) gene is located at chromosome 15q21.2. Aromatase is an essential enzyme involved in estrogen biosynthesis in adolescents and adults. Expressed in the human placenta, aromatase converts fetal androgens to estrogens to protect the mother from the potential virilizing effects of fetal androgens.

Placental aromatase deficiency is a rare autosomal recessive disorder due to inactivating *CYP19A1* mutations (OMIM 613546). Decreased aromatase activity impairs conversion of androgens to estrogens resulting in increased androgen concentrations. At birth, affected 46,XX infants are virilized with varying degrees of labioscrotal fusion, clitoromegaly, and perineal scrotal hypospadias (see Figure 14–11). Affected 46,XX individuals generally manifest delayed puberty characterized by minimal or absent breast development, primary amenorrhea, hypergonadotropic hypogonadism, multicystic ovaries, and decreased bone mineral density. As would be anticipated, affected 46,XY infants typically have normal internal and external genital development and present after puberty with tall stature, delayed skeletal maturation, decreased bone

mineral density, and infertility. Phenotypic heterogeneity has been described. Treatment involves appropriate estrogen replacement therapy.

During pregnancies with affected fetuses, maternal testosterone, DHT, and androstenedione concentrations are elevated whereas estradiol, estrone, and estriol concentrations are low. These hormone alterations lead to progressive maternal virilization characterized by hirsutism, clitoral hypertrophy, acne, and frontal balding during pregnancy. In the postpartum period, some clinical features of androgen excess regress, and the elevated androgen concentrations return to normal levels. Nonetheless, aromatase deficiency in the infant can occur in the absence of maternal virilization.

D. P450 oxidoreductase deficiency

The clinical features of P450 oxidoreductase deficiency include genital ambiguity, skeletal anomalies, and impaired steroidogenesis. This disorder is associated with mutations in the cytochrome P450 oxidoreductase (*POR*) gene, which is mapped to chromosome 7q11-12. The protein encoded by *POR* functions as a mandatory electron donor from reduced nicotinamide adenine dinucleotide phosphate to microsomal steroidogenic and hepatic P450 enzymes and plays a major role in glucocorticoid and sex steroid synthesis. This protein interacts with other steroidogenic enzymes including 21-hydroxylase, 17α-hydroxylase/17,20-lyase, and aromatase (see Figure 14–5). The skeletal manifestations have been attributed to disrupted interactions with enzymes involved in sterol, for example, 4α-lanosterol demethylase (CYP51A1) and squalene epoxidase, and retinoic acid metabolism, for example, CYP26 isozymes.

At birth, genital ambiguity can be noted in both male and female infants. Insufficient testosterone synthesis contributes to the undervirilization of male infants. Virilization of female fetuses is attributed to shunting of the excessive 17-OHP to the "backdoor pathway" resulting in increased DHT and other androgens. Phenotypic heterogeneity has been reported with varying severity of genital ambiguity, adrenal insufficiency, and skeletal anomalies. Hypertension associated with increased corticosterone metabolites can occur. Differing from the virilizing CAHs, progressive postnatal virilization does not occur. Affected females may have delayed puberty and ovarian cysts. Typical laboratory findings include elevated basal and ACTH-stimulated 17-OHP, low sex steroids, and normal mineralocorticoid concentrations. Urinary GC/MS steroid profiles indicate decreased 21-hydroxylase and decreased 17α-hydroxylase/17,20-lyase activities. Some affected individuals may benefit from daily glucocorticoid replacement therapy. Others may need glucocorticoid treatment only for stress dosing.

During pregnancy, some mothers developed signs associated with androgen excess such as acne, hirsutism, and clitoromegaly. Prenatal diagnosis can be established using urinary steroid metabolite analysis of maternal urine. One series reported that identification of malformations on prenatal ultrasound was predictive of a more severe phenotype.

The skeletal malformations include craniosynostosis, midface hypoplasia, phalangeal anomalies, and synostosis of large joints. Similar skeletal anomalies occur in the Antley-Bixler syndrome, an autosomal dominant disorder associated with mutations in the fibroblast growth factor receptor 2 (*FGFR2*) gene. The *FGFR2* gene is located at chromosome 10q26.13. However, individuals with Antley-Bixler syndrome due to *FGFR2* mutations have normal steroidogenesis.

E. Maternal sources: Androgens and progestogens

In general, the 46,XX fetus is protected from excessive androgen exposure by the ability of the fetal-placental unit to aromatize androgens to estrogens. Nevertheless, exposure of mothers to testosterone, other androgenic steroids, or some synthetic progestational agents during pregnancy can be associated with virilization of the external genitalia of 46,XX fetuses (see Figure 14–11). Norethindrone, ethisterone, norethynodrel, medroxyprogesterone acetate, and danazol have all been implicated in masculinization of the female fetus. In rare instances, a maternal androgen secreting ovarian or adrenal tumor or a luteoma of pregnancy can be associated with virilization. Placental aromatase protects most 46,XX fetuses in cases of maternal CAH. Another potential etiology includes environmental endocrine disruptors, which are exogenous chemicals capable of interfering with one or more aspects of hormone action. The diagnosis of 46,XX DSD arising from transplacental passage of androgenic steroids is largely a diagnosis of exclusion. Surgical correction of the genitalia, if needed, is the only therapy necessary.

MANAGEMENT OF PATIENTS WITH DSD

General Aspects

The management of patients with DSD is complex, due to clinical heterogeneity and the multiple factors influencing sexual outcomes. Because of this high variability in phenotype and in DSD clinical expression and outcome, all members of the medical team must be comfortable with individualizing their approach to each patient and each family. DSD conditions should be diagnosed as specifically as possible at the time of presentation, as etiology can be an important guiding factor in management. However, contrary to other conditions in medicine, arriving at a specific diagnosis does not necessarily dictate a specific care plan. Hence, the approach is fundamentally different from that utilized for most other diseases encountered in medicine, in which the primary focus is on diagnosis by which therapy is then defined. Additionally, a commitment to family education (based on age, maturity, sophistication, education level, and cultural milieu) is paramount to an optimal outcome, with the goal of full disclosure and repeated psychological assessments. A long-term care plan needs to be formulated in concert with the family.

Patients with DSD presenting with genital ambiguity, prenatal ultrasound confusion, or inconsistency of prenatal karyotype and genital development encountered by the clinician at birth require thoughtful deliberation, regarding male or female assignment and the need for or benefit of early genital surgery. Based on the initial karyotype, the differential diagnosis typically is categorized under the heading of karyotype (see Table 14–1). However, one negative aspect of this type of categorization occurs when a patient or family

mistakenly assumes that the karyotype is a type of cryptic code indicating maleness or femaleness or that it defines sex and/or gender. Instead, the parents should come to understand that while, in the usual situation, a female has a 46,XX karyotype, there are situations in which a genetic disturbance can direct differentiation in another, at times unpredictable, direction. In fact, many autosomal genes are found to be disease-causing in many DSDs and their identification can be a helpful factor for sex assignment since the genes on sex chromosomes do not alone determine reproductive system development (eg, 46,XX males).

Genital ambiguity is not considered a medical emergency. Nonetheless, the coexistence of a life-threatening condition, such as adrenal insufficiency, should be considered to allow immediate therapy if needed. Beyond this initial diagnostic urgency, it is important that parents be provided with timely and increasingly detailed information. They may not have previously been aware that such a condition could occur, and they need to be provided a perspective that their child can be expected to have a good life and that the team will work with them to ensure the best possible care for their child. Full disclosure and education are crucial. Sharing information in a progressive and timely way helps parents understand how such a situation could develop, together with goals to equip them with current information to make decisions regarding care and long-term outcome information, and how to identify biases or stigma so they can be avoided while carefully protecting confidentiality. In spite of recent attempts to inform, there is still strong evidence of the stigmatizing effect associated with a DSD diagnosis, and underscores the need to educate repeatedly the patient and family. Psychological family support and counseling should be provided at the time of diagnosis, followed by periodic psychologic reassessment to identify those in need of on-going counseling.

The initial session with the family involves a review of the embryonic differentiation including the common origin of the clitoris and penis in the genital tubercle, of the labia majora and scrotum from the embryonic labioscrotal folds, and of the labia minora and penile urethra from the urethral folds, as well as the development of the cortex and medulla of the primordial gonad into the ovary and testes. These explanations can provide a basis for the understanding of how too little or too much androgen can result in masculinized female genitalia or insufficient masculinization of male genitalia and how gonads may be partially developed or differentiated in more than one direction. Further, internal reproductive system differentiation should also be explained including the need for adequate testosterone for male development and the role of AMH in suppressing female internal development. This is the basis for understanding how a 46,XY patient with testicular development may have uterine and Fallopian tube development, or why an individual with inadequately masculinized external genitalia likely has insufficient ductal development.

The physical development of the infant should be examined with the parents observing so they will be comfortable seeing their baby's genitals. Viewing an enlarged phallus while being reminded that this may represent an enlarged clitoris or an incompletely formed penis; and partially fused labial-scrotal folds, which may represent partial scrotal fusion or excessive fusion of labia majora;

and partially fused urethral folds which may represent an incompletely formed penile urethra or excessive fusion of labial minora not only informs the parents of the status of their infant, but also provides a conceptual framework to avoid mystique and stigma and allows them to understand how such a situation can develop. As laboratory tests become available, they should be interpreted within the context of the other elements of history, physical examination, hormonal and genetic testing.

Parent/patient support and advocacy groups should be identified objectively, recognizing that non-representative biases may occur. The caveat should be that the multidisciplinary team as well as these groups both desire optimal health care and decisions that result in the best possible broadly defined QoL for the patient. The perception should be that the diagnosis and care of DSD individuals, who have a life-long condition, continues to evolve based on better diagnostic tools, including genetic and visualization techniques, refinements in surgery and ever improving outcome data. It is important to highlight to families that existing outcome reports do not take into account all of the multiple factors that impact QoL. Outcome studies usually do not include a representative patient sampling and may overly represent patients with valid complaints and underrepresent those with the best outcomes. It is important to provide the concept that most DSD conditions are medically complex, and because they interface with human and societal views on sexuality, it is not always possible to predict adult outcomes. Parents, and later the individual, need to understand that they may be angry or upset that such a condition exists but they need to avoid the tendency to blame the caretakers without coming to terms with the fact that this condition occurred. As health-care providers, our goal is that individuals with DSD will become well-adjusted contributing members of society.

While all agree under ideal circumstances that a **multidisciplinary team**, including an endocrinologist, surgeon, geneticist, and psychologist work together with other care providers to facilitate on-going care, most tertiary care centers lack the availability of experienced individuals to staff this type of arrangement. This is particularly true for focused psychological support, with this role often being assumed by another team member. While centers of excellence may improve this deficit, fiscal and time constraints often make this option unfeasible in many situations as well.

At initial assessment, whether at infancy or later, a **careful history** should be obtained including family history of genital ambiguity, unexplained infant death, maternal exposure to hormonal or toxic substances and any evidence of virilization during pregnancy, consanguinity, infertility, amenorrhea, hirsutism, and any other endocrinopathies.

A careful **physical examination** should be performed with specific attention to reproductive system development. Ranges of penis and clitoral size are available. Such information should be considered in context, and a designation of an abnormality is inappropriate simply for a clitoris that exceeds or a penis that does not meet these criteria. There should be careful documentation of genital anatomy to provide the basis to assess changes over time and for future outcome assessment. For example, the enlarged clitoris in a 46,XX infant with CAH may be larger at birth than

after a few weeks of adrenal suppression when androgens have declined considerably. Such regression may indeed be dramatic, and such that clitoral surgery may no longer be considered. The presence and size of a mass(es) in the labial-scrotal or inguinal area need to be documented, and these may represent testes, ovotestes or rarely the cervix of the uterus in an infant with PMDS. When palpable the location of testes should be documented as: scrotal, upper scrotal, within the inguinal canal, lower abdominal or rarely ectopic in the femoral and perineal regions. The configuration of the phallus, location of the meatus, and estimation of amount of corporal tissue should be noted, together with the width, stretched length and degree of chordee (if present). While a palpable midline structure on rectal examination suggests a uterus, this type of examination is unnecessary when a pelvic ultrasound is being done. Genital phenotype can be documented, using the Prader scales for virilization of female genitalia as occurs with CAH, or with the Quigley scales, as used in 46,XY DSD individuals. It is important to realize that the Prader scale, specifically the location of the urethral meatus does not necessarily correlate with the extent of the underlying corpus spongiosum fusion. This can only be determined with surgical exploration; hence, predicting the likelihood of successful surgical repair can be made only during surgery. Anogenital distance (from the center of the anus to the junction between the smooth perineal skin and rugated skin of the scrotum) can be seen as an indicator of testosterone exposure during early fetal life. The normal distance is 3 ± 0.7 cm. For females, an anogenital ratio (distance from anus to posterior fourchette/distance from anus to base of clitoris) greater than 0.5 suggests excessive androgen exposure.

The risk of malignant transformation of gonadal tissues must be considered. Such involves primarily germ cell tumors. Tumor risk is related to gonadal maturation, presence of portion of the Y chromosome, and anatomic location for testicular tissue. DSD patients with gonadal dysgenesis are particularly at risk. Precursor lesions can be identified and stained for particular genetic expression, such as SOX9 and FOXL2. Embryonic stem cell markers, particularly OCT3/4, are useful. The risk for development of germ cell tumors is related to intrinsic risk alleles, disrupted germ cell development, and environmental factors. Gonadal biopsy is necessary to identify germ cells tumors or tumor precursors. The age at which a biopsy should be done should depend upon the age range of tumor development within the particular DSD. This generally begins around pubertal age.

A comprehensive view of the perspectives of clinicians, patients, and their families have identified **three primary ethical principles** applying to management of DSD patients. They are to: (1) foster the well-being of the child and future adult, (2) uphold the rights of children and adolescents to participate in and/or self-determine decisions that affect them, and (3) respect the family and parent-child relationship. The goal of achieving a balance between the rights, needs and interests are outlined in 9 recommendations. These recommendations include: (1) careful weighing of therapeutic decisions, (2) the ultimate rights of the parents, (3) determining a binary sex does not automatically ensure the child's well-being, (4) respect of the parents' value system, (5) interventions should be based on exhaustive diagnostic studies and

the best possible prognosis, (6) explicit reasoning and justification is necessary for any intervention when conclusive scientific evidence is lacking, (7) providing information to the child commensurate with age, (8) documentation of treatment information to provide to the individual as an adult, and (9) periodic review of recent medical scientific findings.

These ethical principles do not support a moratorium on all genital and gonadal surgery during infancy or delaying interventions until the individual is old enough to decide, as some would advocate. There is no evidence-based data upon which to base this type of moratorium. Furthermore, this type of one sizes fits all approach would undermine the rights of many families, whose unique circumstances leads to a desire for genital surgery for their child. In addition, the proposal to delay surgical interventions does not address how it would be determined that an individual had attained such an age to make the decision autonomously and ignores the complete lack of knowledge regarding the effect of living with genitalia that are inconsistent with sex of rearing. Such a policy would introduce a new type of dogma reminiscent to that of the optimal gender approach, creating a form of social experimentation where basic parental rights and responsibilities are restricted at the behest of a highly vocal minority that uses intimidation and legal challenging to supersede basic human bioethical principles.

Diagnostic Workup

As previously said, systematic rules cannot be applied in the management of all DSD patients. The diagnostic workup varies according to the age at presentation (newborn, child, adolescent), and the main complaint (ambiguous genitalia, discordance between fetal karyotype and genital appearance, polymalformations, pubertal delay/primary amenorrhea, infertility), and usually includes a variable array of endocrine laboratory determinations, imaging studies, histological examinations, and genetic tests.

A. Newborns with ambiguous genitalia: Initial steps
Owing to its frequency and life-threatening potential, CAH needs to be excluded in newborns with ambiguous genitalia, especially in the absence of palpable gonads. Neonatal screening programs can detect elevated levels of 17-OHP, and may give a rapid clue in the cases of CAH due to 21-OHD. A karyotype should also be performed.

Other hormone results should be analyzed considering the particular ontogeny of the reproductive axis in newborns: normally, gonadotropins, androgens and AMH are low in the first week of life in both sexes. However, serum AMH and testosterone levels above a certain threshold indicate the presence of testicular tissue (Table 14–3). From the second week, all hormones progressively increase following a sexually dimorphic pattern, where LH increases more than FSH in males—the opposite is observed in females—and AMH and testosterone become clearly higher in males. The existence of ovarian tissue cannot be easily proven due to the lack of specific markers; in fact, estradiol does not show a clear sexual dimorphism. All steroid determinations should be

TABLE 14–3 Serum levels of gonadotropins and gonadal hormones in normal newborns.

Hormone	Day 2	Day 7	Day 14	Day 21	Day 30
Testosterone (ng/dL)					
Boys	20-100	30-120	30-190	30-190	120-350
Girls	20-40				20-40
AMH (pmol/L)					
Boys	200-550	250-600	300-650	400-700	450-950
Girls	ND-10				ND-30
FSH (IU/L)					
Boys	ND-0.50	0.50-3.50	0.50-3.50	0.70-2.00	0.90-2.20
Girls	ND-0.30				1.00-13.00
LH (IU/L)					
Boys	ND-0.50	0.80-7.00	1.20-4.00	1.20-4.50	1.60-4.50
Girls	ND-0.20				0.20-2.00

performed after extraction procedures to avoid assay interference rendering artificially elevated serum levels.

Genitoscopy and/or genitography are usually needed to establish the morphologic characteristics of the internal genitalia and urinary structures. Due to difficulties with adequate resolution, ultrasonography may give false results, unless performed by a professional with a vast experience in the study of the reproductive tract in newborns.

B. Next steps when karyotype is 46,XX (Table 14–4)
Patients with non-palpable gonads   Since 17-OHP may not be unequivocally elevated in some forms of CAH, hormonal investigations must be repeated together with studies of salt balance (Na$^+$, K$^+$) and PRA. Hypoglycemia and failure to thrive reflect glucocorticoid deficiency, which also results in lack of negative feedback regulation of POMC/ACTH; consequently, ACTH is elevated, and genitalia and nipples are hyperpigmented. The diagnosis of CAH also needs the distinction between salt-wasting and simple virilizing forms. The finding of high levels of PRA, together with hyponatremia and hyperkalemia, is indicative of aldosterone insufficiency, which usually presents in the second or third week of life. Salt wasting is not typically evident in 11β-hydroxylase deficiency owing to accumulation of DOC, but it may be triggered by glucocorticoid treatment. Detailed hormonal and genetic studies in patients with CAH have been discussed earlier.

A history of maternal virilization during pregnancy suggests placental aromatase deficiency. No clinical or biochemical signs of adrenal dysfunction are observed in the newborn. In the first 2 weeks of life, estradiol is below the normal female range and androgens and gonadotropins are elevated. Molecular studies should point to the *CYP19A1* gene.

Ovotesticular DSD should be suspected, if there is no history of maternal virilization and levels of androgens and AMH are between the normal female and male ranges (see Table 14–4).

Patients with palpable gonads   Ovotesticular DSD is the most likely diagnosis. Rarely, dysgenetic testicular DSD may

TABLE 14–4 Laboratory findings in 46,XX DSD.

T	AMH	LH/FSH	17OH-P	Cortisol	Na$^+$	K$^+$	Defect
High	Normal	Normal	High	Low	Low	High	CAH (21-OHD, 11β-OHD)
Slightly high	Normal	Normal	Low	Low	Low	High	CAH (3β-HSD)
High/Normal	Normal	High	High	Normal/Low	Normal	Normal	POR deficiency
High	Normal	High	Normal	Normal	Normal	Normal	Aromatase deficiency
High	High	Normal	Normal	Normal	Normal	Normal	Testicular DSD
High	Normal	Normal	High	High	Normal	Low	GR defect
High/Normal	Normal	Normal	Normal	Normal	Normal	Normal	Virilizing tumor (mother)
High	High	High	Normal	Normal	Normal	Normal	Ovotesticular DSD
Normal	Normal	Normal	Normal	Normal	Normal	Normal	Malformative DSD

Note: Serum levels are considered normal, high, or low as compared to reference values in girls.

Abbreviations: 11β-OHD, 11β-hydroxylase deficiency; 17OH-P, 17 hydroxyprogesterone; 21-OHD, 21-hydroxylase deficiency; AMH, anti-Müllerian hormone; CAH, congenital adrenal hyperplasia; FSH, follicle-stimulating hormone; GR, Glucocorticoid receptor; LH, luteinizing hormone; POR, P450 oxidoreductase.

occur. Usually the amount of functional testicular tissue correlates with the levels of testosterone and AMH.

The definitive diagnosis of ovotesticular or dysgenetic testicular DSD relies on histological studies of both gonads.

When virilization is complete and both gonads are scrotal and of normal size—a discordance between a fetal karyotype and the genital phenotype being the cause for referral of such newborns—the diagnosis of testicular DSD is almost certain. In these cases, serum gonadotropins, testosterone, and AMH are within the normal male range.

Molecular studies should include the search for *SRY* sequences, for *SOX9*, *SOX3*, or *SOX10* duplications, or *RSPO1* or *WNT4* mutations in *SRY*-negative cases.

C. Next steps when karyotype is 46,XY (Table 14–5)

The occurrence of undervirilized genitalia in 46,XY newborns

indicates that either the gonads have not produced enough testosterone or the target organs are not responsive. The assessment of serum testosterone and AMH are very useful for an initial classification into three distinct groups: (1) dysgenetic DSD, (2) isolated androgen deficiency, and (3) androgen end-organ defects. Anatomical assessment by imaging studies and surgical procedures show the existence of uterus and Fallopian tubes in the first case, and their absence in the remaining two.

Low testosterone and AMH: testicular dysgenesis Serum levels of testosterone and AMH below the normal male range for age indicate that both Leydig and Sertoli cell populations are affected (ie, dysgenetic DSD). FSH and LH are elevated, reflecting a lack of negative feedback. The amount of functional testicular tissue usually correlates with the degree of virilization. When the newborn is completely feminized and has come to medical

TABLE 14–5 Laboratory findings in 46,XY or chromosomal DSD with a Y lineage.

T	AMH	LH	FSH	Other Hormonal Features	Diagnosis
Undetectable No response to hCG	Undetectable	High	High	Normal adrenal steroids	Complete gonadal dysgenesis
Low Poor response to hCG	Low	High	High	Normal adrenal steroids	Partial testicular dysgenesis Asymmetric gonadal differentiation
Low/normal Poor/normal response to hCG	Low/normal	Norma/High	Normal/High	Normal adrenal steroids	Mild testicular dysgenesis Ovotesticular DSD
Undetectable/low No/poor response to hCG	Normal/High	High	Normal	All gonadal steroids low Normal adrenal steroids	Leydig cell aplasia/hypoplasia
Undetectable/low No/poor response to hCG	Normal/High	High	Normal	All gonadal and adrenal steroids low	Lipoid congenital adrenal hyperplasia (StAR/P450scc)
Low Poor response to hCG	Normal/High	High	Normal	High pregnenolone and progesterone Low cortisol	17α-hydroxylase deficiency POR deficiency
Low Poor response to hCG	Normal/High	High	Normal	High 17OH-pregnenolone and 17OH-progesterone Normal cortisol	17-20 lyase deficiency
Low Poor response to hCG	Normal/High	High	Normal	High pregnenolone, 17OH-pregnenolone and DHEA Low cortisol	3β-HSD type 2 deficiency
Low Poor response to hCG	Normal/High	High	Normal	High Δ4-androstenedione	17β-HSD type 3 deficiency
Normal or High	Normal	Normal	Normal	Low DHT High urinary 5β/5α-reduced metabolite ratios: Tetrahydrocorticosterone/allotetrahydrocorticosterone Etiocholanolone/androsterone	5α-reductase type 2 deficiency
Normal/High	Normal/High	High	Normal	Normal adrenal steroids	AIS
Normal	Normal	Normal	Normal	Normal adrenal steroids	Malformative DSD

Note: Serum levels are considered normal, high or low as compared to reference values in boys.

Abbreviations: 3β-HSD, 3β-hydroxysteroid dehydrogenase; 17β-HSD, 17β-hydroxysteroid dehydrogenase; AMH, anti-Müllerian hormone; AIS, androgen insensitivity syndrome; DHEA, dehydroepiandrosterone; DHT, dihydrotestosterone; hCG, human chorionic gonadotropin; P450c17, Cytochrome P450 17-hydroxylase/17,20-lyase; P450scc, Cytochrome P450 side-chain cleavage; POR, Cytochrome P450 oxidoreductase; StAR, Steroidogenic Acute Regulatory protein.

attention because of discordance with a fetal karyotype, the diagnosis of complete or "pure" gonadal dysgenesis should be considered if AMH is undetectable.

When the genital abnormality is not associated with other malformations, *SRY*, *NR5A1* (coding for SF1), and *MAP3K1* are the most likely candidate genes, together with partial Xp duplications encompassing the DSS region containing *NR0B1* (encoding DAX1). Renal function particularly the occurrence of proteinuria should be explored in these patients. Absence of renal dysfunction excludes *WT1* mutations or deletions.

In patients with associated primary adrenal insufficiency, *SF1* defects should be considered. Patients with campomelic dysplasia are likely to have a mutation in the *SOX9* gene. Polyneuropathy, which might not be easy to detect in a newborn, is suggestive of *DHH* mutations, whereas mental retardation and α-thalassemia should drive the attention to *ATRX*. When mental retardation, craniofacial dysmorphic features and delayed motor development are found, 9p deletions including *DMRT1* should be suspected.

Low testosterone, AMH normal for male: isolated defect of androgen production

When testosterone is low in the first 3 to 6 months of life but AMH is within or above the normal male range, only Leydig function is affected. LH may be elevated and FSH normal. A prolonged hCG test (6 or 7 IM injections of 1500 IU every other day, with gonadal steroids measured in serum 24 to 72 hours after the last injection) is usually needed. When all steroids are low, but adrenal function is normal, the defect is in the LH/hCG receptor. Conversely, if basal ACTH and PRA are elevated, with low Na$^+$ and high K$^+$, StAR or P450scc deficiency is likely. An ACTH test (6 IM injections [0.5 mg/m^2 of body surface area] of depot ACTH every 12 hours, with adrenal steroids measured before the first injection and 12 hours after the last injection) should make the differential diagnosis.

Low testosterone and cortisol responses to ACTH, associated with elevated pregnenolone and progesterone and low 17OH-pregnenolone/pregnenolone and 17OH-progesterone/progesterone ratios, are suggestive of insufficient 17α-hydroxylase activity due to mutation of the gene encoding P450c17 (see Figure 14–5). Elevated DOC and corticosterone, normal Na$^+$ and K$^+$, and hypertension in older infants are almost confirmatory. The associated occurrence of bone malformations typical of Antley-Bixler syndrome is suggestive of P450 oxidoreductase (POR) deficiency. An isolated deficiency of the 17,20-desmolase activity of P450c17 is suspected when adrenal function is normal, testosterone is low, and the ratios DHEA/17OH-pregnenolone and Δ4-androstenedione/17OH-progesterone are reduced.

More rarely, testosterone and cortisol may show a low response, in association with decreased stimulated ratios of Δ4/Δ5 steroids (progesterone/pregnenolone, 17OH-progesterone/17OH-pregnenolone and Δ4-androstenedione/DHEA). Here, 3β-HSD type 2 deficiency is suspected (see Figure 14–5), even if absolute values of Δ4 steroids (progesterone, 17OH-progesterone, and Δ4-androstenedione) are normal or somewhat elevated.

When testosterone is low but all precursors are elevated, resulting in a low testosterone/Δ4-androstenedione ratio, 17β-HSD type 3 deficiency is most likely (see Figure 14–5).

Male-range testosterone and AMH: androgen end-organ defects

Fetal-onset hypogonadism can be ruled out when both testosterone and AMH are within or above the male range. Androgen target-organ defects, including androgen insensitivity and deficient DHT production, should be suspected (see Figure 14–9).

CAIS is most likely in newborns with completely female external genitalia. Conversely, in patients with ambiguous genitalia, the differential diagnosis between PAIS and 5α-reductase type 2 deficiency is not straightforward. A high testosterone/DHT ratio after an hCG test is suggestive of 5α-reductase type 2 deficiency; however, false negatives may result due to DHT conversion by 5α-reductase type 1 activity, particularly in the infant. On the other hand, false positive results may result from reduced DHT levels observed in PAIS patients; this is due to the fact that 5α-reductase activity is regulated by androgens via the androgen receptor. Urinary 5β/5α-reduced metabolite ratios have a better diagnostic efficiency: high tetrahydrocorticosterone/allotetrahydrocorticosterone and high etiocholanolone/androsterone ratios confirm 5α-reductase type 2 deficiency. Molecular genetic testing may be helpful in this situation.

D. Next steps when karyotype is atypical (Table 14–5)

Sex chromosome DSD, resulting in gonadal dysgenesis containing variable amounts of testicular tissue, is the diagnosis in a newborn with ambiguous genitalia and a sex chromosome mosaicism with at least one cell line carrying a Y chromosome. In patients 45,X/46,XY, 45,X/46,XY/47,XXY, or other similar mosaicisms, gonadal dysgenesis—either symmetrical or asymmetrical (mixed gonadal dysgenesis)—is likely. In patients with 46,XX/46,XY mosaicisms, ovotesticular DSD is the rule. The comments made above for those disorders (see karyotypes 46,XX and 46,XY) apply also here.

E. 46,XX or 46,XY newborns with polymalformative syndromes (see Tables 14–4 and 14–5)

The occurrence of consistent features of undervirilization (ie, micropenis, hypospadias, bifid scrotum, cryptorchidism) in a 46,XY patient suggests that testicular dysgenesis is part of the malformation syndrome. Low testosterone and AMH, together with elevated gonadotropins, confirm the diagnosis. Conversely, when inconsistency is noted between the different genital structures (eg, isolated penile agenesis with normal scrotum and palpable testes), gonadal dysfunction is unlikely. Normal testosterone, AMH, and gonadotropins are found. In some patients, where the malformations of the abdominopelvic wall or the anogenital region interfere with the anatomic assessment of the genitalia, testosterone and AMH determinations allow the establishment of the gonadal sex.

F. Genetic testing in DSD

Families and health-care personnel are interested to establish the genetic and molecular basis in the patient with a disorder of sex development. With the development of newer and high-throughput technologies, it is increasingly possible to identify the specific genetic etiology in an individual patient. Availability of this information decreases anxiety for families and improves the ability of health-care providers to predict

the phenotype of the patient and genetic recurrence risks. Genetic testing is increasingly used in medical decision-making. Although the individual patient's management may not change, identification of a causative variant may predict recurrence risk and can be used for preimplantation genetic diagnosis. In many instances, genetic evaluation of the parents, affected relatives, and other unaffected relatives is essential to ascertain if a mutation is *de novo* and if it segregates with the patient's phenotype. Variants are categorized by likely functional significance and consequences (Table 14–6). With the vast amount of genetic data being collected, public databases have been developed to provide information regarding clinical phenotype, functional significance, and prevalence. One caveat is that the information listed in these databases (Table 14–7) may not have been updated or recently reorganized.

Peripheral blood karyotype analyses remain useful to detect balanced chromosomal translocations and large chromosomal anomalies such as structural rearrangements of the X chromosome. Fluorescent in-situ hybridization (FISH) enhances routine karyotype analyses because it can characterize unknown marker chromosomes and chromosomal rearrangements. For the newborn with ambiguous genitalia, rapid turn-around times to detect X and Y chromosomes may be used to help direct subsequent studies.

Comparative genomic hybridization (CGH) arrays are a high-resolution method that can detect submicroscopic genetic abnormalities. This method can identify copy number variants (CNVs) and detect microdeletions and microduplications. In some instances, these findings represent *de novo* submicroscopic chromosomal rearrangements. However, low level mosaicism and balanced chromosomal rearrangements such as translocation or inversions may overlooked by this technique. CGH has become

useful to identify novel candidate genes associated with DSD. Alterations in gene dosage have been associated with anomalies in gonadal development. The use of customized CGH targeted for CNV associated with DSD can interrogate multiple genes simultaneously which expedites the diagnostic process. During childhood, the phenotypes of patients with mutations in *AR*, *LHCGR*, and *CYP17A1* can overlap. Targeted CGH may be able to differentiate among these genetic disorders and eliminate the need to perform hCG stimulation tests.

TABLE 14–6 Terms used to characterize sequence variants.

Term	Meaning
Pathogenic	Contributes to disease
Likely pathogenic/ implicated	Data consistent with pathogenic role with a defined level of confidence
Benign	Available data indicates that variant does not contribute to disease
Likely benign	Data consistent with non-pathogenic role with a defined level of confidence
Variant of uncertain significance (VUS)	Data inadequate to classify variant
Associated	Variant is significantly enriched in affected individuals compared to matched controls
Damaging	Variant affects the normal levels or biochemical function of a gene product
Deleterious	Variant reduces reproductive fitness of carriers

Genome-wide association studies (GWAS) enable a hypothesis-free approach to identifying genes associated with specific disorders. With this method, allele frequencies of affected persons are compared to controls (case-control analyses). All individuals in both groups are genotyped for a large number of common single-nucleotide polymorphisms (SNPs). The goal is to identify sequence variants associated with the specific phenotype of interest. Many of the associated variants are located outside of the coding region of a gene complicating interpretation of the functional significance. These SNPs may affect gene regulatory elements, influence local chromatin structure, or affect cofactor recruitment. Non-coding genes including microRNAs and long noncoding RNAs need to be considered. Replication of findings is essential, especially for GWAS, to minimize false positive associations due to differences in population architecture.

Whole exome sequencing (WES) is a technique in which the coding regions (exons) of thousands of genes are analyzed simultaneously using next-generation sequencing techniques. Multiple variations in one individual's DNA sequence can be detected by comparing the patient's exome to a normal reference sequence. Technically, WES is accomplished by breaking the DNA into small fragments, sequencing the fragments, aligning the sequences, and using computer software to compare the aligned sequences to the human genome reference sequence. This technique can detect single nucleotide changes and small insertions and deletions. Results are screened for rare variants, variants previously associated with disease, and variants predicted to generate a functional consequence. Whole genome sequencing (WGS) targets the entire genome. Both WES and WGS are hypothesis-free approaches that generate much data with the need for powerful bioinformatics tools. WES provides more coverage of exons and, currently, is less costly than WGS. Typically, WES detects 15,000-20,000 variants and WGS detects 3 to 4 million variants that differ from the human reference genome. However, WES will not identify variants involving non-coding regions. WGS has greater sensitivity to detect small structural variations (eg, insertions, deletions, and translocation). Neither technique adequately identifies larger CNVs, repetitive sequences such as trinucleotide repeats, aneuploidy, or epigenetic alterations. For both techniques, detected genetic alterations need to be validated by polymerase-chain reaction amplification followed by Sanger sequencing or restriction fragment length polymorphism analysis.

Ethics of WES and WGS   These powerful tools can identify genetic variants known to be associated with diseases unrelated to the disorder of interest. Therefore, pretest counseling and informed consent are essential components of the process involved in performing genetic studies. Parents and patients need to be advised that incidental findings unrelated to the reason for testing may be detected. Many, but not all, variants reported to be associated with genetic disorders represent robust associations. However, false assignments of causality remain a major challenge. Clinician and researchers are faced with the responsibility, obligation, and pressure of assessing the functional significance of genetic variants with the potential consequence of misdiagnosis.

Sex Assignment

With the primary goal of sex assignment being an assignment that aligns well with the future gender identity, it is crucial to realize that future gender development cannot be predicted with complete certainty. At best, a probable gender identity is all that can be developed. This uncertainty of gender development, as is increasingly publicly chronicled in non-DSD transgendered persons, creates a formidable barrier to success. Factors to be considered are based on: etiologic diagnoses (when known); degree of external genital development; surgical options; anticipated quality of sexual function (based upon the two previous factors); fertility potential; malignancy risk; familial/social/cultural/psychosocial factors; psychosocial risks for the individual and parents; and degree of fetal androgen exposure. It is important to realize that familial/social/cultural/psychosocial factors; psychosocial risks for the individual and parents, and degree of fetal androgen exposure may on occasion override the gender development anticipated for a specific diagnosis. It is clear that there is a need to limit aggressive surgical removal of potentially fertile gonadal tissue or potentially sexually responsive phallic tissue during infancy.

The general principle for sex assignment is, when the differentiation is primarily female, the assignment should be female, and when male, male. Nonetheless, at all levels of sex assignment, a certain degree of uncertainty is inescapable. This should be shared with parents to instill the flexibility needed to raise a child with DSD with understanding and compassion. However, in each patient, there must be careful consideration to determine whether there is a reason to consider an exception. Major exceptions include when differentiation was not primarily toward one or the other sex, as exemplified by some, but not all, cases of ovotesticular DSD or when there is diminished androgen responsiveness as in some with PAIS. Phenotype variability among those with the same enzyme deficiency and/or diagnosis can be considerable, such that sex assignment must consider all principles on which assignment is based and should not rely on an etiologic diagnosis alone.

The principles used for assignment should carry the greatest probability of adult happiness and success. The concepts include: (1) alignment of physical sex with gender identity; (2) capacity for satisfying sexual function and response; (3) potential for "normal" genitalia; and (4) fertility but only when there is a reasonable probability of alignment of sex assignment with adult gender identity. Since the probabilities may vary within an individual for these key considerations, it is important to consider the composite evidence in a compassionate, flexible and unique way that offers the highest likelihood of adult happiness and success.

The impact of fetal androgen exposure for a female fetus must be judged with care when considering sex assignment with the caveat that those 46,XX infants with a virilized genital tubercle have been exposed to male typical levels of androgens in utero. Evidence of the magnitude of effect is indirect since the impact upon the developing CNS appears to occur mid-gestation. It is important to understand that the extent of external genitalia masculinization reflects androgen levels during the first trimester and that circulating androgen levels obtained after birth reflect greater

hypothalamic-pituitary-gonadal activity during early infancy and that neither is a good surrogate measure of mid-gestational androgen exposure. Furthermore, the impact of androgen levels on sexual identity is not robust beyond the more male type gender role behavior (rough and tumble childhood behavior) seen in children exposed to high levels of androgen in utero. A relationship between degree of masculinization and male type behavior is assumed. As evidenced among most 46,XX DSD patients with classical CAH, the impact of fetal androgen exposure upon gender identity development or sexual orientation is certainly not direct or linear.

The viewpoint needs to shift from the concept of karyotype as definitive evidence for sex assignment to the realization that mutations on genes on sex chromosomes and autosomes may override this. Even though DSD nomenclature categorizes groups based on karyotype as a guide to specific etiologies, the presence of XX or XY should not be viewed, particularly by parents, as substantiation for a female or male assignment.

Assignment is not necessarily the same for an etiologic diagnosis since hormone secretion and differentiation varies. The impact of varying levels of fetal androgen exposure to the CNS, expression of pertinent hormone-responsive genes at various developmental windows during fetal life and later during childhood/adolescence, and gene expression that occurs independently of hormone milieu all make accurate projection of gender development problematic.

Evidence for the impact of prenatal androgens indicates that infants are not born gender neutral. With this realization, there has been a general shift toward male assignment for 46,XY individuals with evidence of testicular derived androgen exposure in utero and postnatal androgen responsiveness, even in those with "inadequate" penis development. The shift in assignment among 46,XY patients preceded publication of the DSD consensus statement in 2006, documented by evidence of 35% of such patients being assigned male before 1990 with 68% since 1999. The same reasoning also challenges one to consider a male assignment in 46,XX patients with CAH with fully male external genitalia based upon the favorable outcome data in those who, owing to a delayed diagnosis, were raised male.

A. Sex assignment for 46,XX DSD individuals with genital ambiguity

The long-term perspective has been that patients with 46,XX DSD, the majority of whom have 21-hydroxylase deficient CAH, should always have a female assignment. This reasoning was based upon the following considerations. (1) Although the external genitalia may be sufficiently virilized to require surgery for functionality and cosmesis, the outcome, when genital sensitivity is preserved, is expected to be satisfactory. (2) Since internal reproductive structures, (ovaries, Fallopian tubes and uterus) are differentiated normally, fertility would be expected after proper treatment. (3) While these patients are exposed to sufficiently elevated fetal androgen levels to result in a tendency to male gender role behaviors, particularly during childhood, gender identity is usually female.

However, it is appropriate to include a consideration of a male assignment among 46,XX patients with essentially male genitalia,

including those with CAH and sex reversal with significant virilization. Outcome data have been obtained from patients who, owing to the presence of near normal male genitalia at birth, were considered male and subsequently identified with the XX karyotype only well after the newborn period. These individuals, though infertile, manifest a clear male gender identity and a reasonable QoL. Between 1896 and 2002, 46 cases assigned male at birth without reassignment were reported. Subsequently 12 46,XX CAH men were reported with male gender identity, sexual orientation toward females, normal male libido, masculinity, frequent satisfactory (orgasmic) sexual activity, and satisfactory body image. Currently, there are many other 46,XX CAH patients being reared with a male sex assignment, as a consequence of parents' choice.

The 2006 consensus statement indicated that all 46,XX CAH patients should be assigned female based on available outcome data showing that 95% identify as female. In failing to address the 5% who do not identify as females, an outcome that has been shown to be related to degree of masculinization of the genitalia, the consensus statement has promoted an algorithmic approach to DSD management. In contrast, we feel a male assignment should be considered for 46,XX, patients with CAH, as in other DSD conditions, in which external genitalia are essentially male and there is evidence of high levels of in utero androgen exposure, while taking into account the social and cultural environment.

B. Sex assignment for 46,XY DSD individuals with genital ambiguity

As noted earlier, among 46,XY DSD patients, there has been a nearly universal shift to male assignment rather than female assignment, when there is indirect evidence of CNS androgen exposure during fetal life and demonstration of androgen responsiveness. This shift was heavily influenced by the male gender development among those 46,XY patients with cloacal exstrophy who had been assigned female at birth and were then gonadectomized. Additionally adult males with very small penises almost invariably identify as male.

Outcome information, particularly QoL, for 46,XY DSD conditions have been inadequately studied. Female assignment is certainly appropriate for those with female genitalia (no genital ambiguity) including CAIS, pure gonadal dysgenesis and LH receptor defect. Because a significant portion of 46,XY patients with DSD are given a diagnosis of PAIS, male assignment should occur only after demonstration of androgen responsiveness.

C. Specific considerations

1. Female assignment remains appropriate for those with CAIS, but the clinician must realize that psychological distress issues exist and need to be recognized and addressed.

2. The recommended sex assignment recommended for those with 5α-reductase deficiency is male, based upon the report that the majority develop a male gender identity when gonads are left intact. However, it would be appropriate to individualize the approach since fertility may be a problem for those raised male. Those raised female have indicated satisfactory sexual function. Categorical male sex assignment for 5α-reductase or 17β-HSD deficiencies, each of which shows

heterogeneous development, carries the risk of repeating the previous generations' mistake of too rigidly applying accepted concepts and should be challenged.

3. Male assignment is also recommended for those with 17β-HSD deficiency, with testes left intact, based upon the development of male gender identity among the majority. For those with this diagnosis, it is appropriate to question whether the recommendation for all should be based upon the outcomes for only a portion of this population without consideration for the variability in the severity of the phenotype. Both those raised males and female have indicated satisfactory sexual function, while those raised male have indicated dissatisfaction with penis length and those raised female have been reported to have clinical distress.

D. Sex assignment consideration for those with variable karyotype, gonadal, external and internal differentiation

Sex assignment for those having ovotesticular DSD and mixed gonadal dysgenesis (or asymmetric gonadal differentiation) continue to require complete assessment regarding the extent of masculine or feminine development, even unilateral, as male or female, considering the basic consideration of potential for fertility, gonadal hormonal secretion, and genital development potentially enabling sexual function.

For ovotesticular DSD, if ovarian tissue containing follicles is present together with a unilateral Fallopian tube, a uterus and some vaginal development, a female assignment may be considered; while if phallic development is judged sufficient to become a functioning penis and testicular tissue containing Leydig cells and germ cells is present, a male assignment could be considered. An important consideration is to retain functional tissue when possible in the event that the patient, whose gender outcome is typically uncertain, wishes to self-reassign gender later in life. When considering fetal CNS androgen exposure, it is crucial to remember that while the extent of masculinization of the external genitalia is evidence of androgen secretion at some phases of fetal life, it does not necessarily correlate with androgen exposure and hence masculinizing effects in the CNS.

Long-term Outcomes

The goal of the multifaceted therapy for patients with DSDs is to minimize the consequences and enhance the ability to live healthy, contented lives and be productive persons with fulfilling social and personal relationships. While care currently is focused upon outcome, guidelines for use in childhood/adolescence can, at best, be generalized because medical, surgical, and psychological care is continually changing and because current outcome data reflect treatment given about two decades ago. Hence, outcome studies from that time are not completely applicable because care has changed based on evolving new information. Perceptions of outcome have also been heavily influenced by intersex activist groups that seek to generalize anecdotal outcomes and often inappropriately provoke negativity because of highly publicized cases with poor outcome in the absence of adequate evidence-based data. Furthermore, the implication promoted by some activist groups that any genital surgery is "torture" and comparable to primitive female circumcision is unfairly provocative. If taken to the groups' intended conclusion, this would impose a belief system onto families/patients for whom surgery may benefit their unique circumstance.

Existing outcome studies, involving endocrine outcomes, tumor development, psychological, surgical, fertility, urinary, and sexual outcomes, do not take into account the multiple factors impacting outcome, nor do they account for changes in the lives of the study subjects that may enhance or hinder satisfaction. An individual's outcomes are related to personality characteristics including the ability to adjust to/accept their situation, and the availability of social support particularly within their families. Outcome reports often involve small numbers of patients, particularly within arbitrary diagnostic categories that are not physiologically or psychologically related, without appropriate control groups, lacking verified tools and without analysis of multiple impacting facets.

However, in the absence of highly quality outcome data, inferences from available studies are pertinent. A summary of outcomes studies published since 2012 include multiple diagnoses (Table 14–8). It is important to realize that there will never be outcome studies that will result in clear directives for managing individuals in most areas of sexual development, because the underlying conditions persist for life. The ultimate QoL depends upon ability to accept that this is a lifelong condition associated with many factors. Better tools are being developed to assess outcome, and multidisciplinary groups have been formed, but the need to individualize our care will remain as the key guideline for the development of a care plan that seeks to maximize the chance for a "good" outcome.

Satisfactory clinical outcomes are more difficult for those with more severe developmental anomalies. Those with the greatest genital ambiguity and insufficiency have the greatest risk for poor outcome. Hence, outcome data should be assessed based upon percentages of those with a given diagnosis considering acceptance of genital appearance cosmetically; perception of quality of sexual function; and availability, quality and consistency of intimate, familial and general social support. Factors need to be individualized and applied for each individual, including the initial phenotype of external and internal genitalia, physical health, social and psychological adjustment, mental QoL, social participation and support, coping skills, treatment satisfaction following outcome of reconstructive surgery, reproductive system function, and overall QoL. In this regard, it is noteworthy that half of parents expressed regret regarding their decision to have distal hypospadias repaired in their sons long before they were physically mature. Variations in perceptions of learning their DSD diagnosis by young women include lack of memory of details concerning their diagnosis but with positive recollections of the clinician's flexibility, adaptability, and support. Later concerns involved potential social, practical, and philosophical issues.

Because of the variation within diagnoses, different factors beyond being raised as male or female impact QoL. It is recognized that a crucial, albeit incompletely understood factor, is fetal androgen exposure to the CNS. This varies among etiologic diagnoses such 5α-reductase and P450c17 deficiency. The interpretation of a fetal androgen exposure concept is complicated because no good index of fetal CNS androgen exposure currently exists.

TABLE 14–8 Summary of outcome reports from 2012.

46,XX DSD

Most with severe ambiguity had surgery

Extent of virilization and number of surgeries affected cosmetic outcome

Sexual function unsatisfactory because of lack of experience and sexuality-related distress

For vaginal hypoplasia, many had short vaginal length, sexual dysfunction, sexual distress

Among CAH:

    Surgical outcome positive regarding appearance but less so for sexual function

    Level of confluence of vagina into urogenital sinus, a major detriment for cosmetic outcome with more surgeries

    For those sexually active, lower functioning re: desire, arousal, pain, but not satisfaction or orgasm, greater sexual distress compared with reference group

    Evidence of good outcome: Self-satisfaction, Happiness indices, Body image perception

    Sex life satisfaction related to family support and medical care

46,XY DSD

Male sex preferable

Among those raised female, sex life dissatisfaction among 1/3 to 1/2 regarding desire, arousal, dyspareunia, and surgical outcome

Among those raised male:

    Genital appearance and function dissatisfaction jeopardizing sexual Quality of Life (QoL)

    Persistence of small penis size with a portion with length insufficient to achieve penetration

    Psychological support-integral part of management

    Body image and psychosexual not different than controls

Among parents of boys with distal hypospadias: regret regarding decision for surgery associated with postoperative complications

Among CAIS after sigmoid colon vaginaplasty: good subjective outcome scores, with rare stenosis and reoperative rates, satisfaction among sexually active

Ovotesticular DSD

Male: female assignment 2:1

Surgery and hormonal replacement need variable based on anatomic development

Significant male urethral post-surgical complications

Sexual activity more frequent among males

Combined diagnoses

Seventy-five percent satisfied with sex assignment, remainder includes those with uncertainty, transgender issues, and identification with neither male or female

Neovagina satisfactory among those with CAIS and vaginal agenesis, 80% married or sexually active

Reduced health-related QoL: self-esteem, physical wellbeing, school functioning, not associated with atypical gender role behavior, but associated with gender dysphoria

In Indonesian population, most without medical or surgical treatment, gender change common, especially female to male among masculinized 46,XY individuals, cross-dressing behavior among girls and dissatisfaction among adolescent/adult females

---

While there may be predictable outcomes related to the underlying condition, other outcomes and comorbidities with medical care and social inputs cannot be predicted. For example, the impact of transition from the pediatric setting to the less holistic approach is uncertain.

Studies of psychological outcomes of DSD remain problematic for several key reasons: lack of standardized or systematic approach, small sample size, heterogeneous populations that are not physiologically related, and the results that extend across a broad range of patient types. Since assessment involves self and sexual identity and image, perception of genital development, and peer and romantic relationships, studies may also be hampered by subject's sense of shame and invasion of intimacy, embarrassment, reticence, perceived stigma, lack of assurance of confidentiality, cultural constraints, and the particular point in time of assessment. The importance of family support and acceptance, the individual's understanding of his/her condition and good quality medical and surgical care are correlated with positive self-satisfaction and body image perception, happiness indices, and satisfactory sexual lives. Overall, the most must be made of what is available while remaining cognizant of study limitations and the risk of applying general principles to individual cases and the resultant loss of an individualized approach.

Recent reports have found the following: In one case series satisfactory gender identity was found among 75%, with 24% identifying with both genders and 3% with neither. Nine percent changed gender and 14% had evidence of increased transgender scores; an endpoint of health-related QoL (HRQOL) among 4 DSD subgroups found no differences in QoL for 46,XX and 46,XY DSD individuals raised male or female, and found no association between HRQOL and atypical gender role behaviors. However, this study did show that CAH females (46,XX) with CAH and gender dysphoria had lower HRQOL scores and that the percent of patients with cross-gender parental responses or cross-gender behaviors was higher than in control girls; in contrast, CAH boys (46,XY) were no different from control boys in the response rates for cross-gender parental responses or cross gender behaviors. Cross-gender behavior was exhibited in 12.5% of the girls with CAH. These data suggest that female patients with CAH in general do well unless they manifest gender dysphoria. Does it also suggest a generalized higher risk for poor outcomes among those exposed to high levels of androgens during fetal life who are assigned females?

Overall the sexual QoL for individuals with both 46,XX and 46,XY DSD until recently has been reported as impaired. Dissatisfaction involves non-sexuality, intercourse frequency, avoidance, anorgasmia, and penetration difficulties, all of which may relate to the underlying atypical development, medical/surgical care or both, but this dissatisfaction also extends to the ability or opportunity to develop social, including romantic and intimate, relationships. Among 46,XX DSD females, overall sexual function remains unsatisfactory, and there is a strong association between severity of ambiguity and the level of the confluence of the urethra and the vagina and the favorability of the cosmetic outcome. Genital surgery did seem to improve appearance, but did not seem to improve sexual functioning among women with CAH more than 15 years of age. Obstacles to a good adult outcome were noted in those with vaginal hypoplasia, in which short vaginal length often persisted after therapy and was associated with sexual dysfunction.

Those with 46,XY DSD conditions cited arousal and orgasm problems, sexual anxiety, communication problems, less sexual activity, and dissatisfaction with function and appearance. While male assignment is now common for most 46,XY patients, some

DSD males often have a penis that is insufficient for penetrative intercourse, and this remains strongly associated with negative sexual outcomes and sexual dissatisfaction in this group. While 46,XY DSD males with micropenis prefer the male gender, they cite diminished penis size as having a negative impact on sexual QoL. While body image indices did not differ from controls, satisfaction with genital appearance is different among men with 46,XY DSDs. Penis length was compromised, sexual function poor, and a significant portion with severe hypospadias were unable to achieve vaginal penetration. Sexual outcomes in three groups of 46,XY DSD patients found significant dissatisfaction among some: those non-virilized (including CAIS) cited lack of desire/arousal and dyspareunia, those virilized but raised female complained of poor surgical outcome and difficulties with clitoral arousal, while the virilized group raised male complained of poor genital function. While male assignment seems to avoid the high risk of gender dysphoria in virilized 46,XY DSD patients, the outcomes remain less than optimal because of surgical/medical limitations on increasing penis size and the strong social/cultural pressure of penetrative intercourse as a measure for male sexual fitness.

Outcome varies within diagnostic categories related to severity of genital ambiguity and whether anatomic development is adequate to enhance a positive body image and sexual function. Hence, a male gender is currently frequently chosen in spite of concerns regarding penis development. The issue of diminished penis size persists. Most with 46,XY DSD report satisfaction with long-term results of masculinizing genitoplasty, but complaints relate to sexual activity and urinary symptoms. While most are satisfied with their sex assignment, the majority indicates that they feel uncomfortable with the opposite sex: issues like penis size, problems with erections and ejaculation, voice pitch and facial hair vary considerably.

The goal for surgical outcome has generally been good cosmetic appearance and potential for sexual experience with sufficient sensitivity for satisfactory responsiveness. Most data are from the relatively common DSD, 46,XX CAH. In this group, fertility is diminished and is correlated with extent of masculinization of external genitalia at birth. Functional outcomes of vaginoplasty, female gender identity, and attitudes regarding self and life in general are reported to be satisfactory among the majority in this group. Women with CAH who had nerve-sparing genital surgery, rather than traditional surgical approaches, had greater clitoral sensitivity. The ability of achieve orgasm was not different from controls nor was this orgasmic ability correlated with clitoral sensitivity. Satisfaction with sexual life was not different from controls, except for those with complete loss of function mutations on both alleles. In the latter group, satisfaction with sexual life was not correlated with ability to orgasm. Satisfaction, including sexual function, is reported after vaginoplasty with sigmoid colon and jejunal flap. After surgery for distal, mid, and proximal hypospadias, men had more urinary problems, shorter penile length and less satisfaction with appearance compared with comparably aged control men. These differences were greater among those having had proximal hypospadias. Among those with ovotesticular DSD, a portion of both males and females were sexually active, while

those assigned male had significant more post-surgical urethral complications.

An evaluation of Indonesian children, adolescents, and adults with DSDs, most of whom had not had medical or surgical treatment reports, findings that may be related to inadequate assessment and care but also to cultural factors, including the role of men and women in society. Gender change, primarily from female to male, primarily involving those with 46,XY karyotype and virilization was frequent among adults (44%). Gender identity behavior problems and cross-dressing behavior was more frequent among girls than boys.

In summary, reports indicate that anatomic insufficiencies, even after current therapies, may not be completely corrected. DSD conditions are lifelong with persistent consequences. While good family and peer relationships are supportive, outcome data indicate a persistence of sociocultural issues. Evidence suggests better cosmetic and functional genitalia after surgery and that satisfaction with sexual function is not primarily related to genital functionality including sensitivity. Hence, psychology factors including self-acceptance and good body image are at least as important as medical and surgical care. Finally, while outcome data for diagnostic groups provide general guidelines, the need for an individualized approach to promote a good outcome must be emphasized.

Fertility Issues

Fertility potential in DSD patients should be analyzed considering the clinical form and sex assignment. Here we will address fertility issues in patients with 46,XY DSD, 46,XX DSD (excluding CAH, dealt with earlier) and sex chromosome DSD (excluding Klinefelter and Turner syndromes, which have been described in detail in other chapters).

A. 46,XY DSD   Patients with complete forms of 46,XY DSD are raised as females. In those cases resulting from **pure gonadal dysgenesis**, although the uterus and Fallopian tubes are present, spontaneous fertility is not possible due to the lack of oocytes and ovarian steroids. Pregnancy might be achieved after replacement therapy and oocyte donation.

In **severe defects of androgen synthesis** or in **CAIS**, Müllerian derivatives are absent. Nonetheless, the successful pregnancy recently reported in a patient with congenital absence of the uterus (Rokitansky syndrome) following uterine transplantation has opened a promising alternative.

As already discussed, partial forms of 46,XY DSD result in a broad phenotypic spectrum. In patients raised as males, fertility might be disturbed for several reasons. Spermatogenic defects are primarily present in patients with **partial testicular dysgenesis**, but may also be seen with **partial defects of androgen synthesis** and **PAIS**. Pubertal development among these patients may be partial, requiring testosterone replacement, and there is an increased risk of germ cell tumors. Longstanding cryptorchidism, anatomic defects—like hypospadias or malformations of the epididymis or vas deferens—and complications of genitourinary surgery are other factors affecting fertility. Most patients

are infertile, but there are reports of fatherhood in patients with testicular dysgenesis due to mutations in *NR5A1*, encoding SF1, and in *MAP3K1*, or with steroidogenic defects.

DHT synthesis defects represent a particular case because DHT has a major role in the masculinization of the urogenital sinus and external genitalia but not in spermatogenesis. Patients with 5α-reductase type 2 deficiency virilize spontaneously at puberty due to 5α-reductase type 1 activity. Adult patients usually have male libido and sexual activity if normal intercourse is not impaired by small penis size. Although semen analysis is characterized by low volume due to poor function of the prostate and seminal vesicles, sperm production occurs due to normal intratesticular testosterone concentration, and fertility has been reported.

In patients with mutations in *AMH* or its receptor *AMHR2*, azoospermia is frequent due to the longstanding cryptorchidism or to damage of testicular blood supply during surgical procedures.

B. 46,XX DSD   As mentioned earlier, 46,XX DSD due to CAH raises particular considerations regarding fertility, which are discussed in detail in the section of this chapter on CAH.

Patients with **aromatase deficiency** are born with ambiguous genitalia and progress to hypergonadotropic hypogonadism with pubertal delay, primary amenorrhea, and hyperandrogenism. Enlarged ovaries with cysts, prone to torsion, have been reported. These factors, along with surgical consequences of genital reconstruction, might affect reproduction but longterm consequences on fertility are unknown.

In patients with **ovotesticular DSD**, the testicular tissue is usually more or less dysgenetic. If the patient is reared as male, the considerations are similar to those previously described for 46,XY partial dysgenesis. The ovarian tissue usually develops more normally. Therefore, in patients raised as females the preservation of ovarian tissue is of major importance. Pregnancy has been reported, either spontaneously or with assisted reproductive techniques, in a limited number of cases. Unfortunately, many of them have had complications, like preterm labor or morbidity related to the delivery process, due to the female reproductive tract defects.

Patients with 46,XX testicular DSD usually have normal testicular function until mid-puberty with spontaneous progression of secondary sex characteristics. However, the existence of two X chromosomes and the absence of a Y chromosome drive to massive germ cell degeneration, small testes and azoospermia.

C. Sex chromosome DSD   Patients with sex chromosome aneuploidies and/or mosaicisms usually have dysgenetic gonads, and the considerations already made for other types of dysgenetic DSD apply. Recently, one case of paternity has been reported after successful intracytoplasmic sperm injection from a 46,XX/46,XY patient raised as male.

Puberty is best considered as one stage in the continuing process of growth and development that begins during gestation and continues until the end of reproductive life. After an interval of childhood quiescence—the juvenile pause—the hypothalamic pulse generator increases activity in the peripubertal period, just before the physical changes of puberty commence. This leads to increased secretion of pituitary gonadotropins and, subsequently, gonadal sex steroids that bring about secondary sexual development, the pubertal growth spurt, and fertility. Historical records show that the age at menarche in girls in Western countries has steadily declined over the last several hundred years; this is probably due to improvements in socioeconomic conditions, nutrition, and, therefore, the general state of health during that period. This trend appears to be continuing but now due to the effects of the obesity epidemic rather than the improvement in general health.

Many endogenous and exogenous factors can alter age at onset of puberty. While obesity may decrease the age of onset of puberty in girls, chronic illness and malnutrition often delay puberty. There is a significant concordance of age at menarche between mother-daughter pairs and within ethnic populations, indicating the influence of genetic factors. Recent study of genetic loci associated with the age of onset of puberty identified several genes that are likely involved in the regulation of menarche and puberty.

PHYSIOLOGY OF PUBERTY

Physical Changes Associated with Puberty

Descriptive standards proposed by Tanner for assessing pubertal development in males and females are in wide use (denoted as Sexual Maturation stages or, often, Tanner stages). They focus attention on specific details of the examination and make it possible to objectively record subtle progression of secondary sexual development that may otherwise be overlooked. Self-assessment of pubertal development by subjects using reference pictures is used in clinical studies but reliability is less than that achieved by physical examination.

A. Female changes   An early sign of puberty in the female, as noted in longitudinal studies, is an increase in height velocity that heralds the beginning of the pubertal growth spurt; girls are not usually examined frequently enough to demonstrate this change in clinical practice, so breast development is the first sign of puberty noted by most examiners. Breast development (Figure 15–1) is stimulated chiefly by ovarian estrogen secretion, although other hormones also play a part. The size and shape of the breasts may
FIGURE 15–1 **(A)** Stages of breast development (B) and female pubic hair development (P), according to Marshall and Tanner. *Stage B1*: Preadolescent; elevation of papilla only. *Stage B2*: Breast bud stage; elevation of breast and papilla as a small mound, and enlargement of areolar diameter. *Stage B3*: Further enlargement of breast and areola with no separation of their contours. *Stage B4*: Projection of areola and papilla

be determined by genetic and nutritional factors, but the characteristics of the stages in Figure 15–1A are similar in all females. Standards are available for the change in areolar (nipple) plateau diameter during puberty: nipple diameter changes little from stages B1 to B3 (mean of 3-4 mm) but enlarges substantially in subsequent stages (mean of 7.4 mm at stage B4 to 10 mm at stage B5), presumably as a result of increased estrogen secretion at the time of menarche. Areolae become more pigmented and erectile as development progresses. Other features reflecting estrogen action include enlargement of the labia minora and majora, dulling of the vaginal mucosa from its prepubertal reddish hue to pink (due to cornification of the vaginal epithelium), and production of a clear or slightly whitish vaginal secretion prior to menarche. Pubic hair development (see Figure 15–1A) is determined chiefly by adrenal and ovarian androgen secretion. Breast development and growth of pubic hair usually proceed at similar rates, but because discrepancies in rates of advancement are possible, it is best to stage breast development separately from pubic hair progression.

Uterine size and shape change with pubertal development as reflected by ultrasonographic studies. With prolonged estrogen stimulation, the fundus-cervix ratio increases, leading to a bulbous form, and the uterus elongates. An endometrial stripe appears with the onset of puberty that is not found in premature thelarche. Ovaries enlarge with pubertal progression. Small cysts are normally present in prepubertal girls and a multicystic appearance develops during puberty, but the polycystic appearance seen in abnormalities of puberty is not present. Experienced ultrasonographers can determine the developmental stage of the uterus and ovaries by comparing measurements with established standards.

It is important to note that girls achieve reproductive maturity prior to physical maturity and certainly prior to psychologic maturity.

B. Male changes The first sign of normal puberty in boys is an increase in the size of the testes to more than 2.5 cm in the longest diameter, excluding the epididymis: this is equivalent to a testicular volume of 4 mL or more. Most of the increase in testicular size is due to seminiferous tubular development secondary to stimulation by follicle-stimulating hormone (FSH), with a smaller component due to Leydig cell stimulation by luteinizing hormone (LH). Thus, if only Leydig cells are stimulated, as with a human chorionic gonadotropin (hCG)-secreting tumor, the testis does not grow as large as in normal puberty. Pubic hair development is brought about by adrenal and testicular androgen secretion and is classified separately from genital development, as noted in Figure 15–1B. A longitudinal study of more than 500 boys suggests adding a stage 2a (absence of pubic hair in the presence of a testicular volume of 3 mL or more) to the classic five stages of pubertal development. Further pubertal development occurred in 82% of the subjects in stage 2a after the passage of 6 months: thus, reaching stage 2a would allow the examiner to reassure a patient that further spontaneous development is likely soon. The appearance of spermatozoa in early morning urinary specimens (spermarche) occurs at a mean chronologic age of 13.4 years or a similar mean bone age; this usually occurs at gonadal stage 3 to 4 and pubic hair stage 2 to 4. Remarkably, spermaturia is more common earlier in puberty than later and boys are reported with spermaturia and no secondary sexual development, suggesting that sperm are directly released into the urine early in puberty while ejaculation may be required for the presence of sperm in the urine of older children.

It is important to note that, like girls, boys achieve reproductive maturity prior to physical maturity and also prior to psychologic maturity.

C. Age at onset Ideally, the upper and lower boundaries encompassing the age at onset of puberty should be set at 2.5 standard deviations (SDs) above and below the mean (encompassing 98.8% of the normal population). Previously, there was no comprehensive study of the start of secondary sexual development adequate to determine the lower limits of normal in U.S. children,

---

to form a secondary mound above the level of the breast. *Stage B5*: Mature stage; projection of papilla only, due to recession of the areola to the general contour of the breast. *Stage P1*: Preadolescent; the vellus over the area is no further developed than that over the anterior abdominal wall (ie, no pubic hair). *Stage P2*: Sparse growth of long, slightly pigmented, downy hair, straight or only slightly curled, appearing chiefly along the labia. This stage is difficult to see on photographs and is subtle. *Stage P3*: Hair is considerably darker, coarser, and curlier. The hair spreads sparsely over the superior junction of the labia majora. *Stage P4*: Hair is now adult in type, but the area covered by it is still considerably smaller than in most adults. There is no spread to the medial surface of the thighs. *Stage P5*: Hair is adult in quantity and type, distributed as an inverse triangle of the classic feminine pattern. Spread is to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle. **(B)** Stages of male genital development (G) and pubic hair development (P), according to Marshall and Tanner. Genital: *Stage G1*: Preadolescent. Testes, scrotum, and penis are about the same size and proportion as in early childhood. *Stage G2*: The scrotum and testes have enlarged, and there is a change in the texture and some reddening of the scrotal skin. There is no enlargement of the penis. *Stage G3*: Growth of the penis has occurred, at first mainly in length but with some increase in breadth; further growth of testes and scrotum. *Stage G4*: Penis further enlarged in length and girth with development of glans. Testes and scrotum further enlarged. The scrotal skin has further darkened. *Stage G5*: Genitalia adult in size and shape. No further enlargement takes place after stage G5 is reached. Pubic hair: *Stage P1*: Preadolescent. The vellus is no further developed than that over the abdominal wall (ie, no pubic hair). *Stage P2*: Sparse growth of long, slightly pigmented, downy hair, straight or only slightly curled, appearing chiefly at the base of the penis. This is subtle. *Stage P3*: Hair is considerably darker, coarser, and curlier and spreads sparsely. *Stage P4*: Hair is now adult in type, but the area it covers is still considerably smaller than in most adults. There is no spread to the medial surface of the thighs. *Stage P5*: Hair is adult in quantity and type, distributed as an inverse triangle. Spread is to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle. Most men have further spread of pubic hair. (Reproduced with permission from Styne DM. *Pediatric Endocrinology, A Clinical Handbook*. Switzerland: Springer International Publishing; 2016.)

as national studies began reporting when children were already 12 years of age or older. Thus, European standards, primarily those of Tanner, were modified for use in the United States. However, a study conducted in medical offices by specially trained pediatricians studying 17,070 girls brought in for routine visits provided information on girls in the United States as young as 3 years. The study revealed that 3% of Caucasian girls reach stage 2 breast development by 6 years of age and 5% by 7 years, whereas 6.4% of African-American girls had stage 2 breast development by 6 years and 15.4% by 7 years. Although this was not a randomly chosen population sampled by longitudinal study (and this led to controversy), it is the largest study available. These data led to the Lawson Wilkins Pediatric Endocrine Society statement that the diagnosis of precocious puberty could be defined as secondary sexual development starting prior to 6 years in African-American girls and prior to 7 years in Caucasian girls who are otherwise healthy. Recent analysis of data from NHANES III demonstrated that children with normal BMI values rarely have breast or pubic hair development before 8 years, although increased BMI in a subset of girls of Hispanic and African American ethnicity led to earlier development. *It is essential to use any such guidelines of the age of onset of puberty only in healthy girls with absolutely no signs of neurologic or other disease that might pathologically advance puberty or a grave diagnosis may be missed.*

Recent data indicate that boys who are overweight have earlier onset of puberty while obese boys have a later onset. However, there has been no change in the standards of the age at onset of puberty of boys in the general population, so 9 years is still taken as the lower limit of normal pubertal development in males, whereas 13½ years is the upper limit of normal development (although 14 years is often used as a simplified limit). **Caucasian** girls have a mean age of menarche later (12.9 years) than **African-American** girls (12.3 years), but this 6-month difference is less than the 1-year difference in the age at onset of other features of puberty between the two groups. A compensation occurs in pubertal development so that those girls who enter puberty at the earliest ages of the normal range take more time to reach menarche, and those who enter at older ages of the normal range progress faster to menarche. This discrepancy is more often found in obese or overweight girls and is attributed to local aromatase activity in adipose tissue.

There is frequent discussion about an earlier age of puberty in children in the United States now than in the past several decades. Data is available from longitudinal studies in the U.S. and abroad. The Bogalusa Heart Study shows that the gap between the age of menarche in **African Americans** and **Caucasians** has widened in the past decades, and this may be due to differing patterns of weight (and fat) gain. However longitudinal study from the Fells Institute shows that those girls who develop early have a tendency to increase their body mass index (BMI) values afterwards more than those who start puberty later. The presence or absence of menarche however, does not affect the interpretation of a BMI value.

Late onset of pubertal development above the upper age limit of normal may indicate hypothalamic, pituitary, or gonadal failure or, alternatively, normal variation (constitutional delay). The time from onset of puberty until adult development is complete is also of importance; significant delays in reaching subsequent stages may indicate any type of hypogonadism.

D. Growth spurt   The striking increase in growth velocity in puberty (pubertal growth spurt) is under complex endocrine control involving thyroid hormone, growth hormone (GH), and estrogen (see Chapter 6, Growth). Hypothyroidism decreases or eliminates the pubertal growth spurt. The amplitude of GH secretion increases in puberty, as does production of insulin-like growth factor (IGF-I); peak serum IGF-I concentrations are reached about 1 year after peak growth velocity, and serum IGF-I levels remain above normal adult levels for up to 4 years thereafter. GH and estrogen are important in the pubertal growth spurt; when either or both are deficient, the growth spurt is decreased or absent. Estrogen indirectly stimulates IGF-I production by increasing the secretion of GH. It also directly stimulates IGF-I production in cartilage. Estrogen is the most important factor in stimulating maturation of the chondrocytes and osteoblasts, ultimately leading to epiphysial fusion. A patient reported with estrogen receptor deficiency was tall, with continued growth past the age of 20 years with a remarkable retardation of skeletal maturation (and decreased bone density). Patients with aromatase deficiency, and therefore, impaired conversion of testosterone to estrogen, also demonstrate diminished advancement of bone age and decreased bone density, as well as continued growth extending into the third decade. With exogenous estrogen administration in the aromatase deficient patients, the bone age advanced, and the bone density increased. Such patients demonstrate the key role played by estrogen in advancing bone age and bringing about the cessation of growth by epiphysial fusion as well as the importance of estrogen in increasing bone density.

In girls, the pubertal growth spurt begins in early puberty and is mostly completed by menarche. In boys, the pubertal growth spurt occurs toward the end of puberty, at an average age 2 years older than in girls. Total height attained during the growth spurt in girls is about 25 cm; in boys, it is about 28 cm. The mean adult height differential of 12 cm between men and women is due in part to heights already attained before onset of the pubertal growth spurt and in part to the height gained during the spurt.

Twin studies from Finland demonstrate that the heritability estimate (proportion of variance of age of onset of puberty attributable to genetic variance) for age at onset of pubertal growth spurt was 0.91, 0.93 for age at peak height velocity, and 0.97 for adult height. In addition, the age at onset of the pubertal growth spurt was negatively associated with BMI in childhood.

Precocious puberty may coexist with GH deficiency: this situation may occur, for example, in a child with a brain tumor causing central precocious puberty who is treated with central nervous system radiation that subsequently causes GH deficiency. The precocious puberty may raise the growth rate to the normal range, thereby cloaking the GH deficiency, but the child does not grow at the excessive rate characteristic of precocious puberty with GH sufficiency.

E. Changes in body composition   Changes in body composition are also prominent during pubertal development.

Prepubertal boys and girls start with equal lean body mass, skeletal mass, and body fat, but at maturity men have approximately 1½ times the lean body mass, skeletal mass, and muscle mass of women, whereas women have twice as much body fat as men. Attainment of peak values of percentage of body fat, lean body mass, and bone mineral density is earlier by several years in girls than in boys, as is the earlier peak of height velocity and velocity of weight gain in girls.

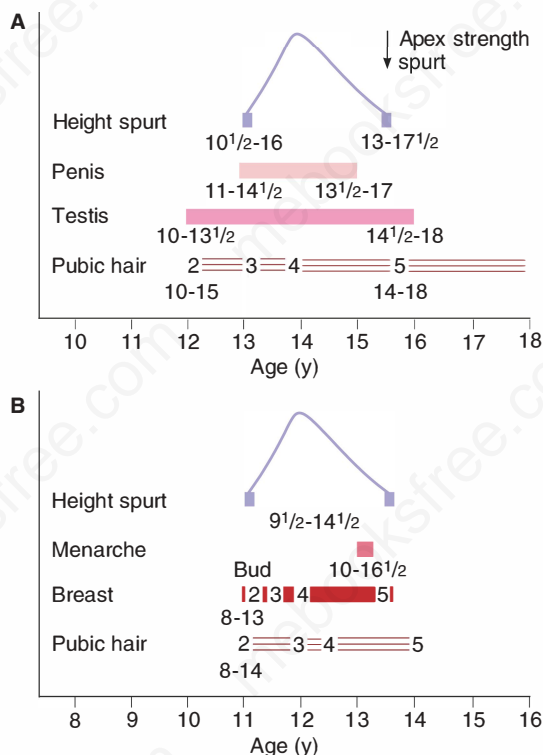
The most important phases of bone accretion occur during infancy and during puberty. Girls reach peak mineralization between 14 and 16 years of age, whereas boys reach a later peak at 17.5 years; both milestones occur after peak height velocity (Figure 15–2). The density of bone is determined by genetic factors; decreased bone mass is found in familial patterns even if subjects are studied before puberty. Patients with delay in puberty for any reason have a significant decrease in bone accretion and a delay in reaching peak bone mineral density, although bone density may later reach normal values in those with constitutional delay in puberty. Moderate exercise increases bone mass, but excessive exercise itself delays puberty; the ultimate outcome of excessive exercise in girls is the combination of exercise-induced amenorrhea, premature osteoporosis, and disordered eating, which is known as the female athletic triad.


FIGURE 15–2 Sequence of secondary sexual development in British males **(A)** and females **(B)**. The range of ages in Britain is indicated. American boys and girls start pubertal stages earlier than these British children (see text) but the sequence is the same. (Reproduced with permission from Marshall WA, Tanner JM. Variations in the pattern of pubertal changes in boys. *Arch Dis Child*. 1970 Feb;45(239):13-23.)

Unfortunately, in the United States, only a minority of adolescents receive the recommended daily allowance of calcium (>1000 mg/d depending on age) and vitamin D, raising concern over future bone health. While a healthy diet is important for all, it is especially important to ensure adequate calcium intake and vitamin D in patients with delayed or absent puberty and in patients treated with gonadotropin-releasing hormone (GnRH) agonists.

F. Other changes of puberty   Other changes that are characteristic of puberty are mediated either directly or indirectly by the change in sex steroids. For example, seborrheic dermatitis may appear, the mouth flora changes, and periodontal disease, rare in childhood, may occur in puberty. Insulin resistance intensifies in normal adolescents as well as those with type 1 diabetes mellitus during puberty. Puberty is a time of extensive change in the anatomy of the brain as pruning of dendritic connections occurs towards the beginning of puberty and myelinization of axons proceeds later; indeed these changes continue until about 25 years of age and are thought to account for the risk-taking behaviors and poor judgment characteristics of early to mid puberty compared to later pubertal individuals who have further maturation of cognitive and executive functions such as judgement. Puberty is also time of the onset of many significant psychiatric disorders including depression. As a reflection of the importance of the changes in brain architecture is the recent discovery of a gene mutation (C4) that inhibits the correct pruning connections in the gray matter and which is associated with the onset of schizophrenia. Sleep patterns change during puberty as, with no light or social cues, adolescents wake up later than in childhood; this change of sleep patterns from a "lark-like" to an "owl-like" pattern of sleep continues until about 19 to 21 years of age.

Endocrine Changes from Fetal Life to Puberty

Pituitary gonadotropin secretion is controlled by the hypothalamus, which releases pulses of GnRH into the pituitary-portal system to reach the anterior pituitary gland by 20 weeks of gestation. Control of GnRH secretion is exerted by a hypothalamic pulse generator in the arcuate nucleus. It is sensitive to feedback control from sex steroids and inhibin, a gonadal protein product that controls the frequency and amplitude of gonadotropin secretion during development in both sexes and during the progression of the menstrual cycle in females (see Chapter 13).

In males, LH stimulates the Leydig cells to secrete testosterone, and FSH stimulates the Sertoli cells to produce inhibin. Inhibin feeds back on the hypothalamic-pituitary axis to inhibit FSH. In females, FSH stimulates the granulosa cells to produce estrogen and the follicles to secrete inhibin, and LH appears to play a minor role in the endocrine milieu until menarche. With menarche, LH triggers ovulation and later stimulates the theca cells to secrete androgens (see Chapter 13). The continuum of development between the fetus and the adult is well illustrated by the changes that occur in the hypothalamic-pituitary-gonadal axis. Gonadotropins are demonstrable in fetal pituitary glands and serum during the first trimester. The pituitary content

of gonadotropins rises to a plateau at midgestation. Fetal serum concentrations of LH and FSH rise to a peak at midgestation and then gradually decrease until term. During the first half of gestation, hypothalamic GnRH content also increases, and the hypophyseal-portal circulation achieves anatomic maturity by midgestation. These data are compatible with a theory of early unrestrained GnRH secretion stimulating pituitary gonadotropin secretion, followed by the appearance of central nervous system factors that inhibit GnRH release and decrease gonadotropin secretion after mid-gestation. Because the male fetus has measurable serum testosterone concentrations but lower serum gonadotropin concentrations than the female fetus, negative feedback inhibition of gonadotropin secretion by testosterone appears to operate after mid-gestation.

A. Changes at birth

At term, serum gonadotropin concentrations are suppressed in the neonate, but with postnatal clearance of high circulating estrogen concentrations, negative inhibition is reduced and postnatal peaks of serum LH and FSH are measurable for several months to up to a few years after birth. Serum testosterone concentrations may be increased to midpubertal levels during the several months after birth in normal males and serum estradiol rises in pulses for the first 2 years in infant girls; this period is considered the mini-puberty of infancy. These peaks of gonadotropins and sex steroids in normal infants complicate the diagnosis of central precocious puberty at these youngest ages, because it is difficult to decide whether to attribute the gonadotropin and sex steroid peaks to central precocious puberty or to normal physiology (the mini-puberty of infancy). While episodic peaks of serum gonadotropins may occur until 2 years of age, serum gonadotropin concentrations are low during later years in normal childhood.

B. The juvenile pause or the mid-childhood nadir of gonadotropin secretion

While serum gonadotropin concentrations are low in midchildhood, sensitive assays indicate that pulsatile secretion occurs and that the onset of puberty is heralded by an increase in amplitude of secretory events and a change in frequency. Twenty-four hour mean concentrations of LH, FSH, and testosterone rise measurably within 1 year before the development of physical pubertal changes. Patients with gonadal failure—such as those with the syndrome of gonadal dysgenesis (Turner syndrome)—demonstrate an exaggeration of the normal pattern of gonadotropin secretion, with exceedingly high concentrations of serum LH and FSH during the first several years of life. Such patients demonstrate that negative feedback inhibition is active during childhood; without sex steroid or inhibin secretion to exert inhibition, serum gonadotropin values are greatly elevated. During midchildhood, normal individuals and patients with primary hypogonadism have lower serum gonadotropin levels than they do in the neonatal period, but the range of serum gonadotropin concentrations in hypogonadal patients during midchildhood is still higher than that found in healthy children of the same age. The decrease in serum gonadotropin concentrations in primary agonadal children during midchildhood is incompletely understood, but has been attributed to an increase in the central nervous

system inhibition of gonadotropin secretion during these years. This inhibition is mediated by gamma aminobutyric acid (GABA) and other inhibitory neuropeptides. The recent discovery of the *MRKN3* (makorin ring finger protein 3) gene which is considered a "brake" on puberty adds considerably more understanding of the juvenile pause; when this gene is silenced, precocious puberty occurs. Thus, the juvenile pause in normal children and those with primary gonadal failure appears to be due to central nervous system restraint of GnRH secretion.

C. Peripubertal gonadotropin increase

Prepubertal children demonstrate a circadian rhythm of LH and FSH secretion of low amplitude with a pattern of low levels of sex steroid secretion lagging behind the gonadotropin rhythm. The delay is presumably due to the time necessary for biosynthesis and secretion of sex steroids. Thus, the changes that occur at puberty do not arise *de novo* but are based on preexisting patterns of endocrine secretion. In the peripubertal period, endogenous GnRH secretion increases in amplitude and frequency during the early hours of sleep and serum testosterone and estrogen concentrations rise several hours later, again suggesting that biosynthesis or aromatization occurs during the period of delay—a pattern that differs from the prepubertal period mainly in the increased amplitude of the secretion encountered in puberty. As puberty progresses in both sexes, the peaks of serum LH and FSH occur more often during waking hours; and, finally, in late puberty, the peaks occur at all times, eliminating the diurnal variation.

During the peripubertal period of endocrine change prior to secondary sexual development, gonadotropin secretion becomes less sensitive to negative feedback inhibition. Before this time, a small dose of exogenous sex steroids virtually eliminates gonadotropin secretion, whereas afterward a far larger dose is required to suppress serum FSH and LH. Thus, an equilibrium balancing pubertal concentrations of gonadotropins and sex steroids is reached.

The switch that triggers the onset of puberty is unknown, but several neurotransmitters are invoked in the process, including GABA and *N*-methyl-D-aspartate. *KISS1*, a human metastasis suppressor gene at locus 19p13.3, which codes for metastin (also known as kisspeptin), a 145 amino acid peptide, is an important agent in the process. Metastin is the endogenous agonist for GPR54, a Gq/11-coupled receptor of the rhodopsin family (metastin receptor), which is found in the brain, mainly in the hypothalamus and basal ganglia, as well as in the placenta. *KISS1* mRNA levels increase with puberty in intact male and female monkeys from the juvenile to midpubertal stages. Furthermore, administration of KISS1 via intracerebral catheters to GnRH-primed juvenile female rhesus monkeys stimulates GnRH release, release that is abolished by infusion of GnRH antagonist. Thus, it is postulated that KISS1 signaling through the GPR54 receptor of primate hypothalamus may be activated at the end of the juvenile pause and contribute to the pubertal resurgence of pulsatile GnRH release of puberty, serving as a trigger for the onset of puberty. A decrease in expression of *MKRN3*, a gene which is considered a brake on pubertal development, occurs in the pubertal period; decreased expression of this imprinted gene is passed through the father and leads to precocious puberty.

Highly sensitive *sandwich* assays (immunoradiometric [IRMA]) and immunochemiluminometric assays (ICMA), "third-generation assays" are available for gonadotropin determination. They can be used to indicate the onset of pubertal development solely with basal samples usually without the necessity for GnRH testing (see GnRH and GnRH agonist testing in the Central Precocious Puberty section). Basal LH values in the pubertal range (different laboratory reference ranges differ) determined by third-generation assays in random blood samples are highly predictive of elevated peak GnRH-stimulated LH and therefore indicate the onset of central precocious puberty or normal puberty. These third-generation assays further reflect the remarkable logarithmic increase in spontaneous LH secretion in the latest stages of prepuberty and earliest stages of puberty as the testicular volume increases from 1 to 2 mL to 10 mL; these increases in serum LH are far greater proportionately than those found in the last stages of pubertal development. The magnitude of increase in serum testosterone is also greater in the early stages of male puberty and correlates with the increase in serum LH during this same period of early pubertal development. Note that standard LH and FSH assays are not sensitive enough to detect the changes seen with the ultrasensitive assays. Furthermore, the laboratory must have pubertal standard values available to permit accurate interpretation of the measurements. Since both types of assays are available commercially, care in ordering is needed to ensure a pediatric assay is chosen.

D. Sex steroid secretion   Sex steroid secretion is correlated with the development of gonadotropin secretion. During the postnatal period of increased episodic gonadotropin secretion, plasma concentrations of gonadal steroids are episodically elevated. This indicates the potential for secretory activity in the neonatal gonad. Later, when gonadotropin secretion decreases in midchildhood, gonadal activity decreases, but the testes can still be stimulated by LH or hCG and the ovaries by FSH, with resulting secretion of gonadal steroids. An ultrasensitive estradiol assay demonstrates higher values of serum estradiol in prepubertal girls than prepubertal boys, indicating basal ovarian activity during the juvenile pause. With the onset of puberty, serum gonadal steroid concentrations progressively increase. While sex steroids are secreted in a diurnal rhythm in early puberty, as are gonadotropins, sex steroids are bound to sex hormone–binding globulin (SHBG), so that the half-life of sex steroids is longer than that of gonadotropins. Thus, random daytime measurements of serum sex steroids are more helpful in determining pubertal status than random measurements of serum gonadotropins but still are not infallible, for example, early pubertal girls may or may not have pubertal values of estradiol on any given sample.

Most (97%-99%) of the circulating estradiol and testosterone is associated with SHBG. The free hormone is the active fraction, but SHBG modulates the activity of the total testosterone and estradiol. Prepubertal boys and girls have equal concentrations of SHBG, but because testosterone decreases SHBG and estrogen increases SHBG, adult males have only half the concentration of SHBG compared with adult females. Thus, lower SHBG levels amplify androgen effects in men. While adult men have 20 times the amount of plasma testosterone that adult women have, adult men have 40 times the amount of free testosterone that adult women have.

E. GnRH stimulation   The use of exogenous GnRH has further clarified the pattern of pubertal development. When GnRH or GnRH agonist is administered to children less than 2 years of age, pituitary secretion of LH and FSH increases markedly. During the juvenile pause, the period of low basal gonadotropin secretion (after age 2 until the peripubertal period), exogenous GnRH has less effect on LH release. By the peripubertal period, GnRH or GnRH agonist induces a greater rise in LH concentrations in boys and girls, and this response continues until adulthood. There is no significant change in the magnitude of FSH secretion after GnRH with the onset of puberty, though females at all ages release more FSH than males.

The rise of LH after GnRH is used as a diagnostic test to differentiate central precocious puberty from the prepubertal state. Values are laboratory specific, but it has been reported that a basal LH value over 0.3 or a peak LH over 5.5 U/L one hour after 10 µg/kg subcutaneous GnRH administration indicates the onset of puberty with 96% specificity in girls. More specificity is reported in boys with a 4-hour peak LH value over 14.8 to 15 units per liter after 10 µg/kg of leuprolide acetate.

Gonadotropins are released in secretory spurts in response to endogenous GnRH, which itself is secreted episodically about every 90 to 120 minutes in response to a central nervous system *pulse generator*. GnRH can be administered to patients in episodic boluses by a programmable pump that mimics the natural secretory episodes. A prepubertal subject without significant gonadotropin peaks demonstrates the normal pubertal pattern of episodic secretion of gonadotropins after only a few days of exogenously administered GnRH boluses. Hypogonadotropic patients, who in the basal state do not have normal secretory episodes of gonadotropin release, may be stimulated to a pattern of normal adult episodic gonadotropin secretion by this method of pulsatile GnRH administration.

This phenomenon is used in clinical practice to bring about ovulation or spermatogenesis to foster fertility. Varying the timing of pulsatile exogenous GnRH administration can regulate the ratio of FSH to LH just as the FSH to LH ratio changes as the frequency of endogenous hypothalamic GnRH release shifts during the menstrual cycle and to some degree in puberty naturally. Increasing the frequency of GnRH pulses increases the LH-FSH ratio; an increased ratio is characteristic of midcycle and peripubertal dynamics. Alternatively, if GnRH is administered continuously rather than in pulses or if long-acting superactive analogs of GnRH are given, a brief period of increased gonadotropin secretion is followed by LH and FSH suppression (see later). This phenomenon is responsible for the therapeutic effects of GnRH analogs in conditions such as central precocious puberty.

F. Leptin and puberty   Leptin is a hormone produced in adipose cells that suppresses appetite through interaction with its receptor in the hypothalamus. Leptin plays a major role in pubertal development in mice and rats. Genetically leptin-deficient mice (ob/ob) do not initiate puberty. Leptin replacement promotes pubertal development in this mouse, and leptin

administration causes an immature normal mouse to progress through puberty. A leptin-deficient girl at 9 years of age was remarkably obese and had a bone age of 13 years (usually appropriate for the onset of normal puberty) but no significant gonadotropin pulses and no physical evidence of pubertal development. With leptin treatment, gonadotropin peaks appeared, and pubertal development followed. Individuals with leptin receptor deficiency also have disordered puberty. Longitudinal studies demonstrate that leptin increases in girls during puberty in synchrony with the increase in fat mass, while leptin decreases in boys, with increased lean body mass and decreased fat mass, in relation to testosterone production. While leptin does not appear to trigger the onset of puberty in normal adolescents, changes in plasma leptin concentrations may accompany pubertal changes rather than cause them. Leptin is a necessary component of pubertal development in human beings but not a major stimulant to this development; leptin is necessary but not sufficient for pubertal development.

Ovulation and Menarche

The last stage in hypothalamic-pituitary development is the onset of positive feedback, leading to ovulation and menarche. The ovary contains a paracrine system that regulates follicular atresia or development; it is only in the last stages of puberty that gonadotropins come into play in the maturation of the follicle. After midpuberty, estrogen in the appropriate amount at the appropriate time can stimulate gonadotropin release, whereas higher doses of estrogen can suppress gonadotropin secretion. The frequency of pulsatile GnRH release increases during the late follicular phase of the normal menstrual cycle and raises the ratio of LH to FSH secretion. This stimulates the ovary to produce more estrogen and leads to the midcycle LH surge that causes ovulation. Administration of pulsatile GnRH by programmable pump can be used to bring about fertility in patients with hypothalamic GnRH deficiency by mimicking this natural pattern as noted earlier.

However, even if the midcycle surge of gonadotropins is present, ovulation may not occur during the first menstrual cycles; 90% of menstrual cycles are anovulatory in the first year after menarche, and it is not until 4 to 5 years after menarche that the percentage of anovulatory cycles decreases to less than 20%. This high prevalence of anovulatory periods may be due to unrecognized PCOS in the population studied sound rather than a normal developmental phenomenon. However, some of the first cycles after menarche may be ovulatory, and fertility is possible in the first cycle.

Adrenarche

Although the hypothalamic-pituitary axis has been well characterized in recent years, our understanding of the mechanism of control of adrenal androgen secretion is still somewhat rudimentary. The adrenal cortex normally secretes the weak androgens dehydroepiandrosterone (DHEA), its sulfate, dehydroepiandrosterone sulfate (DHEAS), and androstenedione in increasing amounts beginning at about 6 to 7 years of age in girls and 7 to 8 years of age in boys (Table 15–1). A continued rise in adrenal androgen secretion persists until late puberty. Thus, adrenarche (the secretion of adrenal androgens) occurs years before gonadarche (the secretion of gonadal sex steroids). Patients with Addison disease, who do not secrete adrenal androgens, and patients with premature adrenarche, who secrete increased amounts of adrenal androgens at an early age, usually enter gonadarche at a normal age. This suggests that age at adrenarche does not significantly influence age at gonadarche. Furthermore, patients treated with a GnRH agonist to suppress gonadotropin secretion progress through adrenarche despite their suppressed gonadarche.

Miscellaneous Metabolic Changes

The onset of puberty is associated with many changes in laboratory values that are either directly or indirectly caused by the rise of sex steroid concentrations and careful attention to the reference range of laboratory data during puberty is important. Thus, in boys, hematocrit rises, and high-density lipoprotein (HDL) concentrations fall as a consequence of increasing testosterone. In both boys and girls, alkaline phosphatase rises normally during the pubertal growth spurt (often this rise is incorrectly interpreted as evidence for a tumor or liver abnormality). Serum IGF-I concentrations rise with the pubertal growth spurt, but IGF-I is more closely correlated with sex steroid concentration than with growth rate. IGF-I levels reach a peak 1 year after peak growth velocity is reached and remain elevated for 4 years thereafter, even though growth rate is decreasing. Prostate-specific antigen (PSA) is measurable after the onset of puberty in boys and provides another biochemical indication of pubertal onset.

DELAYED PUBERTY OR ABSENT PUBERTY (SEXUAL INFANTILISM)

Any girl of 13 or boy of 14 years (13.5 years in some sources) of age without signs of pubertal development falls more than 2.5 SD above the mean and is considered to have delayed puberty (Table 15–2). By this definition, 0.6% of the healthy population is classified as having delay in growth and adolescence. These normal patients need reassurance rather than treatment and ultimately progress through the normal stages of puberty, albeit later than their peers. The examining physician must make the sometimes difficult decision about which patients older than these guidelines are constitutionally delayed and which have organic disease.

Constitutional Delay in Growth and Adolescence

A patient with delayed onset of secondary sexual development, whose stature is shorter than that of age-matched peers but who consistently maintains a normal growth velocity for bone age and whose skeletal development is delayed more than two SD from the mean, is likely to have constitutional delay in puberty (Figure 15–3). These patients are at the older end of the normal distribution curve describing the age at onset of puberty. A family history

XX and XY gonadal dysgenesis

of a similar pattern of development in a parent or sibling supports the diagnosis. A mother or sister who starts menarche after 15 years of age or a father or brother who started shaving or experienced considerable growth after high school are supportive historical details. The subject is usually thin as well. In many cases, even if they show no physical signs of puberty at the time of examination, the initial elevation of gonadal sex steroids has already begun, and their basal LH concentrations measured by ultrasensitive third-generation assays or their plasma LH response to exogenous GnRH or GnRH agonist is pubertal. In boys, an 8 AM serum testosterone value above 20 ng/dL (0.7 mmol/L) also indicates that secondary sexual development will commence within a period of 15 months.

In some cases, observation for endocrine or physical signs of puberty must continue for a period of months or years before the diagnosis is made. Generally, signs of puberty appear after the patient reaches a skeletal age of 11 years (girls) or 12 years (boys), but there is great variation. Patients with constitutional delay in adolescence almost always manifest secondary sexual development by 18 years of chronologic age, although there is one reported case of spontaneous puberty occurring at 25 years of age. Reports of patients with Kallmann syndrome and others with constitutional

delay in puberty within one family suggest a possible relationship between the two conditions (see later and Chapter 4). Adrenarche is reported to be delayed—along with gonadarche—in constitutional delay in puberty.

Hypogonadotropic Hypogonadism

The absent or decreased ability of the hypothalamus to secrete GnRH or of the pituitary gland to secrete LH and FSH characterizes hypogonadotropic hypogonadism. This classification suggests a long-term condition requiring replacement therapy. If the pituitary deficiency is limited to gonadotropins, a patient's stature is usually close to average height for age until the usual age of the pubertal growth spurt, in contrast to shorter patients with constitutional delay. Bone age is usually not delayed in childhood but does not progress normally after the patient reaches the age at which sex steroid secretion usually stimulates further maturation of the skeleton. Patients may reach taller stature than expected for family. However, if GH deficiency accompanies gonadotropin deficiency, severe short stature will result.

A. Central nervous system disorders

1. **Tumors**—A tumor involving the hypothalamus or pituitary gland can interfere with hypothalamic-pituitary-gonadal function as well as control of GH, adrenocorticotropic hormone (ACTH), thyrotropin (TSH), prolactin (PRL), and vasopressin secretion. Thus, delayed puberty may be a manifestation of a central nervous system tumor accompanied by any or all of the following: GH deficiency, secondary hypothyroidism, secondary adrenal insufficiency, hyperprolactinemia, and diabetes insipidus. The combination of anterior and posterior pituitary deficiencies acquired after birth makes it imperative that a hypothalamic-pituitary tumor be eliminated as the cause before assigning another diagnosis.

   Craniopharyngioma is rare but is the most common type of hypothalamic-pituitary tumor leading to delay or absence of pubertal development. This neoplasm originates in Rathke's pouch but may develop into a suprasellar tumor. The peak age incidence of craniopharyngioma is between 6 and 14 years. Presenting symptoms may include headache, visual deficiency, growth failure, polyuria, and polydipsia; presenting signs may include visual defects such as bitemporal hemianopsia due to optic atrophy, or, alternatively, papilledema. Clinical manifestations and laboratory evaluation may reflect endocrinopathies (found in 80% including GH axis abnormalities in 75%, hyperprolactinemia in 20%, hypothyroidism in 25%, adrenal insufficiency in 25%, diabetes insipidus (DI) in 9% to 17%, as well as gonadotropin deficiency in 40% in one large series). Bone age is often delayed at the time of presentation.

   Calcification in the suprasellar region is the hallmark of craniopharyngiomas; 80% of cases have calcifications on lateral skull x-ray, and a higher percentage show this on computed tomography (CT); while calcifications cannot be seen on standard magnetic resonance imaging (MRI), susceptibility weighted imaging (SWI) allows an MRI to reveal calcification. The tumor often presents a cystic appearance on CT or MRI scan and at the time of surgery may contain dark, cholesterol-laden fluid. The rate of growth of craniopharyngiomas is quite variable—some are indolent and some are quite aggressive. Small intrasellar tumors may be resected by transsphenoidal
FIGURE 15–3 Girl, 13-4/12 years old, with constitutional delay in growth and puberty. History revealed a normal growth rate but short stature at all ages. Physical examination revealed a height of 138 cm (−4.5 SD) and a weight of 28.6 kg (−3 SD). The patient recently had early stage 2 breast development, with 1 cm of glandular tissue on the right breast and 2 cm on the left breast. The vaginal mucosa was dulled, and there was no pubic hair. Karyotype was 46,XX. Bone age was 10 years. After administration of GnRH, LH and FSH rose in a pubertal pattern. Estradiol was 40 pg/mL. She has since spontaneously progressed through further pubertal development. (Reproduced with permission from Styne DM, Kaplan SL. Normal and abnormal puberty in the female. *Pediatr Clin North Am*. 1979 Feb;26(1):123-148.)

surgery; larger ones require partial resection and radiation therapy (see Chapter 4). Recurrence of this tumor after apparent complete removal is reported and lends support to the use of radiation therapy in addition to surgery.

Extrasellar tumors that involve the hypothalamus and cause sexual infantilism include germinomas, gliomas (possibly associated with neurofibromatosis), and astrocytomas (see Chapter 4). However, depending on endocrine secretory activity or location, these tumors may alternatively cause central precocious puberty. Intrasellar tumors such as chromophobe adenomas are quite rare in children compared with adults. Hyperprolactinemia—with or without a diagnosed microadenoma or galactorrhea—may delay the onset or progression of puberty; with dopaminergic therapy to decrease PRL concentrations, puberty progresses.

2. **Other acquired central nervous system disorders**—These disorders may lead to hypothalamic-pituitary dysfunction. Granulomatous diseases such as Hand-Schüller-Christian disease or histiocytosis X, when involving the hypothalamus, most frequently lead to diabetes insipidus, but any other hypothalamic defect may also occur, including GH or gonadotropin deficiency. Tuberculous or sarcoid granulomas, other postinfectious inflammatory lesions, vascular lesions, and trauma more rarely cause hypogonadotropic hypogonadism.

3. **Developmental defects**—Developmental defects of the central nervous system may cause hypogonadotropic hypogonadism or other types of hypothalamic dysfunction. Cleft palate or other midline anomalies may also be associated with hypothalamic dysfunction. Optic dysplasia is associated with small, hypoplastic optic disks and, in some patients, absence of the septum pellucidum on CT or MRI (septo-optic dysplasia); associated hypothalamic deficiencies are often present (see Chapters 4 and 6). This may be caused by mutations in *Hesx-1 homeodomain,* (*HESX-1* OMIM*601802). *Homeobox* gene expressed in ES cells (HESX-1 OMIM#182230, septooptic dysplasia).

Optic hypoplasia or dysplasia must be differentiated from optic atrophy; optic atrophy implies an acquired condition and may indicate a hypothalamic-pituitary tumor. Both anterior and/or posterior pituitary deficiencies may occur with either congenital midline defects or acquired hypothalamic-pituitary defects. Early-onset GH deficiency or early onset of a combination of anterior and posterior pituitary deficiencies suggests a congenital defect. Patients who have isolated deficiency of gonadotropins tend to be of normal height until the teenage years but lack a pubertal spurt. They have eunuchoid proportions of increased span for height and decreased upper to lower segment ratios. Their skeletal development is delayed for chronologic age during the teenage years; they continue to grow after an age when normal adolescents stop growing. Adult height is often increased in hypogonadotropic hypogonadal individuals.

4. Radiation therapy—Central nervous system radiation therapy involving the hypothalamic-pituitary area can lead to hypogonadotropic hypogonadism with onset at 6 to 18 months (or longer) after treatment. GH is more frequently affected than gonadotropin secretion, and GH deficiency occurs with exposure to an 18-Gy dose. Other hypothalamic deficiencies such as gonadotropin deficiency, hypothyroidism, and hyperprolactinemia occur more often with higher doses of radiation.

B. Isolated gonadotropin deficiency **Kallmann syndrome 1** is the most common genetic form of isolated gonadotropin deficiency (Figure 15–4). Gonadotropin deficiency in these patients is associated with hypoplasia or aplasia of the olfactory lobes and olfactory bulb causing hyposmia or anosmia. Remarkably, patients may not notice that they have no sense of smell, although olfactory testing reveals the finding. GnRH-containing neurons fail to migrate from the olfactory placode (where they originate) to the medial basal hypothalamus in Kallmann syndrome. This is a familial syndrome of variable manifestations in which anosmia may occur with or without hypogonadism in a given member of a kindred. **X-linked Kallmann syndrome** is due to gene deletions in the region of Xp22.3 (OMIM#308700. KAL1), causing the absence of the *KAL1* gene which encodes for anosmin, an adhesion molecule that plays a key role in the migration of GnRH neurons and olfactory nerves to the hypothalamus.

There is an association of Kallmann syndrome 1 with X-linked ichthyosis due to steroid sulfatase deficiency, developmental delay, and chondrodysplasia punctata, probably due to a microdeletion. Associated abnormalities in Kallmann syndrome 1 may affect the kidneys and bones, and patients may have undescended testes, gynecomastia, and obesity. Mirror hand movements (bimanual synkinesia) are reported, with MRI evidence of abnormal development of the corticospinal tract. Adult height is normal, although patients are delayed in reaching adult height. **Kallmann syndrome 2** (OMIM#147950) is inherited in an autosomal dominant pattern and is due to a mutation in the *FGFR1* (*fibroblast growth factor receptor 1* OMIM*136350) gene. **Kallmann syndrome 3** (OMIM#244200) exhibits an autosomal recessive pattern and appears to be related to mutations in *PROKR2* and *PROK2*, encoding prokineticin receptor-2 and prokineticin-2, respectively. FGF8 may also be involved.

While kisspeptin (OMIM*603286, KISS1 METASTASIS SUPPRESSOR; KISS1) and GRP54 (G protein–coupled receptor 54 (OMIM*604161, KISS1 RECEPTOR; KISS1R)) play roles of importance in the onset of puberty, only rare patients have been reported with defects in the kisspeptin-GPR54 axis due to a loss of function mutation in the gene for the GRP54 receptor (OMIM#614842). The first human beings with defects in these molecules were reported in several kindreds, some consanguineous,
FIGURE 15–4 Boy, 15-10/12 years old, with Kallmann syndrome. His testes were originally undescended, but they descended into the scrotum after human chorionic gonadotropin treatment was given. His height was 163.9 cm (−1.5 SD), and the US-LS ratio was 0.86 (eunuchoid). The penis measurement was prepubertal at 6.3 cm × 1.8 cm. Each testis was 1 cm × 2 cm, prepubertal. Plasma LH was not detectable and rose little after administration of 100 μg of GnRH; FSH rose minimally. Testosterone did not change from 17 ng/dL. He had no ability to smell standard odors. (Reproduced with permission from Yen SSC, Jaffe RB. *Reproductive Endocrinology*. Philadelphia: WB Saunders; 1978.)

presenting with hypogonadotropic hypogonadism. Other cases of hypogonadotropic hypogonadism may occur sporadically or in an autosomal recessive pattern without anosmia; there are 22 types of HH with or without anomia listed on the Online Mendelian Inheritance in Man (OMIM) site. The *GnRH* gene would seem a likely candidate for a mutation as the cause of the condition, but while mutations of the *GnRH receptor* gene (OMIM#146110), *GnRHR*, were noted years ago, not until 2009 were mutations in the *GnRH1* gene demonstrated (OMIM#614841). Other mutations causing hypogonadotropic hypogonadism without anosmia include the *SF-1* (*steroidogenic factor 1*), *HESX-1* (*Hesx-1 homeodomain*), *LHX3* (OMIM*600577) (*LIM homeobox gene 3*), *PROP-1* (*prophet of PIT1*) genes. X-linked congenital adrenal hypoplasia is associated with hypogonadotropic hypogonadism (*DAX1* OMIM#300200). Adrenal hypoplasia, congenital AHC, glycerol kinase deficiency, and muscular dystrophy have also been linked to this syndrome. The gene locus is at Xp21.3-p21.2 and involves a mutation in the *DAX1* gene in many but not all patients. An autosomal recessive form of congenital adrenal hypoplasia is reported. Some hypogonadal patients lack only LH secretion and have spermatogenesis without testosterone production (fertile eunuch syndrome); others lack only FSH (see Chapters 12 and 13).

While a specific genetic diagnosis for hypogonadotropic hypogonadism suggests a permanent defect, long-term studies do not always bear this out. Men with a variety of mutations followed for years are reported to revert to normal or near-normal gonadotropin function in 10% to 20% of cases. Thus, long-term follow-up is indicated.

C. Idiopathic hypopituitary dwarfism (growth hormone deficiency in the absence of defined anatomic or organic defects)

Patients with congenital GH deficiency have early onset of growth failure (Figure 15–5); this feature distinguishes them from patients with GH deficiency due to hypothalamic tumors, who usually have late onset of growth failure. Even without associated gonadotropin deficiency, untreated GH-deficient patients often have delayed onset of puberty associated with their delayed bone ages. With appropriate human growth hormone (hGH) therapy, however, onset of puberty occurs at a normal age. Patients who have combined GH and gonadotropin deficiency do not undergo puberty even when bone age reaches the pubertal stage. Idiopathic hypopituitarism is usually sporadic, but may follow an autosomal recessive or X-linked inheritance pattern due to one of the gene defects listed earlier.

The syndrome of microphallus (penile length <2 cm at birth due to congenital gonadotropin or GH deficiency) and neonatal hypoglycemic seizures (due to congenital ACTH deficiency or GH deficiency) must be diagnosed and treated early to avoid central nervous system damage due to hypoglycemia (these findings may also occur in septo-optic dysplasia). Patients with this syndrome do not undergo spontaneous pubertal development. Testosterone in low doses (testosterone enanthate, 25 mg intramuscularly every month for three doses) can increase the size of the penis in infants diagnosed with congenital hypopituitarism without significantly advancing the bone age. Males with isolated
FIGURE 15–5 Twenty-year-old male with congenital deficiency of GRF, GnRH, TRF, and CRF. Height was 8 SD below the mean, and the phallus was 2 cm × 1 cm. Bone age was 10 years, and the sella turcica was small on lateral skull x-ray. LH rose minimally from a low basal value after administration of 100 μg of GnRH. Testosterone was virtually undetectable and did not rise after administration of GnRH. (Reproduced with permission from Yen SSC, Jaffe RB. *Reproductive Endocrinology*. Philadelphia: WB Saunders; 1978.)

GH deficiency can also have microphallus; the penis enlarges with hGH therapy in these patients. It is important to note that microphallus due to hypopituitarism may be successfully treated with testosterone leading to adult male sexual function, and sex reversal should not be considered (see Chapter 14).

Birth injury, asphyxia, or breech delivery is more common in the neonatal history of patients with idiopathic hypopituitarism, especially affected males. While some subjects with breech delivery have central nervous system MRI abnormalities including interrupted pituitary stalk and ectopic posterior pituitary gland, cause and effect is not established as some individuals with breech delivery and hypopituitarism have no such MRI findings.

D. Miscellaneous disorders

1. **Chronic disease and malnutrition**—A delay in sexual maturation may be due to chronic disease or malnutrition. For example, children with intractable asthma have delayed pubertal development leading to short stature during the teenage years, although they ultimately reach an appropriate adult height for family. Children with other chronic diseases may not fare so well in long-term follow-up; for example, HIV infection

in adolescence causes poor growth and poor pubertal progression. Weight loss to less than 80% of ideal body weight, caused by disease or voluntary dieting, may result in gonadotropin deficiency; weight gain toward the ideal usually restores gonadotropin function but there is often a delay after the weight gain.

Chronic disease may have effects on sexual maturation separate from nutritional state. For example, there is a high incidence of hypothalamic hypogonadism in thalassemia major, even with regular transfusion and chelation therapy.

Celiac disease can be found in approximately 1% of the general population and in about 10% of type I diabetes patients. This immunological disorder of gluten intolerance produces numerous clinical sequelae including late puberty, poor growth, delayed menarche, and osteopenia.

2. **Weight loss and anorexia nervosa**—Anorexia nervosa involves weight loss associated with a significant psychologic disorder. This condition usually affects girls who develop a disturbed body image and exhibit typical behavior such as avoidance of food and induction of regurgitation after ingestion. Weight loss may be so severe as to cause fatal complications such as immune dysfunction, fluid and electrolyte imbalance, or circulatory collapse. Primary or secondary amenorrhea is a classic finding in these patients and has been correlated with the degree of weight loss, although there is evidence that patients with anorexia nervosa may cease to menstruate before their substantial weight loss is exhibited. Other endocrine abnormalities in anorexia nervosa include elevated serum GH and decreased IGF-I (these are characteristic of other types of starvation), decreased serum triiodothyronine, decreased serum 1,25-dihydroxyvitamin D and elevated 24,25-hydroxyvitamin D levels. Weight gain to the normal range for height, however, does not ensure immediate resumption of menses. There is an increased incidence of anorexia nervosa in ballet dancers or ballet students; the incidence of scoliosis and mitral valve insufficiency is also increased in these patients. Functional amenorrhea may also occur in women of normal weight, some of whom demonstrate evidence of psychologic stress. Decreased LH response to GnRH administration, impaired monthly cycles of gonadotropin secretion, and retention of a diurnal rhythm of gonadotropin secretion are found in anorexia nervosa patients, patterns that indicate a reversion to an earlier stage of the endocrine changes of puberty.

3. **Increased physical activity**—Girls who regularly participate in activities such as strenuous athletics and ballet dancing may have delayed thelarche, delayed menarche, and irregular or absent menstrual periods. Increased physical activity and not decreased weight appears to be the cause of the amenorrhea in some girls; such amenorrheic patients may resume menses while temporarily bedridden and inactive even though weight does not yet change. Statistical analysis of mothers' ages at menarche and the type of sport pursued by their daughters indicates that late maturation of some gymnasts may be referable to a familial tendency to late menarche, suggesting that gymnastic activity may not be the primary cause of late menarche. On the other hand, there are studies indicating that intensive gymnastics training at an early age leads to a decrease in ultimate stature.

4. **Hypothyroidism**—Hypothyroidism can delay all aspects of growth and maturation, including puberty and menarche. Galactorrhea may occur in severe primary hypothyroidism due to concomitant elevation of serum PRL due to TSH stimulation. With thyroxine therapy, catch-up growth and resumed pubertal development and menses occur. Conversely, severe primary hypothyroidism may be associated with precocious puberty and galactorrhea (due to elevated serum PRL) in some patients (Van Wyk-Grumbach syndrome). There is evidence that excessive TSH can stimulate FSH receptors, leading to estrogen secretion and breast development in these patients.

5. **Genetic syndromes**
   a. **Prader-Willi syndrome**—Prader-Willi syndrome (OMIM#176270) occurs sporadically and is associated with fetal and infantile hypotonia, short stature, poor feeding in infancy but insatiable hunger later, leading to marked obesity, characteristic facies with almond-shaped eyes, small hands and feet after infancy, developmental delay, and emotional instability in patients of either sex. Delayed menarche in females and micropenis and cryptorchism in males is common; while there is hypothalamic hypogonadism, there is also testicular dysfunction reported in males. Osteoporosis is common in these patients during the teenage years, but sex steroid replacement, when indicated, may increase bone density, although the effects are not proven to be long lasting if sex steroid administration ceases. Behavioral modification may improve the usual pattern of rampant weight gain, but the constant vigilance of caregivers is necessary. Patients have absence of activity of paternally derived gene at 15q11-13 due to deletion of the area on the father's chromosome, uniparental disomy (both areas derived from mother; UPD) or defects in the imprinted area. If an abnormality in this area derives from the mother, Angelman syndrome results. Genetic testing starts with a methylation test for 15q11.2-q13, which identifies over 99% of those with the syndrome; genetic consultation is requested for those suspected of having the syndrome but not diagnosed with methylation testing. This test is available commercially for diagnosis.
   b. **Bardet-Biedl syndromes**—This autosomal recessive but genetically heterogeneous condition is characterized by obesity, short stature, developmental delay, kidney dysfunction, polydactyly, and retinitis pigmentosa. Hypogonadotropic hypogonadism and primary hypogonadism have variously been reported in affected patients. There are presently 19 identified types of this condition listed in OMIM.

Hypergonadotropic Hypogonadism

Primary gonadal failure is heralded by elevated gonadotropin concentrations due to the absence of negative feedback effects of gonadal sex steroids and inhibin. The most common causes of hypergonadotropic hypogonadism are associated with chromosomal and somatic abnormalities (see Chapter 14), but isolated gonadal failure can also present with delayed puberty without other physical findings. When hypergonadotropic hypogonadism is present in patients with a Y chromosome or a fragment of a Y chromosome (genetic males or conditions noted later), testicular dysgenesis must be considered in the differential diagnosis. The risk of testicular cancer rises in testicular dysgenesis (testicular cancer in normal boys is rare; eg, the incidence in Scandinavia is rising but still 0.5 per 100,000 in childhood).

A. Syndrome of seminiferous tubule dysgenesis (Klinefelter syndrome)   A common form of primary testicular failure is Klinefelter syndrome (47,XXY karyotype), with an incidence of 1:1000 males. Before puberty, patients with Klinefelter

syndrome have decreased upper segment-lower segment ratios, small testes, and an increased incidence of developmental delay and personality disorders. Onset of puberty is not usually delayed, because Leydig cell function is characteristically less affected than seminiferous tubule function in this condition and testosterone is adequate to stimulate pubertal development. Serum gonadotropin levels rise to castrate concentrations after the onset of puberty; the testes become firm and are rarely larger than 3.5 cm in diameter. After the onset of puberty, there are histologic changes of seminiferous tubule hyalinization and fibrosis, adenomatous changes of the Leydig cells, and impaired spermatogenesis. Gynecomastia is common, and variable degrees of male secondary sexual development are found. Surviving sperm have been found by microdissection of some seminiferous tubules in a few patients leading to successful fertilization of a partner's ovum. Other forms of male hypergonadotropic hypogonadism are found with 46,XX/47,XXY, 48,XXYY, 48,XXXY, and 49,XXXXY karyotypes. Phenotypic males are described with 46,XX karyotypes and some physical features of Klinefelter syndrome; they may have the *SRY* gene translocated to an X chromosome (see Chapter 14).

B. Other forms of primary testicular failure Patients surviving treatment for malignant diseases form a growing category of testicular failure. Chemotherapy—primarily with alkylating agents—or radiation therapy directed to the gonads may lead to gonadal failure. Injury is more likely if treatment is given during puberty than if it occurs in the prepubertal period, but even prepubertal therapy leads to risk. Normal pubertal development may occur in boys treated with chemotherapy before puberty, although they demonstrate elevated peak serum LH and elevated basal and peak serum FSH after GnRH, as well as a high incidence of decreased or absent sperm counts. This indicates that prepubertal status does not protect a child against testicular damage from chemotherapy and that normal physical development may hide significant endocrine and reproductive damage.

The **Sertoli cell only syndrome** (germinal cell aplasia) is a congenital form of testicular failure manifested by azoospermia and elevated FSH concentrations but generally normal secondary sexual characteristics, normal testosterone concentrations, and no other anomalies. A mutation in a gene at Yq11.23, the azoospermia factor *(AZF)* (OMIM#415000 spermatogenic failure, nonobstructive, Y-linked) appears to play a role in the lack of production of spermatocytes.

Patients with Down syndrome may have elevated LH and FSH levels even in the presence of normal testosterone levels, suggesting some element of primary gonadal failure.

Advances in the treatment of cancer allow long-term survival past childhood. Chemotherapy and radiation therapy often affect the gonads and lead to infertility. The field of oncofertility is rapidly advancing and promises the potential for fertility preservation. Sperm banking is possible before therapy in males and there are advances in ovarian preservation for girls.

C. Cryptorchism or anorchia Phenotypic males with a 46,XY karyotype but no palpable testes have either cryptorchism or anorchia. Cryptorchid males should produce a rise in

testosterone levels greater than 2 ng/dL within 72 hours after intramuscular administration of hCG (3000 U/m^2) in the newborn period, although repeated doses are required after the first postnatal months. Testes may also descend during 2 weeks of treatment with hCG given three times a week.

Patients with increased plasma testosterone levels in response to hCG administration, but without testicular descent, have cryptorchism. Their testes should be brought into the scrotum by surgery to decrease the likelihood of further testicular damage due to the elevated intra-abdominal temperature and to guard against the possibility of undetected tumor formation. Cryptorchid testes may demonstrate congenital abnormalities and may not function normally even if brought into the scrotum early in life. Furthermore, the descended testis in a unilaterally cryptorchid boy may itself show abnormal histologic features; such patients have a 69% incidence of decreased sperm counts. Thus, unilateral cryptorchid patients can be infertile even if they received early treatment of their unilateral cryptorchism. Since both the descended and the undescended testes may be affected, there may be preexisting disease that is manifested by the lack of descent of one testis. In addition, patients undergoing orchiopexy may sustain subtle damage to the vas deferens, leading to the later production of antibodies to sperm that may result in infertility. This finding may depend on the surgical technique used.

It is important to determine if any testicular tissue is present in a boy with no palpable testes, because unnoticed malignant degeneration of the tissue is a possibility. The diagnosis of anorchia due to the testicular regression syndrome may be pursued by ultrasound, MRI, laparotomy, or laparoscopic examination. There are other endocrine evaluations besides the hCG test that may help in diagnosis. The presence of anti-Müllerian factor in a young child indicates the presence of testicular tissue, although during puberty anti-Müllerian factor becomes undetectable, and this test cannot be employed at that stage. Inhibin may be measured as an indication of functioning testicular tissue. Except for the absence of testes, 46,XY patients who are otherwise normal and have the *vanishing testes* syndrome of late fetal loss of the testes have normal infantile male genital development, including Wolffian duct formation and Müllerian duct regression. The testes were presumably present in these patients early in fetal life during sexual differentiation, but degenerated after the 13th week of gestation for unknown reasons (see Chapter 14). When these boys reach adulthood, they are reported to establish a normal male gender identity. The presence of normal basal gonadotropin levels in a prepubertal boy without palpable testes at least suggests the presence of testicular tissue even if the testosterone response to hCG is low, whereas the presence of elevated gonadotropin levels without any testosterone response to hCG suggests anorchia.

The rate of cryptorchidism has increased from 2.7% in the 1950s to 5% in the early 21st century in England and Denmark with a corresponding rise in testicular carcinoma. Likewise an international trend to lower sperm production and decreased testosterone values appear associated with a falling fertility rate found in Europe and Japan. The hypothesis of the testicular dysgenesis syndrome (TDS) postulates that environmental exposures to

endocrine disruptors in utero and later lead to these significant changes in reproductive function.

D. Syndrome of gonadal dysgenesis (Turner syndrome)

45,XO gonadal dysgenesis is associated with short stature, female phenotype with sexual infantilism. Patients have streak gonads consisting of fibrous tissue without germ cells. Other classic but variable phenotypic features include micrognathia, *fish* mouth (downturned corners of the mouth), ptosis, low-set or deformed ears, a broad shield-like chest with the appearance of widely spaced nipples, hypoplastic areolae, a short neck with low hairline and webbing of the neck (pterygium colli), short fourth metacarpals, cubitus valgus, structural anomalies of the kidney, extensive nevi, hypoplastic nails, and vascular anomalies of the left side of the heart (most commonly coarctation of the aorta associated with hypertension proximal to the coarctation). However, some affected girls can have almost normal female phenotypes. The medical history of patients with the syndrome of gonadal dysgenesis often reveals small size at birth, lymphedema of the extremities most prominent in the newborn period, and loose posterior cervical skin folds. (The terms *Bonnevie-Ullrich syndrome* and *infant Turner syndrome* are applied to this neonatal appearance.) Affected patients often have a history of frequent otitis media with conductive hearing loss. There may be frequent urinary tract infections associated with a horseshoe-shaped kidney, duplication of ureters, or other anatomic defects. Intelligence is normal, but there is often impaired spatial orientation, which may lead to difficulty in mathematics, especially geometry. Patients have no pubertal growth spurt, and reach a mean adult height of 143 cm. Short stature is a classic feature of Turner syndrome, but not of other forms of hypergonadotropic hypogonadism that occur without karyotype abnormalities. The short stature is linked to the absence of the (*short stature homeobox*) *SHOX* homeobox gene of the pseudoautosomal region of the X chromosome (Xpter-p22.32) (OMIM*312865). GH function is usually normal in Turner syndrome. However, exogenous hGH treatment improves growth rate and increases adult stature toward the normal range in affected girls. It improves lipid profiles and decreases diastolic blood pressure (see Chapter 6). Pubic hair may appear late and is usually sparse in distribution owing to the absence of any ovarian secretions; adrenarche progresses in Turner syndrome even in the absence of gonadarche. Autoimmune thyroid disease (usually hypothyroidism) is common in Turner syndrome, and determination of thyroid function and thyroid antibody levels is important in evaluation of these patients.

Serum gonadotropin concentrations in Turner syndrome are extremely high between birth and about age 4 years. They decrease toward the normal range in prepubertal patients in the juvenile pause and then rise again to castrate levels after age 10 years (see Chapter 14).

Sex chromatin–positive variants of gonadal dysgenesis include 45,X/46,XX, 45,X/47,XXX, and 45,X/46,XX/47,XXX mosaicism with chromatin-positive buccal smears. Patients with these karyotypes may resemble patients with the classic syndrome of gonadal dysgenesis, or they may have fewer manifestations and normal or nearly normal female phenotypes. Streak gonad formation is not invariable; some patients have had secondary sexual development, and menarche and rare pregnancies have been reported.

Sex chromatin–negative variants of the syndrome of gonadal dysgenesis have karyotypes with 45,X/46,XY mosaicism. Physical features vary; some patients have the features of classic Turner syndrome, whereas others may have ambiguous genitalia or even the features of phenotypic males. Gonads are usually dysgenetic but vary from streak gonads to functioning testes. These patients are at risk for gonadoblastoma formation; this is a benign tumor that has the potential for malignant transformation and then may metastasize. Because gonadoblastomas may secrete androgens or estrogens, patients with gonadoblastoma may virilize or feminize as though they had functioning gonads, confusing the clinical picture. Gonadoblastomas may demonstrate calcification on abdominal x-ray. Malignant germ cell tumors may arise in dysgenetic testes, and gonadectomy (orchiectomy is a more precise term) is generally indicated. In some mosaic patients with one intact X chromosome and one chromosomal fragment, it is difficult to determine whether the fragment is derived from an X chromosome or a Y chromosome. Polymerase chain reaction techniques to search for specific Y chromosome sequences are helpful if a karyotype reveals no Y chromosomal material.

Patients with Turner syndrome who desire fertility can be treated with *in vitro* fertilization techniques. After exogenous hormonal preparation, a fertilized ovum (possibly a sister's ovum fertilized by the patient's male partner, or an extra fertilized ovum from another couple undergoing *in vitro* fertilization) can be introduced into the patient's uterus, and the pregnancy is then brought to term by support with exogenous hormone administration. A serious possible complication is uterine rupture which makes this a very dangerous procedure.

E. Other forms of primary ovarian failure

Ovaries appear to be more resistant to damage from the chemotherapy used in the treatment of malignant disease than are testes. Nonetheless, ovarian failure can occur with medical therapy. Damage is common if the ovaries are not surgically moved out of the path of the beam or shielded by lead in abdominal radiation therapy. Normal gonadal function after chemotherapy does not guarantee normal function later. Late-onset gonadal failure has been described after chemotherapy. Bone marrow transplantation with whole-body irradiation for acute lymphoblastic leukemia or non–Hodgkin lymphoma appears to cause the most damage to endocrine function.

Premature menopause has also been described in otherwise healthy girls owing to the presence of anti-ovarian antibodies. Patients with Addison disease may have autoimmune oophoritis as well as adrenal failure. A sex steroid biosynthetic defect due to 17α-hydroxylase deficiency (P450c17) manifests as sexual infantilism and primary amenorrhea in a phenotypic female (regardless of genotype) with hypokalemia and hypertension (see Chapter 14). A patient with 17α-hydroxylase deficiency may have ovaries or testes and still present as a phenotypic female. The syndrome of androgen resistance may present as a female phenotype with amenorrhea, in a manner suggesting ovarian failure, but the problem in such an individual with a 46,XY karyotype is the absence of androgen receptors.

F. Noonan syndrome (pseudo–Turner syndrome, Ullrich syndrome, male Turner syndrome [OMIM#163950 Noonan syndrome 1; NS1]) Noonan syndrome is associated with some phenotypic manifestations of Turner syndrome such as webbed neck, ptosis, short stature, cubitus valgus, and lymphedema, but other additional clinical findings such as a normal karyotype, triangular facies, pectus excavatum, right-sided heart disease, and an increased incidence of developmental delay differentiate these patients from those with Turner syndrome. Males may have undescended testes and variable degrees of germinal cell and Leydig cell dysfunction. Noonan syndrome follows an autosomal dominant pattern of inheritance with incomplete penetrance (gene locus 12q24). hGH is approved by the FDA to increase stature in these patients.

G. Familial and sporadic forms of 46,XX or 46,XY gonadal dysgenesis These forms of gonadal dysgenesis are characterized by structurally normal chromosomes and streak gonads or partially functioning gonads. They do not have the physical features of Turner syndrome. If there is some gonadal function, 46,XY gonadal dysgenesis may present with ambiguous genitalia or virilization at puberty; 46,XY complete gonadal dysgenesis is also known as Swyer Syndrome. If no gonadal function is present, patients appear as phenotypic sexually infantile females. Patients with 46,XY gonadal dysgenesis and dysgenetic testes should undergo gonadectomy to eliminate the possibility of malignant germ cell tumor formation.

H. Primary amenorrhea associated with normal secondary sexual development If a structural anomaly of the uterus or vagina interferes with the onset of menses but the endocrine milieu remains normal, the patient presents with primary amenorrhea in the presence of normal breast and pubic hair development. A transverse vaginal septum may seal the uterine cavity from the vaginal orifice, leading to the retention of menstrual flow—as may an imperforate hymen. The Rokitansky-Küster-Hauser syndrome (OMIM#277000) combines congenital absence of the vagina with abnormal development of the uterus, ranging from a rudimentary bicornuate uterus that may not open into the

vaginal canal to a virtually normal uterus; surgical repair may be possible in patients with minimal anatomic abnormalities, and fertility has been reported. Associated abnormalities include major urinary tract anomalies and spinal or other skeletal disorders. The rarest anatomic abnormality in this group is absence of the uterine cervix in the presence of a functional uterus.

46,XY disorder of sexual development (DSD), previously called male pseudohermaphroditism, is an alternative cause of primary amenorrhea if a patient has achieved thelarche. The syndrome of complete androgen resistance leads to female external genitalia and phenotype without axillary or pubic hair development in the presence of pubertal breast development (syndrome of testicular feminization; see Chapter 14).

Differential Diagnosis of Delayed Puberty (Table 15–3)

Patients who do not begin secondary sexual development by age 13 (girls) or age 13.5–14 (boys) and patients who do not progress through development on a timely basis (girls should menstruate within 5 years after breast budding; boys should reach stage 5 pubertal development 4 and a half years after onset) should be evaluated for hypogonadism. The yield of diagnosable conditions is quite low in children younger than these ages, but many patients and families request evaluation well before these limits. Without significant signs or symptoms of disorders discussed above, it is best to resist evaluation and offer support until these ages in most cases.

A patient with constitutional delay may have a characteristic history of short stature for age with normal growth velocity for bone age and a family history of delayed but spontaneous puberty. The patient's mother may have had late onset of menses, or the father may have begun to shave late or continued growing after high school. Not all patients with constitutional delay are so classic, and gonadotropin-deficient patients may have some features similar to those of constitutional delay in adolescence. Indeed, patients with Kallmann syndrome and others with constitutional delay are occasionally found in the same kindred.

If the diagnosis is not obvious on the basis of physical or historical features, the differential diagnostic process begins with

TABLE 15–3 Differential diagnosis of delayed puberty.

	Serum Gonadotropins	Serum Gonadal Steroids[a]	Miscellaneous
Constitutional delay in growth and adolescence	Prepubertal (low)	Low	Patient usually has short stature for chronologic age but appropriate height and growth rate for bone age. Both adrenarche and gonadarche are delayed.
Hypogonadotropic hypogonadism	Prepubertal (low)	Low	Patient may have anosmia (Kallmann syndrome) or other associated pituitary hormone deficiencies. If gonadotropin deficiency is isolated, the patient usually has normal height and growth rate but lacks a pubertal growth spurt. Adrenarche may occur at a normal stage in spite of absent gonadarche (serum DHEAS may be pubertal).
Hypergonadotropic hypogonadism	Elevated	Low	Patient may have abnormal karyotype and stigmatas of Turner syndrome or Klinefelter syndrome.

[a]In a pediatric specific assay.

determination of whether plasma gonadotropins are (1) elevated due to primary gonadal failure or (2) decreased due to secondary or tertiary hypogonadism or constitutional delayed puberty. Gonadotropins must be measured in a third-generation assay with pediatric standards, as the customary gonadotropin determinations are too insensitive to reveal the small changes of puberty. A single ultrasensitive, third-generation determination of serum LH concentration in the pubertal range suggests that puberty is progressing. Determination of the rise in LH after administration of GnRH or GnRH agonist is helpful in differential diagnosis; secondary sexual development usually follows within months after conversion to a pubertal LH response to GnRH. Because it is difficult, if not impossible, to obtain GnRH presently, GnRH agonists are frequently used for diagnosis with serum LH values measured after administration.

Values are laboratory-specific, but it has been reported that a basal LH value over 0.3 U/L or a peak LH over 3.2 U/L one hour after 10 μg/kg subcutaneous GnRH administration indicates the onset of puberty in girls with 90% specificity with a stimulated LH over 5.5 U/L providing 96% specificity. A 4-hour LH value over 14.8 U/L after 10 μg/kg of leuprolide acetate in boys provides 100% sensitivity, while a value over 19 U/L provides 100% specificity in identifying the onset of puberty.

Frequent nighttime sampling (every 20 minutes through an indwelling catheter) to determine the amplitude of peaks of LH secretion during sleep is an alternative to GnRH or GnRH agonist testing but is too cumbersome for a clinical settings. Unfortunately, the results of GnRH infusions or nighttime sampling are not always straightforward. Patients may have pubertal responses to exogenous GnRH but may not spontaneously secrete adequate gonadotropins to allow secondary sexual development. In females with amenorrhea, the frequency and amplitude of gonadotropin secretion may not change to allow monthly menstrual cycles. The retention of a diurnal rhythm of gonadotropin secretion (normal in early puberty) into late puberty is a pattern linked to inadequate pubertal progression. In males, a morning serum testosterone concentration over 20 ng/dL (0.7 mmol/L) indicates the likelihood of pubertal development within 6 months. Measurement of testosterone or estradiol must be done in an ultrasenstive assay with pediatric standards or, as with gonadotropin assays, the small changes of pubertal development will be missed. Presently highly sensitive high performance liquid chromatography (HPLC) tandem mass spectroscopy (HPLC MS/MS) assays are available at national laboratories for this purpose.

Other methods of differential diagnosis between constitutional delay and hypogonadotropic hypogonadism have been proposed but are complex or are not definitive. Clinical observation for signs of pubertal development and laboratory evaluation for the onset of rising levels of sex steroids may have to continue until the patient is 18 years of age before the diagnosis is definite. In most cases, if spontaneous pubertal development is not noted by 18 years of age, the diagnosis is gonadotropin deficiency. Of course, the presence of neurologic impairment or other endocrine deficiencies should immediately lead to investigation for central nervous system tumor or congenital defect in a patient with delayed puberty. MRI scanning is invoked in this situation.

Treatment of Delayed Puberty

A. Constitutional delay in growth and adolescence

Psychologic support   Teenagers who are so embarrassed about short stature and lack of secondary sexual development that they have significant psychologic problems may require psychological evaluation and therapy if they have passed the ages of 13 years for girls or 14 years for boys. Patients with constitutional delay in growth and adolescence should be counseled that normal pubertal development will occur spontaneously. Peer pressure and teasing can be oppressive. Although the majority of these patients do quite well, severe depression must be treated appropriately, because short patients with pubertal delay have become suicidal. In some cases, it helps to excuse the patient from physical education class, because the lack of development is most apparent in the locker room. In general, boys feel more stress than girls when puberty is delayed.

Sex steroids   New preparations of topical sex steroids, that have different systemic effects and length of action than parenteral or oral sex steroids, have enlarged the therapeutic armamentarium for delayed puberty. The classic recommendation for girls has been a 3-month course of conjugated estrogen (0.3 mg) or ethinyl estradiol (5-10 μg) given orally each day. Topical estrogen is said to carry less risk of hypertension, gallstones, increased fat mass, decreased insulin sensitivity, and increased triglycerides (topical estrogen does not, however, increase HDL cholesterol and decrease low-density lipoprotein [LDL] cholesterol, as does oral estrogen). Estrogen-impregnated patches are available and might be used to initiate puberty, but the lowest dose available leads to serum estrogen values higher than physiologic levels found in early puberty. They might be used for only a few days each week to reduce the delivered dose. Alternatively, 17-beta estradiol patches (0.025 mg/patch; Vivelle Dot matrix patch) may be cut into fragments the size of one-eighth to one-fourth of a patch fragments to initiate pubertal development with more physiologic estrogen values. However, the use of such topical estrogen preparations is not approved by the Food and Drug Administration (FDA) for induction of puberty.

The classic recommendation for boys is a 3-month course of testosterone enanthate or cypionate (50 mg) given intramuscularly once every 28 days for three doses. The possibility that a higher dose will cause priapism limits the initial dose to 50 mg. The initial doses are increased over months to 100 or 150 mg every 28 days or lower doses every 14 days. Patch or testosterone gel preparations could be used to initiate puberty, but the dose in manufactured packets or pumps is too high to mimic the physiologic levels found in early puberty as these preparations are made for full replacement in adult males. The entire gel packet or lowest-dose patch could be used every other day over the 3-month period of treatment, although this leads to variable daily dosage. The gel available in a pump may be approximated to a lower dose of one-half a single pump depression. The testosterone patches are not impregnated like the estrogen patches and cannot be cut down in size. Thus, to date, the low-dosage injection of testosterone or the use of an estimated one-half or less of the 5 mg

testosterone gel packet or pump are the only methods of reaching appropriate dosage. The topical use of testosterone is not approved by the FDA for pubertal onset. Therapy with oxandrolone has been suggested as a method of increasing secondary sexual development and increasing growth without advancing skeletal development. This method is not widely preferred. Furthermore, testosterone, which can be aromatized to estradiol, increases the generally low endogenous GH secretion in constitutional delayed puberty to normal, whereas oxandrolone, which cannot be aromatized, does not increase GH secretion.

Hormonal treatment of boys or girls elicits noticeable secondary sexual development and a slight temporary increase in stature. The low doses recommended do not advance bone age substantially and do not significantly change adult height if used for 3 months. Low-dose sex steroid treatment has been reported to promote spontaneous pubertal development after sex steroid therapy is discontinued, although responding individuals may include those boys who are on the brink of further pubertal development and are, therefore, most likely to achieve a growth response to androgen therapy. However, a short course of therapy may improve patients' psychologic outlook and allow them to await spontaneous pubertal development with greater confidence. Continuous gonadal steroid replacement in these patients is not indicated, because it advances bone age and leads to epiphyseal fusion and a decrease in ultimate stature. After a 3 to 6 month break to observe spontaneous development, a second course of therapy may be offered if no spontaneous pubertal progression occurs during observation.

B. Persistent hypogonadism Once a patient has been diagnosed as having delayed puberty due to apparently permanent primary or secondary hypogonadism, replacement therapy must be considered at the average age of onset of puberty in most cases.

Males with hypogonadism may be treated with testosterone gel, testosterone patches, or testosterone enanthate or cypionate given intramuscularly every month, as described earlier for constitutional delay. Testosterone gel or patches, as described earlier, are used for persistent, long-term replacement but are not FDA-approved for individuals less than 16 years. Treatment as for constitutional delay should be started and gradually increased to the adult range over months to years to mimic the normal progression of puberty and to avoid abrupt exposure to high-dose androgen and the possibility of frequent erections or priapism. Oral halogenated testosterone and methylated testosterone are never recommended because of the risk of hepatocellular carcinoma or cholestatic jaundice. Testosterone therapy may not cause adequate pubic hair development, but patients with secondary or tertiary hypogonadism may benefit from hCG administration with increased pubic hair growth resulting from endogenous testicular androgen secretion in addition to the exogenous testosterone.

Girls may be treated with oral ethinyl estradiol (increasing from 5 µg/d to 10 to 20 µg/d depending on clinical results), or conjugated estrogens (0.3 or 0.625 mg/d). One may start with daily doses with eventual conversion to treatment on days 1 to 21 of the month after several months of daily ingestion when vaginal secretions increase. Five to 10 mg of medroxyprogesterone acetate

are then added on days 12 to 21 after physical signs of estrogen effect are noted and breakthrough bleeding occurs (and always within 6 months after initiating estrogen). Neither hormone is administered from day 22 to the end of the month to allow regular withdrawal bleeding (see Chapter 13). Later, the patient may be switched to sequential oral contraceptives to simplify treatment. As described earlier, estrogen patch therapy may have benefits (but these are not proven) over oral estrogen and may be preferable (but these are not FDA-approved for individuals under 16 years of age). Low-dose estrogen oral contraceptives may be used after initial induction phase. Gynecologic examinations should be performed yearly for those on replacement therapy.

Hypothalamic hypogonadism may be treated with GnRH pulses by programmable pumps to achieve fertility or to promote pubertal development. Likewise, in the absence of a functional pituitary gland, hCG and menotropins (human postmenopausal gonadotropin) may be administered in pulses. These techniques are cumbersome and best reserved for the time when fertility is desired.

C. Coexisting GH deficiency The treatment of patients with coexisting GH deficiency requires consideration of their bone age and amount of growth left before epiphyseal fusion. If such a patient has not yet received adequate treatment with GH, sex steroid therapy may be kept at the lower dosage or even delayed to optimize adult height. The goal is to allow appropriate pubertal changes to support psychologic development and to allow the synergistic effects of combined sex steroids and GH without fusing the epiphyses prematurely.

Constitutional delayed puberty may be associated with decreased GH secretion in 24-hour profiles of spontaneous secretion or in stimulated testing. GH secretion increases when pubertal gonadal steroid secretion rises due to the effects of estrogen, so decreased GH secretion in this condition should be considered temporary. Nonetheless, true GH-deficient patients may have delayed puberty due to the GH deficiency or to coexisting gonadotropin deficiency. Therefore, deciding whether a pubertal patient has temporary or a permanent GH deficiency can be difficult; previous observation may indicate a long history characteristic of constitutional delay in adolescence, whereas a recent decrease in growth rate may suggest the onset of a brain tumor or other cause of hypopituitarism.

D. The syndrome of gonadal dysgenesis In the past, patients with the syndrome of gonadal dysgenesis were frequently not given estrogen replacement until after age 13 years, for fear of compromising adult height. However, low-dose estrogen therapy (5-10 µg of ethinyl estradiol orally) can be administered to allow feminization and improve psychologic status at 12 to 13 years of age without decreasing final height, as shown in several studies. Low-dose estrogen increases growth velocity, whereas high-dose estrogen suppresses it. Even if growth velocity is increased, however, adult height is not increased with such estrogen treatment. Treatment of Turner syndrome with GH successfully increases adult stature (see Chapters 6 and 14). During childhood these girls must be regularly screened for strabismus, hearing loss, and

autoimmune thyroid disease as well as learning difficulties. There are several recommendations for the preparation of these girls to transition to adult care and necessary follow-up for issues that will affect their later life, including monitoring for the development of aortic dilation at 5- to 10-year intervals since this defect may progress to aortic aneurysms.

E. Bone mass   After infancy, most bone mass accrual takes place during the second decade of life, and disorders of puberty may affect this process. Delayed puberty in boys causes decreased cross-sectional bone density, when the subjects are tested as young adults, because they have not yet reached peak bone acquisition. Although there is some controversy, it appears likely that normalization of volumetric bone density occurs with maturity and exposure to a normal androgen milieu. A range of defects in girls such as anorexia nervosa, athletics-induced delayed puberty, and Turner syndrome also cause decreased bone density. The use of testosterone in boys and estrogen and progesterone in girls with hypogonadotropic hypogonadism is helpful in increasing bone mass but has not been demonstrated to result in normal adult bone mass. Appropriate ingestion of dairy products containing calcium or calcium supplementation and vitamin D should be encouraged in hypogonadal or constitutionally delayed patients as well as in normal children at least as a common sense measure. No long-term follow-up is yet available, however, to prove the efficacy of this therapy in susceptible subjects.

PRECOCIOUS PUBERTY (SEXUAL PRECOCITY)

All sources agree that the appearance of secondary sexual development before the age of 9 years in boys is precocious puberty. However, there remains controversy over the lower limits of normal in girls. The Pediatric Endocrine Society states that the appearance of secondary sexual development before the age of 7 years in Caucasian girls and 6 years in African American girls constitutes precocious sexual development but others remain concerned that pubertal development between 7 and 8 years for Caucasian and 6 and 8 for African American girls indicate a pathological state (Table 15–4). However, if a girl has the onset of puberty before 8 years, one must have a high index of suspicion for pathology. The child must have absolutely no sign of central nervous system disorder or other possible cause that might trigger pathologic precocious puberty. A careful search for historical or physical features of organic disease must occur before a girl with precocious puberty before 8 years is considered normal. When the cause of precocious puberty is premature activation of the hypothalamic-pituitary axis and the condition is gonadotropin-dependent, the diagnosis is **central (complete or true) precocious puberty**; if ectopic gonadotropin secretion occurs in boys or autonomous sex steroid secretion occurs in either sex, the condition is not gonadotropin-dependent, and the diagnosis is peripheral or **incomplete precocious puberty**. If feminization occurs in girls and virilization occurs in boys, the condition is **isosexual**

TABLE 15–4 Classification of precocious puberty.

Central (complete or true) GnRH-dependent isosexual precocious puberty
Constitutional
Idiopathic
Central nervous system disorders (including congenital defects)
Tumors
Infection
Trauma
Radiation
Following androgen exposure
Peripheral or incomplete GnRH-independent isosexual precocious puberty
Males
Gonadotropin-secreting tumors
Excessive androgen production
Testicular or adrenal tumors
Virilizing congenital adrenal hyperplasia
Premature Leydig and germinal cell maturation
Females
Ovarian cysts
Estrogen-secreting neoplasms
Severe hypothyroidism
Males and females
McCune-Albright syndrome
Peripheral or incomplete contrasexual precocity
Males
Estrogen-secreting tumor
Females
Androgen-secreting tumor
Virilizing congenital adrenal hyperplasia
Iatrogenic sexual precocity due to gonadotropin or sex steroid exposure
Variation in pubertal development
Premature thelarche
Premature menarche
Premature pubarche
Adolescent gynecomastia

precocity, but if the feminization occurs in boys and virilization in girls, the condition is **contrasexual precocity**. In all forms of sexual precocity, there is an increase in growth velocity, somatic development, and skeletal maturation. When unchecked, this rapid skeletal development may lead to tall stature during the early phases of the disorder but to short final stature because of early epiphysial fusion. This is the paradox of the tall child growing up to become a short adult. Plasma IGF-I values may be elevated for age but are appropriate for pubertal stage in untreated precocious puberty.

Central (Complete or True) Precocious Puberty (Figure 15–6)

A. Constitutional or familial central (complete or true) precocious puberty   Otherwise normal children who demonstrate isosexual precocity at an age slightly more than 2.5 SD below the mean may simply represent the lower reaches of the distribution curve describing the age of onset of puberty; often there is a familial tendency toward early puberty. True precocious
FIGURE 15–6 Boy 2-5/12 years of age with idiopathic true precocious puberty. By 10 months of age, he had pubic hair and phallic and testicular enlargement. At 1 year of age, his height was 4 SD above the mean; the phallus was 10 cm × 3.5 cm; each testis was 2.5 cm × 1.5 cm. Plasma LH was pubertal and rose in an adult pattern after administration of 100 μg of GnRH. Plasma testosterone was 416 ng/dL. At the time of the photograph, he had been treated with medroxyprogesterone acetate (to suppress LH and FSH secretion) for 1½ years, with reduction of his rapid growth rate and decreased gonadotropin and testosterone secretion. At that point his height was 95.2 cm (>2 SD above mean height for his age); plasma testosterone was 7 ng/dL, and after 100 μg of GnRH, plasma LH rose only slightly, demonstrating suppression. (Reproduced with permission from Yen SSC, Jaffe RB. *Reproductive Endocrinology*. Philadelphia: WB Saunders; 1978.)

puberty is reported, rarely, to be due to an autosomal dominant or (in males) X-linked dominant trait.

B. Idiopathic central (complete or true) isosexual precocious puberty Affected children, with no familial tendency toward early development and no organic disease, may be considered to have idiopathic central isosexual precocious puberty. Epilepsy and developmental delay are associated with central precocious puberty in the absence of a central nervous system anatomic abnormality, indicating a central nervous system process is responsible for the condition.

Pubertal development may follow the normal course or may wax and wane. Serum gonadotropin and sex steroid concentrations and response to GnRH or GnRH agonists are similar to those found in normal pubertal subjects. In idiopathic central precocious puberty, as in all forms of true isosexual precocity, testicular enlargement in boys should be the first sign; in girls, breast development or, rarely, pubic hair appearance may be first. Girls present with idiopathic central precocious puberty more commonly than boys. Children with precocious puberty have a tendency toward obesity based on elevated body mass index in the untreated state in some studies.

C. Genetic causes of precocious puberty While families with inactivating mutations of the *GRP54* gene have absent or delayed puberty, a patient presented with isosexual precocious puberty and demonstrated a mutation of *GRP54* that led to prolonged activation of intracellular signaling pathways in response to kisspeptin. This further emphasizes the importance of the GRP54-kisspepetin axis in the control of puberty. A boy is described with a mutation in the gene for *KISS1* leading to prolonged activity of the ligand and precocious puberty.

The *MRKN3* gene is maternally imprinted leading to silencing of the maternal allele. This is considered to exert a braking effect on pubertal development, and thus, when a paternal inactivating mutation occurs, since the maternal allele is silenced, the child experiences precocious puberty. Numerous families are now reported with such mutations with affected girls experiencing a median age of onset of puberty of 6 years while boys are less affected and experience a later onset of puberty.

Other syndromes with chromosomal abnormalities associated with precocious puberty include the Williams-Beuren syndrome, Russell-Silver syndrome, Temple syndrome, Prader Willi syndrome, and reminiscent of Rett syndrome.

D. Central nervous system disorders

1. **Tumors**—Central nervous system tumors are more common causes of central precocious puberty in boys than in girls but may occur in either, so a high index of suspicion is essential. Optic gliomas or hypothalamic gliomas, astrocytomas, ependymomas, germinomas, and other central nervous system tumors may cause precocious puberty by interfering with neural pathways that inhibit GnRH secretion, thus releasing the central nervous system restraint of gonadotropin secretion. Patients with optic gliomas and neurofibromatosis type 1 may have precocious puberty, but no patients with isolated neurofibromatosis (that did not have optic gliomas) are reported with precocious puberty. Remarkably, craniopharyngiomas, which are known to cause delayed puberty, can also trigger precocious pubertal development. Radiation therapy is often indicated in radiosensitive tumors such as germinomas and craniopharyngiomas, where complete surgical extirpation is impossible. Reportedly, complete removal of craniopharyngiomas is associated with unexpected recurrence; radiation therapy appears to be a key therapy for this tumor in addition to surgery.

Hamartomas of the tuber cinereum contain GnRH and neurosecretory cells similar to those found in the median eminence; they may cause precocious puberty by secreting GnRH. Some hypothalamic hamartomas associated with central precocious puberty do not elaborate GnRH but instead contain transforming growth factor (TGF)-α, which stimulates GnRH secretion itself. With improved methods of imaging the central nervous system, hamartomas, with their characteristic radiographic appearance, are now more frequently diagnosed in

patients who were previously thought to have idiopathic precocious puberty. These tumors do not enlarge and so pose no additional threat to the patients in the absence of intractable seizures. These seizures are rare in patients with the pedunculated hamartomas causing central precocious puberty. Because of the location of the hamartoma, surgery is a dangerous alternative to GnRH analog therapy.

Tumors or other abnormalities of the central nervous system may cause GH deficiency in association with central precocious puberty. GH deficiency may also occur after irradiation therapy for such tumors, even if precocious puberty was the sole endocrine finding before irradiation. Such patients grow much faster than isolated GH-deficient patients but slower than children with classic precocious puberty and adequate GH secretion. Often, the GH deficiency is unmasked after successful treatment of precocious puberty. This combination must be considered during the diagnostic process (see also Chapter 6).

2. Other causes of true precocious puberty—Infectious or granulomatous conditions such as encephalitis, brain abscess, postinfectious (or postsurgical or congenital) suprasellar cysts, sarcoidosis, and tuberculous granulomas of the hypothalamus can cause central precocious puberty. Suprasellar cysts and hydrocephalus cause central precocious puberty that is particularly amenable to surgical correction. Brain trauma may be followed by either precocious or delayed puberty. Radiation therapy for acute lymphoblastic leukemia of the central nervous system, or prior to bone marrow transplantation, is characteristically associated with hormonal deficiency, but there are increasing reports of precocious puberty occurring after such therapy. Higher doses of radiation may be more likely to cause GnRH deficiency, and lower doses down to 18 Gy may lead to central precocious puberty.

D. Virilizing syndromes   Patients with long-untreated virilizing adrenal hyperplasia who have advanced bone ages may manifest precocious puberty after treatment with glucocorticoid suppression. Children with virilizing tumors or those given long-term androgen therapy may follow the same pattern when the androgen source is removed. Advanced maturation of the hypothalamic-pituitary-gonadal axis appears to occur with any condition causing excessive androgen secretion and advanced skeletal age.

Peripheral or Incomplete Isosexual Precocious Puberty in Boys

Males may manifest premature sexual development in the absence of hypothalamic-pituitary maturation from either of two causes: (1) ectopic or autonomous endogenous secretion of hCG or LH or iatrogenic administration of hCG, which can stimulate Leydig cell production of testosterone; or (2) autonomous endogenous secretion of androgens from the testes or adrenal glands or from iatrogenic exogenous administration of androgens. (In females, secretion of hCG does not by itself cause secondary sexual development.)

A. Gonadotropin-secreting tumors   These include hepatomas or hepatoblastomas of the liver as well as teratomas or choriocarcinoma of the mediastinum, gonads, retroperitoneum, or pineal gland and germinomas of the central nervous system. The testes are definitely enlarged but not to the degree found in central precocious puberty since only Leydig cells are stimulated by hCG.

B. Autonomous androgen secretion   Secretion of androgens can occur because of inborn errors of adrenal enzyme function, as in 21-hydroxylase deficiency (P450c21 OMIM#201910 adrenal hyperplasia, congenital, caused by 21-hydroxylase) or 11β-hydroxylase deficiency (P450c11β OMIM#202010; adrenal hyperplasia, congenital, caused by steroid 11-beta-hydroxylase deficiency), virilizing adrenal carcinomas, interstitial cell tumors of the testes, or premature Leydig and germinal cell maturation. Late-onset congenital adrenal hyperplasia, generally of the 21-hydroxylase deficiency form, may occur years after birth with no congenital or neonatal manifestations of virilization. Adrenal rest tissue may be found in the testes as a vestige of the common embryonic origin of the adrenal glands and the testes. Congenital adrenal hyperplasia associated with testicular adrenal rest tissue (TART) can enlarge (sometimes to remarkable size) and secrete adrenal androgens (see Chapter 14). TART has been reported to lead to testicular neoplasia.

In boys with familial gonadotropin-independent premature Leydig and germinal cell maturation (OMIM#176410. precocious puberty, male-limited), plasma testosterone levels are in the pubertal range, but plasma gonadotropin levels and the LH response to exogenous GnRH are in the prepubertal range or lower because autonomous testosterone secretion suppresses endogenous GnRH release. The cause of this sex-limited dominant condition lies in a constitutive activation of the LH receptor (leaving the LH receptor on), causing increased cyclic adenosine monophosphate (cAMP) production in the absence of LH and continuous testosterone secretion. Several mutations have been reported in the LH receptor gene in different families (eg, Asp[578] to Gly or Met[571] to Ile). The differential diagnosis rests between testosterone-secreting tumor of the adrenal, testosterone-secreting Leydig cell neoplasm, and premature Leydig and germinal cell maturation.

If hCG secretion due to a tumor causes peripheral male isosexual precocity, FSH is not elevated. As only the Leydig cells are stimulated and because the seminiferous tubules are not stimulated, the testes do not enlarge as much as in complete sexual precocity. If peripheral sexual precocity is due to a testicular tumor, the testes may be large, asymmetric, and irregular in contour. Symmetric bilateral moderate enlargement of the testes suggests familial gonadotropin-independent premature maturation of Leydig and germinal cells, which is a sex-limited dominant condition. The testes are somewhat smaller in this condition, than in true precocious puberty, but are still over 2.5 cm in diameter.

Peripheral or Incomplete Contrasexual Precocity in Boys

Estrogen may be secreted by rare adrenal tumors leading to feminization in boys. Sertoli cell tumors associated with Peutz-Jeghers syndrome is another possible etiology.

Peripheral or Incomplete Isosexual Precocious Puberty in Girls

Females with peripheral isosexual precocity have a source of excessive estrogens. In all cases of autonomous endogenous estrogen secretion or exogenous estrogen administration, serum LH and FSH levels are low.

A. Follicular cysts If follicular cysts are large enough, they can secrete sufficient estrogen to cause breast development and even vaginal withdrawal bleeding; some girls have recurrent cysts that lead to several episodes of vaginal bleeding. Patients with cysts may have levels of serum estrogen high enough to mimic a tumor. Larger follicular cysts can twist on their pedicles and become infarcted, causing symptoms of acute abdomen in addition to the precocious estrogen effects.

B. Other ovarian tumors Juvenile granulosa cell tumor of the ovary is a rare sex chord tumor that can secrete estrogen and lead to precocioius puberty, as 5% are prepubertal. They are palpable in 80% of cases. Gonadoblastomas are found in streak gonads, lipoid tumors, and cystadenomas. Granulosa-theca cell ovarian tumors are even rarer; they secrete androstenedione which can be converted into estrogen. Ovarian carcinomas are rare ovarian sources of estrogens or androgens. Secretory tumors of the ovary may present with abdominal pain, adnexal mass and precocious puberty.

C. Exogenous estrogen administration Ingestion of estrogen-containing substances (eg. oral contraceptives) or even cutaneous absorption of estrogen can cause feminization in children. Epidemics of gynecomastia and precocious thelarche in Puerto Rico and Italy have variously been attributed to ingestion of estrogen-contaminated food, estrogens in the environment, soy formula, or undetermined causes. One outbreak of gynecomastia in boys and precocious thelarche in girls in Bahrain was traced to ingestion of milk from a cow which was given continuous estrogen treatment by its owner to ensure uninterrupted milk production. Tea tree and lavender oils have estrogenic effects in children, and exposure can cause thelarche.

D. Hypothyroidism Severe untreated hypothyroidism can be associated with sexual precocity and galactorrhea (Van Wyk-Grumbach syndrome); treatment with thyroxine corrects hypothyroidism, halts precocious puberty and galactorrhea, and lowers PRL levels. The cause of this syndrome was initially postulated to be increased gonadotropin secretion associated with the massive increase in TSH secretion. However, it appears that TSH, at high concentrations, can activate FSH receptors.

E. McCune-Albright syndrome McCune-Albright syndrome (OMIM#174800. McCune-Albright syndrome; MAS) is classically manifested as a triad of irregular café au lait spots, fibrous dysplasia of long bones with cysts, and precocious puberty. However, hyperthyroidism, adrenal nodules with Cushing syndrome, acromegaly, hyperprolactinemia, hyperparathyroidism, hypophosphatemic hyperphosphaturic rickets, or autonomous endogenous-functioning ovarian cysts (in girls) also occur. Precocious puberty may be central or peripheral; longitudinal studies demonstrate that the history of some patients starts with incomplete precocious puberty and progresses to central precocious puberty. Long-term follow-up of patients with McCune-Albright syndrome reveals a high incidence of pathologic fractures and orthopedic deformities due to the bone cysts, as well as hearing impairment due to the thickening of the temporal area of the skull. Thickening of the skull base can impinge on local brain structures with fatal consequences. Bone growth may be partly mediated by elevated GH secretion and may cease with somatostatin analogue therapy. Patients may have a mutation of Arg_{201} in exon 8 of the gene encoding the Gs alpha subunit that stimulates cAMP formation; this mutation impairs GTPase activity of the alpha subunit and increases adenylate cyclase activity in the affected tissue leading to hormone secretion and the endocrine abnormalities described earlier. This defect originates in somatic rather than germ cells, leading to genetic mosaicism wherever the defective gene product is expressed; thus, a wide variety of tissues can be affected.

Peripheral or Incomplete Contrasexual Precocity in Girls

Excess androgen effect can be caused by premature adrenarche or more significant pathologic conditions such as congenital or non-classic adrenal hyperplasia or adrenal or ovarian tumors. P450c21 adrenal hyperplasia can be diagnosed on the basis of elevated serum 17-hydroxyprogesterone concentrations in the basal or ACTH-stimulated state (other adrenal metabolites may be elevated depending on the defect under investigation) (see Chapter 14). Both adrenal and ovarian tumors are associated with elevation of serum testosterone; adrenal tumors preferentially secrete DHEA. Thus, the source of the tumor may be difficult to differentiate if it produces only testosterone. MRI or CT scanning may be inadequate to diagnose the tumor's organ of origin, and selective venous sampling may be needed. Rare families reported with aromatase deficiency had contrasexual development although not precocious puberty per se. One affected 46,XX individual had virilized genitalia at birth and further virilization at a pubertal age with the additional feature of polycystic ovaries. The patient, in spite of high serum testosterone concentrations, had elevated FSH and LH in the absence of estrogen production.

Variations in Pubertal Development

A. Premature thelarche The term **premature thelarche** denotes unilateral or bilateral breast enlargement without other signs of androgen or estrogen secretion. Patients are usually younger than 3 years of age; the breast enlargement may regress within months or remain until actual pubertal development occurs at a normal age. Areolar development and vaginal mucosal signs of estrogen effect are usually absent or minimal. Premature thelarche may be caused by brief episodes of estrogen secretion from ovarian cysts. Plasma estrogen levels are usually low in this

disorder, perhaps because blood samples are characteristically drawn after the initiating secretory event. However, ultrasensitive estradiol assays show a difference in estrogen production between control girls and those with premature thelarche. Classically, premature thelarche is self-limited and does not lead to central precocious puberty. However, there are reports of progression to central precocious puberty in a minority of cases, and follow-up for such progression is indicated. Other abnormalities in ovulation and menstruation have been reported following premature thelarche. Girls with fluctuating thelarche were reported as having mutations in the *GNAS1* gene, though without other signs of McCune-Albright syndrome.

B. Premature menarche   In rare cases, girls may begin to menstruate at an early age without showing other signs of estrogen effect. An unproved theory suggests that they may be manifesting increased uterine sensitivity to estrogen. In most subjects, menses stop within one to 6 years, and normal pubertal progression occurs thereafter.

C. Premature Adrenarche   The term **premature adrenarche** denotes the early appearance of pubic or axillary hair without other signs of virilization or puberty. This nonprogressive disorder is compatible with the occurrence of other signs of puberty at the normal age for puberty. Premature adrenarche is more common in girls than in boys, and premature adrenarche is usually found in children over 6 years of age. Sometimes premature adrenarche can overlap with the new age limits of puberty in girls. Plasma and urinary DHEAS levels are generally elevated to stage 2 pubertal levels, higher than normally found in this age group but well below those seen with tumors of the adrenal glands. Bone and height ages may be slightly advanced for chronologic age. Patients may have abnormal electroencephalographic tracings without other signs of neurologic dysfunction.

The presenting symptoms of late-onset adrenal hyperplasia may be similar to those of premature adrenarche, and the differential diagnosis may require ACTH stimulation testing (see Chapter 14). This condition may also present in a manner similar to polycystic ovarian syndrome (PCOS) (see Chapter 13). Infants born small for gestational age (SGA) have a predilection to develop premature adrenarche. These girls may also progress to PCOS. Daughters of women with PCOS demonstrate elevated androgen concentrations before the age of puberty, and these daughters may progress themselves to develop PCOS.

D. Adolescent gynecomastia   Up to 75% of boys have transient unilateral or bilateral gynecomastia, usually beginning in stage 2 or 3 of puberty and regressing about 2 years later. Serum estrogen and testosterone concentrations are normal, but the estradiol-testosterone ratio may be elevated and SHBG concentrations may be high. Reassurance is usually all that is required, but some severely affected patients with extremely prominent breast development require reduction mammoplasty if psychologic distress is extreme. After 2 years of gynecomastia, the likelihood of spontaneous regression decreases due to the formation of scar tissue in the breast. Early studies of aromatase inhibitors in the medical treatment of gynecomastia were disappointing.

Some pathologic conditions such as Klinefelter syndrome and the syndromes of incomplete androgen resistance are also associated with gynecomastia; these disorders should be clearly differentiated from the gynecomastia of normal puberty in males. Certain medications list gynecomastia as a side-effect but in most cases it appears to be adipose tissue rather than true glandular breast development. Most of them, including the atypical antipsychotics, raise prolactin levels; hyperprolactinemia does not by itself cause substantial breast development but does cause galactorrhea from activity of the secretory glands. Marijuana use can also increase the risk for gynecomastia.

Differential Diagnosis of Precocious Puberty

The history and physical examination should be directed toward one of the diagnostic possibilities discussed earlier. Serum gonadotropin and sex steroid concentrations are determined in order to distinguish gonadotropin-mediated secondary sexual development (serum gonadotropin and sex steroid levels elevated to pubertal levels) from autonomous endogenous secretion or exogenous administration of gonadal steroids (serum gonadotropin levels suppressed and sex steroid levels elevated). Gonadotropins must be measured in a third-generation assay with pediatric standards, as the customary gonadotropin determinations are too insensitive to reveal the small changes of puberty.

Measurement of testosterone or estradiol must be done in an ultrasensitive assay with pediatric standards or, as with gonadotropin assays, the small changes of pubertal development will be missed. Highly sensitive high performance liquid chromatography tandem mass spectroscopy (HPLC MS/MS) assays are available at national laboratories for this purpose. Third-generation ultrasensitive immunoassays can identify the onset of increased gonadotropin secretion with a single basal unstimulated serum sample. In the past, a GnRH test was required to confirm an increase in LH secretion at puberty because of the overlap of pubertal and prepubertal values of LH in the basal state. These third-generation gonadotropin assays can be applied to urine as well as serum samples; this may someday eliminate the need for GnRH agonist testing or serial serum sampling.

If serum LH concentrations, measured in an assay that cross-reacts with hCG, are quite high in a boy or if a pregnancy screening test (β-hCG) is positive, the likely diagnosis is an extra-pituitary, hCG-secreting tumor. β-LH values are suppressed, so no confusion with hCG levels is possible. If no abdominal or thoracic source of hCG is found, MRI of the brain with particular attention to the hypothalamic-pituitary area is indicated to evaluate the possibility of a germinoma of the pineal gland.

If serum sex steroid levels are very high and gonadotropin levels are low in third-generation assays, an autonomous source of gonadal steroid secretion must be assumed. If plasma gonadotropin and sex steroid levels are in the pubertal range, the most likely diagnosis is complete precocious puberty (Table 15–5).

TABLE 15–5 Differential diagnosis of precocious puberty.

Differentiation between premature thelarche and central precocious puberty is usually accomplished by physical examination, but determination of serum estradiol or gonadotropins may be required. The evaluation of uterine size by ultrasound may also be useful, because premature thelarche causes no increase in uterine volume while central precocious puberty does. Central precocious puberty is also associated with an "endometrial stripe" on ultrasound evaluation. Ovarian size determination is a less useful method of distinguishing between the two possibilities but may reveal pubertal ovarian cysts. As noted earlier, some girls initially thought to have precocious thelarche progress to complete precocious puberty, but there is no way presently to distinguish girls who will progress from those who will not.

The onset of true or complete precocious puberty may indicate the presence of a hypothalamic tumor. Boys more often than girls have central nervous system tumors associated with complete precocious puberty. Skull x-rays are not usually helpful, but CT or MRI scanning is indicated in children with true precocious puberty. The present generation of CT and MRI scanners can make thin cuts through the hypothalamic-pituitary area with good resolution; small hypothalamic hamartomas are now being diagnosed more frequently. Generally, MRI is preferable to CT because of better resolution; the use of contrast may help evaluate possible central nervous system lesions.

Treatment of Precocious Puberty

A. Central precocious puberty   In the past, medical treatment of true precocious puberty involved medroxyprogesterone acetate or cyproterone acetate—progestational agents that reduce gonadotropin secretion by negative feedback.

However, current treatment for central precocious puberty, either idiopathic or due to a central nervous system lesion, involves the use of GnRH agonists that suppress sexual maturation and decrease growth rate and skeletal maturation. Chronic administration of highly potent and long-acting analogs of GnRH has been shown to down regulate GnRH receptors and reduce pituitary gland response to GnRH, thereby causing decreased secretion of gonadotropin and sex steroids and rapidly stopping the progression of sexual precocity. In girls, pubertal enlargement of the ovaries and uterus reverts toward the prepubertal state, and the multicystic appearance of the pubertal ovary regresses as well. This suppressive effect is reversed after therapy is discontinued and puberty progresses. GnRH agonist treatment has been successful for idiopathic precocious puberty and precocious puberty caused by hamartomas of the tuber cinereum, neoplasms of the central nervous system, or long-term androgen exposure. The GnRH agonists were originally given by daily subcutaneous injection or intranasal insufflation. Injection of GnRH agonists in depot preparations every 4 weeks, or every 3 months in a more recent preparation, or in an implantable silastic pellet which is left in place for one or 2 years has now made treatment much more effective. The FDA has approved histrelin, a GnRH agonist administered on a daily basis, and leuprolide acetate, a long-acting GnRH agonist, administered every 28 days, or every 3 months, for the management of precocious puberty. Individual monitoring

is essential to ascertain gonadotropin suppression. An implantable depot preparation of the GnRH agonist histrelin may be left in for 1 to 2 years without the requirement for frequent monitoring. Complete suppression of pubertal devlopment is necessary because an incompletely suppressed patient may appear to have arrested pubertal development while actually secreting low but significant levels of sex steroids. Without clinical suppression, bone age advances while the growth rate is decreased, leading to even shorter adult stature. However gonadotropin secretion need not be completely suppressed for effective management of precocious puberty as there are reports in which patients were clinically controlled while gonadotropins values were not suppressed to the prepubertal range. Side-effects of these agonists have generally been limited to allergic skin reactions and elevation of immunoglobulins directed against GnRH. Significant anaphylactic reactions to an injection have rarely been reported. Decrease in bone mineral density is a potential side-effect of GnRH agonists; increased dietary calcium and supplementation of vitamin D intake is wise especially because there are frequent deficiencies in the majority of children.

Growth velocity decreases within 5 months after the start of therapy, and rapid bone age advancement decreases to a rate below the increase in chronologic age. Without therapy, adult height in patients with central precocious puberty approaches 152 cm in girls and 155 to 164 cm in boys. The first patients treated with GnRH agonists have now reached adult height: the girls have a mean height of 157 cm and the boys a mean height of 164 cm—a definite improvement over the untreated state. The shortest height prognosis is found in children with an early onset of precocious puberty who are not treated. The best outcomes of therapy are noted when diagnosis and therapy are achieved early, and as earlier diagnosis is now made in children with central precocious puberty and earlier therapy is offered, better results are expected in the future. Menarche and even pregnancy are reported after the discontinuation of therapy in girls, indicating a reversion to normal pubertal endocrine function following GnRH agonist treatment. The new lower age limits of normal pubertal development in girls have led clinicians to reassess the criteria used to identify appropriate candidates for therapy. Patients without significant elevation of serum estrogen, who have a predicted height appropriate for family and who have slowly progressing variants without early menarche, will likely achieve an appropriate adult height without therapy.

The somatic changes or menses frighten some children and may make them the object of ridicule. These patients do not experience social maturation to match their physical development, although their peers, teachers, and relatives tend to treat them as if they were older because of their large size. Thus, supportive counseling must be offered to both patient and family. Children with precocious puberty are more often sexually targeted and subsequently abused, so appropriate precautions are necessary.

B. Peripheral or Incomplete precocious puberty   Treatment of the disorders discussed earlier under peripheral precocious puberty is directed toward the underlying tumor or abnormality rather than toward the signs of precocious puberty. If the primary

cause is controlled, signs of sexual development are halted and may even regress.

Males with familial Leydig and germ cell maturation do not initially respond to GnRH agonist therapy, but some have improved with medroxyprogesterone acetate. Affected boys were successfully treated with ketoconazole, an antifungal agent that can block 17,20-lyase activity and, therefore, decrease testosterone production. However, ketoconazole also suppresses adrenal function as a significant side-effect. After initial control with ketoconazole, the boys developed central precocious puberty, because prolonged exposure to androgens led to maturation of their hypothalamic-pituitary axis; treatment with a GnRH agonist then effectively halted this pubertal progression.

Newer therapy for McCune-Albright syndrome in girls is a combination of testolactone (an aromatase inhibitor) and spironolactone (which acts as an antiandrogen). Long-term follow-up demonstrated some decrease in menses, improvement in growth patterns and bone age advancement. Some escaped from control, necessitating the addition of a GnRH agonist, which then suppressed pubertal development. The combination of tamoxifen or fulvesent, estrogen receptor blockers, with aromatase inhibitors (such as letrazole) has demonstrated some success in decreasing uterine bleeding and advancement in bone age in clinical trials. Girls with recurrent estrogen-secreting ovarian cyst formation may have a decreased incidence of cysts with medroxyprogesterone acetate therapy. A GnRH agonist may also be effective in such cases. Surgical removal of ovarian cysts may be unnecessary if such medical therapy is utilized first.

Precocious thelarche or adrenarche requires no treatment, as both are self-limited benign conditions. No therapy has been reported for premature menarche. Severe, persistent cases of adolescent gynecomastia have reportedly been treated successfully by testolactone and dihydrotestosterone heptanoate, although surgical removal of breast tissue is often necessary, as noted earlier.

Throughout pregnancy, the fetal-placental unit secretes protein and steroid hormones and eicosanoids that alter the function of every endocrine gland in the mother's body. Both clinically and in the laboratory, pregnancy can mimic hyperthyroidism, Cushing disease, pituitary adenoma, diabetes mellitus, polycystic ovary syndrome, and more.

The endocrine changes associated with pregnancy are adaptive, allowing the mother to nurture the developing fetus. Although maternal reserves are usually adequate, in cases of gestational diabetes or hypertensive disease of pregnancy, a woman may develop overt signs of disease as a direct result of pregnancy.

Aside from creating a satisfactory nutritive environment for fetal development, the placenta serves as an endocrine, respiratory, alimentary, and excretory organ. Measurements of fetal-placental products in the maternal serum provide one means of assessing fetal well-being. This chapter will consider the changes in maternal endocrine function in pregnancy and during-parturition as well as fetal endocrine development. The chapter concludes with a discussion of some endocrine disorders complicating pregnancy.

CONCEPTION AND IMPLANTATION

Fertilization

In fertile women, ovulation occurs approximately 12 to 16 days after the onset of the previous menses. The ovum must be

fertilized within 24 to 48 hours if conception is to result. For about 48 hours around ovulation, cervical mucus is copious, non-viscous, slightly alkaline, and forms a gel matrix that acts as a filter and conduit for sperm. Sperm begin appearing in the outer third of the fallopian tube (the ampulla) 5 to 10 minutes after coitus and continue to migrate to this location from the cervix for about 24 to 48 hours. Of the 200×10^6 sperm that are deposited in the vaginal fornices, only approximately 200 reach the distal tube. Fertilization normally occurs in the ampulla.

Implantation and hCG Production

After fertilization and zygote transport into the endometrial cavity, blastocyst invasion of the uterus occurs during a specific window of implantation 8 to 10 days after ovulation. Vitronectin, an alpha-v-beta-3 integrin receptor ligand, serves as one of several links between the maternal and embryonic epithelia. Two layers of placental epithelial cells, cytotrophoblasts and syncytiotrophoblasts, develop after the blastocyst invades the endometrium (Figure 16–1).
FIGURE 16–1 Microanatomy of the human placental bed. Oxygen, nutrients, and waste products are exchanged between the fetus and the mother across this interface. In normal placental development (upper panel), invasive cytotrophoblasts of fetal origin transform the maternal spiral arteries, displacing maternal endothelial cells and remodeling the vessels from small-caliber resistance vessels to high-caliber capacitance vessels capable of placental perfusion adequate to sustain fetal growth. In preeclampsia and some cases of fetal growth restriction, cytotrophoblasts fail to adopt an invasive endothelial phenotype. Instead, invasion of the spiral arteries is shallow and they remain small-caliber resistance vessels (lower panel). This can lead to placental ischemia. (Reproduced with permission from Karumanchi SA, Maynard SE, Stillman IE, et al. Preeclampsia: a renal perspective. *Kidney Int*. 2005 Jun;67(6):2101-2113.)

Columns of invading cytotrophoblasts anchor the placenta to the endometrium. The differentiated syncytiotrophoblast, derived from fusion of cytotrophoblasts, is in direct contact with the maternal circulation. The syncytiotrophoblast is the major source of hormone production, containing the cellular machinery needed for synthesis and secretion of both steroid and polypeptide hormones.

In most spontaneously conceived pregnancies, the dates of ovulation and implantation are not known. Weeks of gestation (*gestational age*) are by convention calculated from the first day of the last menstrual period. Within 24 hours after implantation, or at about 3 weeks of gestation, human chorionic gonadotropin (hCG), produced by syncytiotrophoblasts (see Figure 16–1), is detectable in maternal serum. Under the influence of increasing hCG production, the corpus luteum secretes progesterone, estradiol, and relaxin in increasing quantities.

Ovarian Hormones of Pregnancy

The hormones produced by the corpus luteum include progesterone, 17-hydroxyprogesterone, relaxin, and estradiol. The indispensability of the corpus luteum in early pregnancy has been demonstrated by ablation studies, in which luteectomy or oophorectomy before 42 days of gestation results in precipitous decreases in levels of serum progesterone and estradiol, followed by abortion. Exogenous progesterone will prevent abortion, proving that progesterone alone is required for maintenance of early pregnancy. After about the seventh gestational week, the corpus luteum can be removed without subsequent abortion owing to compensatory progesterone production by the placenta.

Because the placenta does not express the 17α-hydroxylase enzyme (P450C17), it cannot produce appreciable amounts of 17-hydroxyprogesterone; thus, this steroid provides a marker of corpus luteum function. As shown in Figure 16–2, the serum concentrations of estrogens and total progesterone exhibit a steady increase, but the concentration of 17-hydroxyprogesterone rises and then declines to low levels that persist for the duration of the pregnancy. Another marker of corpus luteum function is the polypeptide hormone relaxin, a protein with a molecular mass of about 6000. Pharmacologically, relaxin ripens the cervix, softens the pubic symphysis, promotes decidual angiogenesis, and acts synergistically with progesterone to inhibit uterine contractions.

Symptoms and Signs of Pregnancy

Breast tenderness, fatigue, nausea, absence of menstruation, softening of the uterus, and a sustained elevation of basal body temperature are mostly attributable to hormone production by the corpus luteum and developing placenta.

FETAL-PLACENTAL-DECIDUAL UNIT

The function of the placenta is to establish effective communication between the mother and the developing fetus while maintaining the immune and genetic integrity of both individuals. Initially, the placenta functions autonomously. By the end of the first trimester, however, the fetal endocrine system is sufficiently developed to complement placental function and to provide some hormone precursors to the placenta. From this time, it is useful to consider the endocrine conceptus as the fetal-placental unit.

The decidua is the endometrium of pregnancy. Decidual cells are capable of synthesizing a variety of polypeptide hormones, including relaxin, prolactin (PRL), and a variety of paracrine factors, in particular vascular endothelial growth factor (VEGF) and insulin-like growth factor (IGF)-binding protein 1. The precise function of the decidua as an endocrine organ has not been established, but its role as a source of prostaglandins during labor is certain (see "Endocrine Control of Parturition," later).

POLYPEPTIDE HORMONES

Human Chorionic Gonadotropin

The first marker of trophoblast differentiation and the first measurable product of the placenta is hCG, a glycoprotein consisting of 237 amino acids. It is similar in structure to the pituitary glycoprotein hormones in that it consists of two chains: a common alpha chain and a specific beta chain, which determines receptor interaction and ultimate biologic specificity. The alpha chain is identical in sequence to the alpha chains of thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The beta chain has 67% sequence homology with LH and an additional 30 carboxy terminal amino acids not found in LH beta.

In early pregnancy (up to 6 weeks), the concentration of hCG doubles every 1.7 to 2 days, and serial measurements provide a sensitive index of early trophoblast function and viability. Maternal plasma hCG peaks during the tenth gestational week and then declines gradually in the third trimester. Peak concentrations correlate temporally with the establishment of maternal blood flow in the intervillous space (see Figure 16–1, upper panel).

The long plasma half-life of hCG (24 hours) allows the tiny mass of cells comprising the blastocyst to produce sufficient hormone to be detected in the peripheral circulation within 24 hours of implantation. Thus, pregnancy can be diagnosed several days before symptoms occur or a menstrual period has been missed. Antibodies to the unique beta-carboxyl terminal segment of hCG do not cross-react significantly with any of the pituitary glycoproteins.

hCG is also produced in gestational trophoblastic neoplasia (GTN) by hydatidiform mole and choriocarcinoma, and the concentration of hCG-beta is used as a tumor marker for diagnosis and for monitoring the success of chemotherapy in these disorders. Women with very high hCG levels due to GTN may become clinically hyperthyroid due to the action of hCG on TSH receptors; they can revert to euthyroidism as hCG is reduced during chemotherapy.

Human Placental Lactogen

A second placental polypeptide hormone is human placental lactogen (hPL). hPL is produced by early trophoblasts, but detectable

SYSTEM	HORMONE	PATTERN	AVERAGE PEAK CONCENTRATION (TIME)
Placenta and corpus luteum	Progesterone	Rises to term	190 ng/mL (552 nmol/L) (term)
	17-Hydroxy-progester-one	Peaks at 5 wk, then declines	6 ng/mL (19 nmol/L) (5 wk)
Adrenal	Cortisol	Increases to 3 times prepreg-nancy values at term	300 ng/mL (0.83 µmol/L) (term)
	Aldosterone	Plateaus at 34 wk with small rise near term	100 ng/mL (277 nmol/L) (term)
	DOC	Increases to 10 times prepreg-nancy value at term	1200 pg/mL (3.48 nmol/L) (term)
Thyroid	Total T$_4$	Increases during first trimester, then plateaus	150 ng/mL (193 pmol/L)
	Free T$_4$	Unchanged	30 pg/mL (38.6 pmol/L)
	Total T$_3$	Increases during first trimester, then plateaus	2 ng/mL (3.1 nmol/L)
	Free T$_3$	Unchanged	4 pg/mL (5.1 pmol/L)
FIGURE 16–2 Maternal serum hormone changes during pregnancy.

SYSTEM	HORMONE	PATTERN	AVERAGE PEAK CONCENTRATION (TIME)
Anterior pituitary	GH	Unchanged	
	LH, FSH	Low, basal levels	
	ACTH	Unchanged	
	TSH	Reaches nadir during first trimester, then plateaus	
	PRL	Rise to term	200 ng/mL (9 nmol/L) (term)

Placental proteins	hCG	Peaks at 10 wk, then decreases to a lower plateau	5 µg/mL (0.2 µmol/L) (end of first trimester)
	hPL	Rises with placental weight	5-25 µg/mL (term) (0.2-1.0 µmol/L)
	CRH	Rises acutely about 20 d before delivery	1-3 ng/mL (2-6 nmol/L) at term

Fetoplacental estrogens	Estriol	Increases to term	15-17 ng/mL (55-62 nmol/L) (term)
	Estradiol	Increases to term	12-15 ng/mL (42-52 nmol/L) (term)
	Estrone	Increases to term	5-7 ng/mL (18.5-26 nmol/L) (term)

Fetoplacental androgens	Testosterone	Rises to 10 times pre-pregnancy values	2000 pg/mL (6.9 nmol/L) (term)
	DHEA	Falls during pregnancy	5 ng/mL (17.3 nmol/L) (pre-pregnancy)
	Androstenedione	Small increase	2.6 ng/mL (9.0 nmol/L) (term)
FIGURE 16–2 (*Continued*)

serum concentrations are not reached until 4 to 5 gestational weeks (see Figure 16–2). hPL is a protein of 190 amino acids whose primary, secondary, and tertiary structures are similar to those of growth hormone (GH) and PRL. hPL is diabetogenic and lactogenic, but it has minimal growth-promoting activity as measured by standard GH bioassays.

The physiologic role of hPL during pregnancy remains controversial, and normal pregnancy without detectable hPL production has been reported. Although not clearly shown to be a mammotropic agent, hPL contributes to altered maternal glucose metabolism and mobilization of free fatty acids; causes a hyperinsulinemic response to glucose loads; appears to directly stimulate pancreatic islet insulin secretion; and contributes to the peripheral insulin resistance characteristic of pregnancy. Along with prolonged fasting and insulin-induced hypoglycemia, pre-beta-HDL and apoprotein A-I are two factors that stimulate release of hPL. hPL production is roughly proportionate to placental mass. Actual production rates may reach as much as 1 to 1.5 g/d at term.

Serum hPL concentrations were used historically as a clinical indicator of the health of the placenta, but the range of normal values was wide, and serial determinations were necessary; they are therefore no longer used clinically.

Other Chorionic Peptide Hormones and Growth Factors

Other chorionic peptides have been identified, but their functions remain poorly defined. Activin, inhibin, corticotropin-releasing hormone, and multiple peptide growth factors, including fibroblast growth factor (FGF), epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and the IGFs all have been isolated from placental tissue. Placental growth factor (PlGF) and the related VEGF are suggested to play a role in placental angiogenesis, preeclampsia, and fetal growth.

STEROID HORMONES

In contrast to the impressive synthetic capability exhibited in the production of placental proteins, the placenta does not have the ability to synthesize steroids de novo. However, the trophoblasts have remarkable capacity to efficiently interconvert steroids derived from maternal or fetal precursors. This activity is demonstrable even in the early blastocyst, and by the seventh gestational week, when the corpus luteum undergoes involution, the placenta becomes the dominant source of steroid hormones.

Progesterone

The placenta relies on maternal cholesterol as its substrate for progesterone production. Fetal death has no immediate influence on progesterone production, suggesting that the fetus is a negligible source of substrate. Enzymes in the placenta cleave the cholesterol side chain, yielding pregnenolone, which in turn is isomerized to progesterone; 250 to 350 mg of progesterone are produced daily by the third-trimester placenta, and most enters the maternal circulation (see Figure 16–2). Whereas exogenous

hCG stimulates progesterone production in early pregnancy, hypophysectomy, adrenalectomy, or oophorectomy have no effect on progesterone levels after the luteo-placental shift at 7 to 9 weeks of gestation. Likewise, the administration of adrenocorticotropin (ACTH) or cortisol does not influence placental progesterone secretion.

Progesterone is necessary for establishment and maintenance of pregnancy. Insufficient production of progesterone may contribute to failure of implantation, recurrent pregnancy loss, and preterm delivery. Progesterone, along with relaxin and nitric oxide, maintains uterine quiescence during pregnancy. Clinical trials have indicated that the administration of 17α-hydroxyprogesterone caproate can reliably prevent preterm delivery in high-risk pregnancies. Progesterone also inhibits T cell–mediated allograft rejection. Thus, high local concentrations of progesterone may contribute to immunologic tolerance by the uterus of invading trophoblast tissue from the semiallogeneic fetus.

Estrogens

Estrogen production by the placenta also depends on circulating precursors, but in this case both fetal and maternal steroids are important sources. Most of the placental estrogens are derived from fetal androgens, primarily dehydroepiandrosterone (DHEA) sulfate. Fetal DHEA sulfate, produced mainly by the fetal adrenal, is converted by placental sulfatase to free DHEA and then, through enzymatic pathways common to steroid-producing tissues, to androstenedione and testosterone. These androgens are finally aromatized by the placenta to estrone and estradiol, respectively. 17α-Hydroxysteroid dehydrogenase type II prevents fetal exposure to potent estrogens by catalyzing the conversion of estradiol to less potent estrone.

Most fetal DHEA sulfate is metabolized to produce a third estrogen: estriol. Estriol is a weak estrogen with 1/10 the potency of estrone and 1/100 the potency of estradiol. Serum estrone and estradiol concentrations are increased during pregnancy about 50-fold over their maximal prepregnancy values, but estriol increases approximately 1000-fold. The substrate for the reaction is 16α-hydroxy-DHEA sulfate produced in the fetal adrenal and liver, not in maternal or placental tissues. The final steps of desulfation and aromatization to estriol occur in the placenta. Maternal serum or urinary estriol measurements, unlike measurements of progesterone or hPL, reflect fetal as well as placental function. Rising serum or urinary estriol concentrations were once used as biochemical indicators of fetal well-being (see Figure 16–2). Decreased estriol production can result from congenital derangements or iatrogenic intervention. Maternal estriol remains low in pregnancies with placental sulfatase deficiency and in cases of fetal anencephaly. In the first case, DHEA sulfate cannot be hydrolyzed; in the second, little fetal DHEA is produced because fetal adrenal growth stimulation by ACTH is lacking. Maternal administration of glucocorticoids also inhibits fetal ACTH and lowers maternal estriol. Administration of DHEA to the mother during a healthy pregnancy increases estriol production. Placental corticotropin-releasing hormone (CRH) also may be an important regulator of fetal adrenal DHEA sulfate secretion.

Modern methods of screening for fetal chromosomal aneuploidy, particularly trisomy 21 (Down syndrome), utilize circulating biochemical markers. Screening by maternal age alone (>35 years) led to the prenatal identification of only about 25% of aneuploid fetuses. As an aneuploid chromosome complement affects both fetal and placental tissues, their protein and steroid profiles can be informative. A combination of alpha-fetoprotein (AFP), hCG, inhibin-A and unconjugated estriol concentrations, measured in maternal serum between 15 and 18 weeks of gestation, can be used to identify fetal Down syndrome and trisomy 18 with a detection rate of >80% over all age groups.

MATERNAL ADAPTATION TO PREGNANCY

As a successful *parasite*, the fetal-placental unit manipulates the maternal *host* for its own gain but normally avoids imposing excessive stress that would jeopardize the pregnancy. The prodigious production of polypeptide and steroid hormones by the fetal-placental unit directly or indirectly results in physiologic adaptations of virtually every maternal organ system. These alterations are summarized in Figure 16–3. Most of the commonly measured maternal endocrine function tests are radically changed. In some cases, true physiologic alteration has occurred; in others, the changes are due to increased production of hormone–binding proteins by the liver or to decreased serum levels of albumin due to the mild dilutional anemia of pregnancy. In addition, some endocrine changes are mediated by altered clearance rates due to increased glomerular filtration, decreased hepatic excretion, or metabolic clearance of steroid and protein hormones by the placenta. The changes in endocrine function tests are summarized in Table 16–1. Failure to recognize normal pregnancy-induced alterations in endocrine function tests can lead to unnecessary diagnostic tests and interventions that may be seriously detrimental to mother and fetus.

Maternal Pituitary Gland

The mother's anterior pituitary gland hormones have little influence on pregnancy after implantation has occurred. The gland itself enlarges by about one-third, with the major component of this increase being hyperplasia of the lactotrophs in response to the high plasma estrogens. PRL, the product of the lactotrophs, is the only anterior pituitary hormone that rises progressively during pregnancy and peaks at the time of delivery. In spite of its high serum concentrations, pulsatile release of PRL and food-induced and nocturnal increases persist. Hence, the normal neuroendocrine regulatory mechanisms appear to be intact in the maternal adenohypophysis. In nonlactating women, maternal PRL decreases to pregestational levels within 3 months of delivery. Pituitary ACTH and TSH secretion remain unchanged. Serum FSH and LH fall to the lower limits of detectability and are unresponsive to GnRH stimulation during pregnancy. GH concentrations are not significantly different from nonpregnant levels, but pituitary response to provocative testing is markedly altered. GH response

to hypoglycemia and arginine infusion is enhanced in early pregnancy but thereafter becomes depressed. Established pregnancy can continue in the face of hypophysectomy, and in women hypophysectomized prior to pregnancy, induction of ovulation and normal pregnancy can be achieved with appropriate gonadotropin replacement therapy. In cases of primary pituitary hyperfunction, the fetus is not affected.

Maternal Thyroid Gland

The thyroid becomes palpably enlarged during the first trimester, and a subtle bruit may be present. Thyroid iodide clearance and thyroidal ^{131}I uptake, which is clinically contraindicated in pregnancy, have been shown to be increased. These changes are due in large part to the increased renal clearance of iodide, which causes a relative iodine deficiency. Although total serum thyroxine is elevated as a result of estrogen-stimulated increased thyroid hormone–binding globulin (TBG), free thyroxine and triiodothyronine are normal (see Figure 16–2). High circulating concentrations of hCG, particularly asialo-hCG, which has weak TSH-like activity, contribute to the thyrotropic action of the placenta in early pregnancy. In fact, there is significant, though transient, biochemical hyperthyroidism associated with hCG stimulation in early gestation.

Maternal Parathyroid Gland

The net calcium requirement imposed by fetal skeletal development is estimated to be about 30 g by term. This is met by hyperplasia of the maternal parathyroid glands and elevated serum levels of parathyroid hormone. The maternal serum calcium concentration declines to a nadir at 28 to 32 weeks, largely due to the mild hypoalbuminemia of pregnancy but also to fetal bone formation. Ionized calcium is maintained at normal concentrations throughout pregnancy.

Maternal Pancreas

The nutritional demands of the fetus require alteration of maternal metabolic homeostatic control, which results in both structural and functional changes in the maternal pancreas. The size of pancreatic islets increases, and insulin-secreting beta cells undergo hyperplasia. Basal levels of insulin are lower or unchanged in early pregnancy but increase during the second trimester as a result of increased secretion rather than decreased metabolic clearance. Thereafter, pregnancy is a hyperinsulinemic state, with resistance to its peripheral metabolic effects. Pancreatic production of glucagon remains responsive to the usual endocrine stimuli and is suppressed by glucose loading, although the degree of responsiveness has not been well evaluated in pregnancy.

The major roles of insulin and glucagon involve the intracellular transport of nutrients, specifically glucose, amino acids, and fatty acids. Insulin is not transported across the placenta, but rather exerts its effects on transportable metabolites. During pregnancy, peak insulin secretion in response to meals is accelerated, and glucose tolerance curves are characteristically altered. Fasting glucose levels are maintained at low-normal levels. Excess

SYSTEM	PARAMETER	PATTERN
Cardiovascular	Heart rate	Gradually increases 20%
	Blood pressure	Gradually decreases 10% by 34 wk, then increases to prepregnancy values
	Stroke volume	Increases to maximum at 19 wk, then plateaus
	Cardiac output	Rises rapidly by 20%, then gradually increases an additional 10% by 28 wk
	Peripheral venous distention	Progressive increase to term
	Peripheral vascular resistance	Progressive decrease to term
Pulmonary	Respiratory rate	Unchanged
	Tidal volume	Increases by 30%-40%
	Expiratory reserve	Gradual decrease
	Vital capacity	Unchanged
	Respiratory minute volume	Increases by 40%
Blood	Volume	Increases by 50% in second trimester
	Hematocrit	Decreases slightly
	Fibrinogen	Increases
	Electrolytes	Unchanged
Gastrointestinal	Sphincter tone	Decreases
	Gastric emptying time	Increases
FIGURE 16–3 Maternal physiologic changes during pregnancy.

SYSTEM	PARAMETER	PATTERN
Renal	Renal flow	Increases 25%-50%
	Glomular filtration rate	Increases early, then plateaus
Weight	Uterine weight	Increases from about 60-70 g to about 900-1200 g
	Body weight	Average 11-kg (25-lb) increase
FIGURE 16–3 (*Continued*)

carbohydrate is converted to fat, and fat is readily mobilized during decreased caloric intake.

Maternal Adrenal Cortex

Total plasma cortisol concentrations increase to three times nonpregnant levels by the third trimester. Most of the changes can be explained by increased estrogens causing higher corticosteroid-binding globulin (CBG) production. The actual production of cortisol by the zona fasciculata also is increased in pregnancy. The net effect of these changes increases plasma-free cortisol, which is approximately doubled by late pregnancy. In spite of cortisol

TABLE 16–1 Effect of pregnancy on endocrine function tests.

	Test	Result
Pituitary FSH, LH	GnRH stimulation	Unresponsive from third gestational week until puerperium
GH	Insulin tolerance test	Response increases during the first half of pregnancy and then is blunted until the puerperium
	Arginine stimulation	Hyperstimulation during the first and second trimesters, then suppression
TSH	TRH stimulation	Response unchanged
Pancreas Insulin	Glucose tolerance	Peak glucose increases, and glucose concentration remains elevated longer
	Glucose challenge	Insulin concentration increases to higher peak levels
	Arginine infusion	Insulin response is blunted in mid to late pregnancy
Adrenal Cortisol	ACTH infusion	Exaggerated cortisol and aldosterone responses
	Metyrapone	Diminished response
Mineralocorticoids	ACTH infusion	No DOC response
	Dexamethasone suppression	No DOC response

concentrations approaching those found in Cushing syndrome, diurnal variation in plasma cortisol is maintained. The elevated free cortisol concentration probably contributes to the insulin resistance of pregnancy and possibly to the appearance of striae, but most signs of hypercortisolism do not occur in pregnancy. It is suggested that high progesterone levels act to antagonize glucocorticoid effects.

Serum aldosterone also is markedly elevated in pregnancy, due to an eightfold increased production rate by the zona glomerulosa. Renin substrate is increased due to the influence of estrogen on hepatic synthesis, and renin also is elevated, leading to increased angiotensin. In spite of these dramatic changes, normal pregnant women show few signs of hyperaldosteronism. There is no tendency toward hypokalemia or hypernatremia, and blood pressure at midpregnancy—when changes in the renin-angiotensin-aldosterone system are maximal—actually tends to be lower than in the nonpregnant state. Progesterone is an effective competitive inhibitor of mineralocorticoids in the distal renal tubules. Thus, increases in renin and aldosterone may simply be an appropriate response to the high gestational levels of progesterone. Elevated angiotensin II does not normally result in hypertension, because of diminished sensitivity of the maternal vascular system to angiotensin and possibly due to the vasodilatory activity of the Ang 1-7 proteolytic product. Exogenous angiotensin provokes a smaller increase in blood pressure than in the nonpregnant state. Finally, in patients with preeclampsia, the most common form of pregnancy-related hypertension, serum renin, aldosterone, and angiotensin levels are unchanged or even lower than in normal pregnancy, thus ruling out a primary role for the renin-angiotensin system in this disorder.

In normal pregnancy, the maternal production of androgens is slightly increased but these are buffered by sex hormone–binding globulin (SHBG). Levels of SHBG are increased by estrogens. Testosterone, which binds avidly to SHBG, increases to the normal male range by the end of the first trimester, but free testosterone levels are actually lower than in the nonpregnant state. DHEA sulfate does not bind significantly to SHBG, and plasma concentrations of DHEA sulfate actually decrease during pregnancy.

The desulfation of DHEA sulfate by the placenta and the conversion of DHEA to estrogens by the fetal-placental unit are important factors in its increased metabolic clearance.

FETAL ENDOCRINOLOGY

Because of the physical inaccessibility of the human fetus, much of our information about fetal endocrinology is derived indirectly. Most early studies of fetal endocrinology relied on observations of infants with congenital disorders or inferences from ablation studies or acute manipulation in experimental animals. The development of effective cell culture methods and sensitive immunoassays, as well as the ability to achieve stable preparations of chronically catheterized monkey fetuses, have increased our understanding of the dynamics of intrauterine endocrine events. The endocrine system is among the first to develop in fetal life, but its study is complicated by its relative physical isolation as well as the multiplicity of sources of the various hormones. Dating of events in fetal development is usually given in *fetal weeks*, which begin at the time of fertilization. Thus, fetal age is always 2 weeks less than gestational age.

Fetal Pituitary Hormones

The characteristic anterior pituitary cell types are discernible as early as 8 to 10 fetal weeks, and all of the hormones of the adult anterior pituitary are extractable from the fetal adenohypophysis by 12 weeks. Similarly, the hypothalamic hormones thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), and somatostatin are present by 8 to 10 weeks. The direct circulatory connection between hypothalamus and pituitary develops later, with capillary invasion initially visible at about 16 fetal weeks.

The role of the fetal pituitary in organogenesis during the first trimester appears to be negligible. None of the pituitary hormones are released into the fetal circulation in large quantities until after 20 fetal weeks. Even GH appears not to be influential, and in fact total absence of GH is consistent with normal development at birth. Development of the gonads and adrenals during the first trimester appears to be directed by hCG rather than by fetal pituitary hormones, so that these organs initially develop even in the face of anencephaly.

During the second trimester, there is a marked increase in secretion of all of the anterior pituitary hormones, which coincides with maturation of the hypophysial portal system. Female fetuses exhibit higher FSH levels in both pituitary and serum than do males. Differentiation of the gonads is crucial for normal male sexual development and reproductive potential in both sexes. ACTH rises significantly during the second trimester and assumes an increasing role in directing the maturation of the differentiated adrenal, as shown by the anencephalic fetus, in which the fetal zone of the adrenal undergoes atrophy after 20 weeks. Fetal PRL secretion also increases after the twentieth fetal week, but its functional significance is unknown. Vasopressin and oxytocin are demonstrable by 12 to 18 weeks in the fetal posterior pituitary gland and correlate with the development of their sites of production, the supraoptic and paraventricular nuclei, respectively.

Fetal Thyroid Gland

The fetal thyroid gland develops initially in the absence of detectable TSH. By 12 weeks the thyroid is capable of iodine-concentrating activity and thyroid hormone synthesis, but prior to 16 to 20 weeks, the maternal thyroid appears to be the primary source for fetal T_4. This has implications in that infants born to even mildly hypothyroid mothers are reported to have lower IQs and other health problems. The function of the fetal thyroid hormones appears crucial to somatic growth and for successful neonatal adaptation. In particular, auditory maturational events are regulated by thyroid hormones.

During the second trimester, TRH, TSH, and free T_4 all begin to rise. The maturation of feedback mechanisms is suggested by the subsequent plateau of TSH at about 20 fetal weeks. Fetal T_3 and reverse T_3 do not become detectable until the third trimester. The hormone produced in largest amount throughout fetal life is T_4, with the metabolically active T_3 and its inactive derivative, reverse T_3, rising in parallel to T_4 during the third trimester. At birth, conversion of T_4 to T_3 is demonstrable. Goitrogenic agents such as propylthiouracil are transferred across the placenta and may induce fetal hypothyroidism and goiter.

Fetal Adrenal Cortex

The fetal adrenal cortex is identifiable as early as 4 weeks of fetal age, and by the seventh week, steroidogenic activity can be detected in the inner zone layers.

During gestation, the adrenal cortex differs anatomically and functionally from the adult gland and occupies as much as 0.5% of total body volume. Most of this tissue is composed of a unique fetal zone that subsequently is transformed into the definitive (adult) zone during the early neonatal period. The inner fetal zone is responsible for the majority of steroids produced during fetal life and comprises 80% of the mass of the adrenal. During the second trimester, the inner fetal zone continues to grow, while the outer zone remains relatively undifferentiated. At about 25 weeks, the definitive (adult) zone develops, ultimately assuming the principal role in steroid synthesis during the early postnatal weeks.

Fetal Gonads

The testis is histologically identifiable by about 6 fetal weeks. Primary testis differentiation begins with development of the Sertoli cells at 8 weeks of gestation. SRY, the sex-determining locus on the Y chromosome directs the differentiation of the Sertoli cells, the sites of anti-Müllerian hormone (AMH) synthesis. AMH, a member of the transforming growth factor-beta family of growth factors, specifically triggers the ipsilateral resorption of the Müllerian tract in males and prevents development of female internal structures. Embryonic androgen production begins in the developing Leydig cells at about 10 weeks, coincident with the peak production of placental hCG. Binding of hCG to fetal testes with stimulation of testosterone release has been demonstrated in the laboratory. Other fetal testicular products of importance are inhibin and the 5α-reduced testosterone metabolite dihydrotestosterone. Dihydrotestosterone is responsible for development of the male external genital structures.

Little is known about early fetal ovarian function, but by 7 to 8 weeks of intrauterine life the ovaries become morphologically recognizable. Oogonia mitosis is active and steroid-producing theca cell precursors are identifiable at 20 weeks. This corresponds

with peak gonadotropin levels from the fetal pituitary. Activin and inhibin peptide subunits are expressed in the midtrimester human testis but not in the midtrimester human ovary. In contrast to the male fetus, ovarian steroid production by the fetus is not essential for female phenotypic development (see Chapter 13).

ENDOCRINE CONTROL OF PARTURITION

During the last few weeks of pregnancy, two processes herald impending labor. Sporadic uterine contractions, usually painless, become increasingly frequent, and the lower uterine segment and cervix become softer and thinner, a process known as effacement, or ripening. While false alarms are fairly common, especially at term, the onset of true labor is usually fairly abrupt, with the establishment of regular contractions every 2 to 5 minutes, leading to delivery in less than 24 hours. The exact mechanisms, however, leading to this state of parturition remain largely unknown. Reasons for this deficit of knowledge are manifold. Firstly, control of parturition in most other species is substantially different from that in humans, rendering the study of animal models for human parturition ineffective. Secondly, ethical issues largely prevent experimental studies in human pregnancy. Hence, much of the available information on human parturition has been extrapolated from animal models that may not accurately reflect the complex, species-specific process of human labor. It is assumed that parturition is a multifactorial process in which the fetus and mother mutually "cooperate." At a minimum, the placenta and amnion play key roles.

Progesterone and Nuclear Progesterone Receptors

The "progestational" effects of this steroid hormone have been elucidated since the "progesterone block" hypothesis was put forth by Arpad Csapo in the 1950s. He proposed that progesterone maintains uterine relaxation by inhibiting myometrial contractility, and that withdrawal of progesterone triggers parturition. In species where the corpus luteum is the primary source of progesterone in pregnancy (such as mice, rats, and rabbits), the demise of this ovarian structure shortly preceding parturition is mediated by prostaglandin F2α (PGF2α). Similarly in humans, up to the seventh week of pregnancy when the luteoplacental shift in progesterone synthesis occurs, luteectomy without progesterone supplementation results in abortion. Agents that inhibit the actions of progesterone, such as mifepristone (RU486), or block the conversion of pregnenolone to progesterone, induce labor in most species. While parturition is triggered by a systemic decline in plasma progesterone levels in many mammals, human parturition occurs without such a demonstrable decline. This apparent paradox has spawned the concept of a "functional progesterone withdrawal" in human labor.

Progesterone's classical actions are exerted via binding to ligand-activated nuclear receptors that function as transcription factors, modulating downstream genomic activity. In the human,

two primary progesterone receptors have been identified. Progesterone receptor A (PGR-A) and progesterone receptor B (PGR-B) are products of the same gene but under control of two distinct promoters, resulting in full-length PGR-B and truncated PGR-A isoforms. Most genomic actions of progesterone are mediated through PGR-B, whereas PGR-A primarily functions to repress PGR-B activity. Progesterone responsiveness is determined by the relative amounts of the opposing isoforms, known as the PGR-A:PGR-B ratio. Early and mid-gestation are dominated by PGR-B abundance, while in late gestation, the ratio is reversed, with a preponderance of PGR-A. Inflammation and altered processing of PGRs have been implicated in the ratio switch, resulting in "functional progesterone withdrawal" and labor.

Progesterone has been shown to directly inhibit myometrial contractility via hyperpolarization, decreased amplitude of action potentials and by augmenting activity of the cAMP/protein kinase-A (PKA) signaling cascade, promoting uterine relaxation by preventing intracellular calcium release. Progesterone and PGR-B also maintain myometrial quiescence by repression of contraction associated protein (CAP) genes. Notable CAPs include the oxytocin receptor (OTR), prostaglandin F2α receptor, various prostaglandin metabolizing enzymes and the gap junction protein, connexin 43 (Cx43). When systemic progesterone levels fall or PGR antagonists are introduced, CAPs are activated.

Estrogens and Nuclear Estrogen Receptors

Placental production of estrogens peaks before parturition (see Figure 16–2) and these hormones also play a role in the transition from uterine relaxation to contractility. Administration of estrogen boluses to non-laboring women at term increases uterine contractility within 4–6 hours and accelerates delivery. Furthermore, treatment with high doses of estrogen or androstenedione (which is converted to estrogen) at mid-gestation has been shown to precipitate preterm labor. Resistance of the myometrium to the pro-labor effects of estrogen in early gestation is likely attributable to the relatively low tissue levels of ER-α and ER-β at this stage. With the onset of parturition and change in the PGR-A/PGR-B ratio, levels of ERs dramatically increase, facilitating estrogen action. Treatment with RU486 at mid-gestation also increases ER-α levels, functionally linking progesterone and estrogen action in the pregnant myometrium.

Corticotropin-releasing Hormone (CRH)

CRH is synthesized in the placenta as well as the hypothalamus, but its regulation is distinctive. Whereas cortisol inhibits hypothalamic CRH release, in the placenta cortisol exerts positive feedback on CRH expression. Thus, within the pregnant uterus, placental CRH drives an increase in fetal pituitary ACTH, which in turn increases adrenal production of cortisol, and the latter stimulates further placental CRH production. This autoregulation is thought to be responsible for the exponential rise of maternal CRH during labor. Moreover, as term approaches there is fall in CRH binding protein levels, leading to elevated free CRH levels. Progesterone decreases CRH production, whereas cytokines, such

as TNF-α, and lipopolysaccharide stimulate CRH, providing a clinically recognized link between inflammation and labor.

Placental CRH and cortisol also act on the fetal lungs to produce surfactant protein A (SP-A), which activates NF-κB and inflammatory cytokines within the uterus, enhancing myometrial contractility and coordinating fetal pulmonary maturity with uterine activity. CRH also directly influences CAPs, such as Cx43 and the myometrial response to PGF2α.

Oxytocin

Oxytocin infusion is commonly used to induce or augment labor. Both maternal and fetal oxytocin levels increase spontaneously during labor, but neither has been convincingly shown to trigger labor, and even women with posterior pituitary failure, manifested as diabetes insipidus, are able to deliver without oxytocin augmentation. The ability of oxytocin deficient mice (OT$^{-/-}$) to deliver normally suggests that alternate pathways for labor must exist. At term, increased sensitivity of uterine tissue to oxytocin is attributed to increased synthesis and density of oxytocin receptors (OTR). Clinical studies using the OTR inhibitor, atosiban, have demonstrated that delivery can be delayed by 24 to 48 hours, but meta-analyses do not show much clinical improvement in neonatal outcome.

Prostaglandins (PGs)

PGF2α administered intra-amniotically, vaginally, or intravenously is an effective abortifacient as early as 14 weeks of gestation. PGE2 administered vaginally induces labor in most women in the third trimester. The amnion and chorion contain high concentrations of arachidonic acid, and the decidua contains active PG synthetases. As signaling molecules, PGs act in a paracrine or autocrine manner to activate intracellular signaling and gene transcription via binding to G-protein receptors. PGs are almost certainly involved in maintenance of labor once it is established and are believed to be the final common pathway of parturition.

PRETERM LABOR/BIRTH

Preterm birth (PTB) is one of the most important problems in obstetrics today as it complicates approximately 12% of all births in the United States and 5% to 9% in other developed countries. Complications of preterm birth are significant; prematurity accounts for 75% of perinatal mortalities and more than 50% of long-term infant morbidities, resulting in high health-care costs. Approximately 50% of PTB is idiopathic or spontaneous, leading to delivery before 37 weeks of gestation. Thirty percent of cases follow preterm rupture of membranes (PROM) and the other 20% are attributed to medically indicated preterm delivery, typically due to worsening maternal disease or fetal compromise. The PTB rate rose more than 30% from 1981 to 2006, with late preterm births (at 34-36 weeks of gestational age) accounting for two-thirds of the increase. Annual costs of PTB have been calculated to approach 10 billion dollars in the USA alone.

PTB has a complex pathophysiology with heterogeneous genetic and environmental susceptibilities. Risk factors for preterm labor are varied and include history of prior preterm labor, uterine anomalies, multiple gestation, maternal medical complications, low prepregnancy body mass index, gestational bleeding, low socioeconomic status, minority race, behavioral habits such as smoking, alcohol and drug abuse, stressful events, limited or no prenatal care, and infection. The etiology of preterm labor is not well understood but may result from mechanical factors, hormonal changes, infection, or interruption of normal mechanisms responsible for sustaining uterine quiescence. Survival rates have improved due to the use of antenatal corticosteroids and improvements in neonatal resuscitation and intensive care. There is a well-documented racial disparity in rates of PTB with African Americans at 17% versus only 11% in Caucasians. Further, the infant mortality rate for African-American babies is 2.5 times higher than Caucasians. Population-based studies indicate that this disparity cannot be explained by socioeconomic status, maternal behavior, marital status, or education alone and likely point to true genetic differences or social stress.

Four major mechanistic pathways leading to PTB have been proposed: (1) stress or activation of maternal or fetal hypothalamic-pituitary-adrenal axis, (2) pathologic uterine distention, (3) inflammation/infection, and (4) decidual hemorrhage and coagulation. These are summarized in Figure 16–4. Each of these pathways has different epidemiologic, clinical, and biochemical features, but all are likely to initiate labor via PG production, myometrial activation, and degradation of extracellular matrix components leading to premature rupture of membranes and cervical dilation. The fetoplacental endocrine unit can trigger labor prematurely, activating CRH release in cases of a hostile intrauterine environment such as stress or chorioamnionitis.

Endotoxins from bacteria induce proinflammatory mediators such as IL-1β and TNF-α from the decidua, which stimulate PG production. Double knockout mice missing IL-1β and TNF-α have decreased rates of PTB after administration of microorganisms. Inflammatory cytokines in uterine tissue have been shown to increase the stability of PGR-A and affect the PGR-A:PGR-B ratio, precipitating functional progesterone withdrawal. Furthermore cytokines may partly explain racial disparity in PTB. Elevated IL-1β and TNF-α concentrations are seen in African-American cases of PTB, whereas high IL-6 and IL-8 levels are more commonly associated with preterm birth in Caucasians. Single nucleotide polymorphisms in genes regulating or encoding these cytokines may be a cause of this disparity.

Predictors/Prevention of Preterm Labor

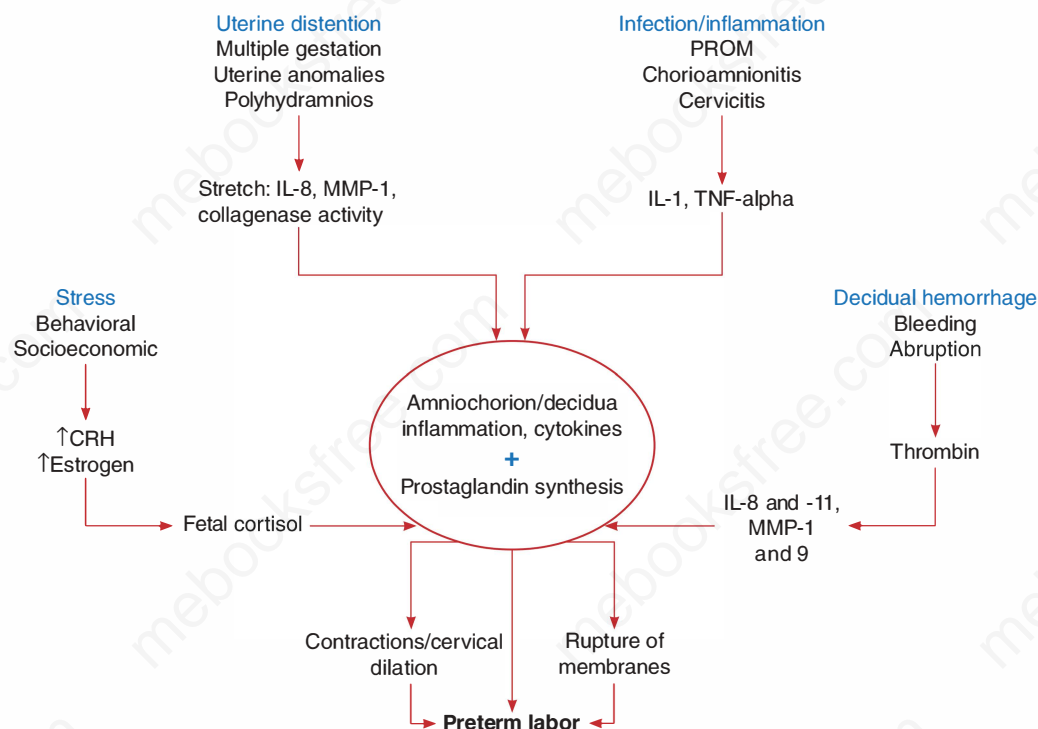
Unfortunately, clinical symptoms are too inaccurate and unreliable to identify women at risk for PTB. Given the medical, emotional, and financial gravity of preterm birth, many tests have been promoted to identify women at risk for PTB. Home uterine activity monitors are not recommended as they have not been shown to improve outcome. The presence of bacterial vaginosis (BV) has been associated with preterm delivery independent of other known risk factors, however, insufficient data support screening


FIGURE 16–4 Major mechanistic pathways leading to preterm birth.

and treating women with positive cultures. Maternal estriol levels have been used to predict activation of the fetal hypothalamic-pituitary-adrenal axis, but trials failed to establish accurate prediction of preterm labor. Numerous studies have confirmed the association between cervical shortening and subsequent preterm delivery. Transvaginal cervical ultrasonography has been shown to be a reliable way to assess the length of the cervix and is a useful screen in women with a history of PTB. Studies have shown that supplementation of vaginal progesterone in women without prior PTB and with a cervical length <2.5 cm reduces the risk of PTB. In patients with a cervix shorter than 2.5 cm, cerclage is an effective strategy. Weekly injections of 17α-hydroxyprogesterone caproate from 16 to 20 weeks until 36 weeks of gestation have been found to significantly reduce recurrent PTB in women with a past history of preterm delivery. A meta-analysis of 10 placebo-controlled trials found progesterone therapy reduced the incidence of recurrent preterm birth from 36% to 26%. Given the lack of other available treatments, many providers are using progesterone as preventative therapy in high-risk patients, but progesterone does not reverse established labor. Fetal fibronectin (fFN) is a basement membrane protein of placental membranes and decidua. Clinical trials have shown that the risk of PTB is increased in the presence of fFN and decreased in its absence. A negative fFN test indicates a 95% likelihood of not delivering within 14 days; therefore it is particularly useful for ruling-out preterm delivery.

Management of Preterm Labor

Once preterm labor has been diagnosed, care should be taken to determine if patient warrants tocolysis, expectant management, or

delivery. It is critical to confirm an accurate gestational age because if less than 34 weeks, glucocorticoids should be administered to promote neonatal lung maturity. Tocolytic therapy is used to attempt to prolong pregnancy to allow time for corticosteroid administration. In general, tocolytic drugs prolong pregnancy for 2 to 7 days. There is no first-line tocolytic drug and the choices include beta-mimetics, calcium channel blockers, and NSAIDs. In Europe, the OTR antagonist atosiban is approved. Tocolytic choice should be based on maternal/fetal conditions, side effects, and gestational age. Serious adverse events are rare but potentially life-threatening. Beta-mimetics and calcium channel blockers are associated with a risk of pulmonary edema. Magnesium sulfate may cause maternal lethargy, nausea and vomiting and respiratory depression and is no longer recommended. NSAIDs can cause fetal oligohydramnios, premature closure of the ductus arteriosus and neonatal necrotizing enterocolitis. Calcium channel blockers used as a single agent appear to have a good maternal and fetal safety profile. Combining tocolytic drugs potentially increases maternal morbidity and should be used with caution.

POSTTERM PREGNANCY

Postterm pregnancy refers to gestation that has extended to or beyond 42 weeks and is associated with significant risks to the fetus. Most importantly, the perinatal mortality rate (stillbirths plus early neonatal deaths) beyond 42 weeks is twice that at term (4-7 deaths vs 2-3 deaths per 1000 deliveries) and is sixfold higher after 43 weeks or more. Potential causes include uteroplacental insufficiency, meconium aspiration, and intrauterine infection.

Postterm pregnancy is also a risk factor for low Apgar scores, oligohydramnios, and neonatal complications such as hypoglycemia, seizures, respiratory insufficiency, and increased risk of death within the first year of life. Postterm pregnancy is associated with some complications for the mother including a twofold increased risk of severe perineal injury and cesarean delivery. Because pregnancy past 41 weeks is associated with high costs of antenatal testing and induction of labor, as well as a source of significant anxiety for pregnant women, there has been a movement in obstetrics to effect delivery before 41 completed weeks. The most common cause of a prolonged gestation is incorrect dating; other risk factors include primiparity, prior postterm pregnancy, and male sex of the fetus. Recently, obesity has been identified as a modifiable risk factor. The mechanism for this association is unclear but it is likely due to a derangement in endocrine factors that initiate labor. In rare cases, postterm pregnancy has been associated with placental sulfatase deficiency or fetal anencephaly.

Management of Postterm Pregnancy

Standard management of postterm pregnancy focuses on antenatal fetal surveillance and timely initiation of delivery if spontaneous labor does not occur. Although antepartum testing for postterm pregnancies is universally accepted, it has not been validated in prospective trials to decrease perinatal mortality. Given the ethical and medicolegal concerns for a control group, randomized studies to prove benefit will likely never be done. Timing of delivery is generally recommended when risks to continuing the pregnancy are greater than the benefit to mother or fetus after or during birth. In high-risk cases such as diabetics and hypertensives, pregnancy should not be allowed to progress beyond 41 weeks. However, management of low-risk postterm pregnancy is more controversial. Because vaginal delivery cannot always be induced readily, maternal risks and considerations complicate this decision. Factors to consider include gestational age, results of antepartum fetal testing, cervical examination, and maternal preference after counseling regarding the risks, benefits, and alternatives to expectant management with antepartum monitoring versus labor induction.

ENDOCRINOLOGY OF THE PUERPERIUM

Extirpation of any active endocrine organ leads to compensatory changes in other organs and systems. Delivery of the infant and placenta causes both immediate and long-term adjustment to loss of the pregnancy hormones. The sudden withdrawal of fetal-placental hormones at delivery permits determination of their serum half-lives and some evaluation of their effects on maternal systems.

Physiologic and Anatomic Changes

Some physiologic and anatomic adjustments that take place after delivery are both hormone dependent and independent. For example, major readjustments of the cardiovascular system occur in response to the normal blood losses associated with delivery and to loss of the low-resistance placental shunt. By the third postpartum day, blood volume is estimated to decline to about 80% of predelivery values. These cardiovascular changes influence renal and liver function, including clearance of pregnancy hormones.

Uterine Changes

The uterus involutes progressively at the rate of about 500 g/wk and continues to be palpable abdominally until about 2 weeks postpartum, after which it reoccupies its position entirely within the pelvis. Nonpregnant size and weight (60-70 g) are reached by 6 weeks postpartum. The reversal of myometrial hypertrophy occurs with a decrease in size of individual myometrial cells rather than by reduction in number. The endometrium, which is sloughed at the time of delivery, regenerates rapidly; by the seventh postpartum day there is restoration of surface epithelium. These rapid regenerative changes do not apply to the area of placental implantation, which requires much longer for restoration and retains pathognomonic histologic evidence of placentation indefinitely.

Endocrine Changes

A. Steroids   With expulsion of the placenta, many steroid levels decline precipitously, with half-lives of minutes. Plasma progesterone falls to luteal-phase levels within 24 hours after delivery and to follicular-phase levels within several days. Removal of the corpus luteum results in a fall to follicular levels within 24 hours. Estradiol reaches follicular phase levels within 1 to 3 days after delivery.

B. Pituitary hormones   The pituitary gland, which enlarges during pregnancy owing primarily to an increase in lactotrophs, does not diminish in size until after lactation ceases. Secretion of FSH and LH continues to be suppressed during the early weeks of the puerperium, and stimulus with bolus doses of GnRH results in subnormal release of LH and FSH. Over the ensuing weeks, responsiveness to GnRH gradually returns to normal and most women exhibit follicular-phase serum levels of LH and FSH by the third or fourth postpartum week.

C. Prolactin   Serum PRL, which rises throughout pregnancy, falls with the onset of labor and then exhibits variable patterns of secretion depending on whether breast-feeding occurs. Delivery is associated with a surge in PRL, which is followed by a rapid fall in serum concentrations over 7 to 14 days in the nonlactating mother. In nonlactating women, the return of normal cyclic function and ovulation may be expected within 3 months, with the initial ovulation occurring at an average of 9 to 10 weeks postpartum. In actively lactating women, PRL can cause a persistence of anovulation. Surges of PRL are believed to act on the hypothalamus to inhibit GnRH secretion. Administration of exogenous GnRH during this time induces normal pituitary responsiveness, and occasional ovulation may occur spontaneously even during lactation.

LACTATION

Development of the breast alveolar lobules occurs throughout pregnancy. This period of mammogenesis requires the concerted participation of estrogen, progesterone, PRL, GH, and glucocorticoids. hPL may also play a role but is not indispensable. Lactation requires PRL, insulin, and adrenal steroids and is associated with further enlargement of the lobules, followed by synthesis of milk constituents such as lactose and casein. Lactopoiesis does not occur until unconjugated estrogens fall to nonpregnant levels at about 36 to 48 hours postpartum. Evidence from GH-deficient and hypothyroid patients suggests that GH and thyroid hormone are not required.

PRL is essential to milk production. Its action involves induced synthesis of large numbers of PRL receptors. These receptors appear to be autoregulated because PRL increases receptor levels in cell culture and bromocriptine, an inhibitor of PRL release, causes a decrease in both PRL and its receptors. In the absence of PRL, milk secretion does not take place. However, even in the presence of high levels of PRL during the third trimester, milk secretion does not take place until after delivery, due to the blocking effect of high levels of estrogen.

Milk secretion requires the additional stimulus of suckling, which activates a neural arc. Milk ejection occurs in response to a surge of oxytocin, which induces a contractile response in the smooth muscle surrounding the gland ductules. Oxytocin release is occasioned by stimuli of a visual, psychologic, or physical nature that prepare the mother for breast-feeding; whereas PRL release is limited to the suckling reflex arc.

ENDOCRINE DISORDERS AND PREGNANCY

Hyperthyroidism in Pregnancy

Pregnancy mimics hyperthyroidism because it causes thyroid enlargement, increased cardiac output, and peripheral vasodilation. Owing to the increase in TBG in pregnancy, total serum thyroxine is in the range expected for hyperthyroidism. Free thyroxine, the free thyroxine index, and TSH levels, however, remain in the normal range (see Chapter 7).

True hyperthyroidism complicates 1 to 2 per 1000 pregnancies. The most common form of hyperthyroidism during pregnancy is Graves disease. Hyperthyroidism is associated with an increased risk of preterm delivery (11%-25%) and may modestly increase the risk of early abortion. In Graves disease, thyroid-stimulating immunoglobulin, a 7S immune gamma globulin, is actively transported across the placenta and may cause fetal goiter and transient neonatal hyperthyroidism.

A. Management of the mother   The treatment of maternal hyperthyroidism is complicated in pregnancy. Radioiodine is strictly contraindicated. Iodide therapy can lead to huge fetal goiter and is contraindicated except as acute therapy to prevent thyroid storm before thyroid surgery. All antithyroid drugs cross the placenta and may cause fetal hypothyroidism and goiter or cretinism in the newborn. However, propylthiouracil in doses of 300 mg/d or less has been shown to be reasonably safe, although even at low doses about 10% of newborns will have a detectable goiter. A reasonable plan of management is to begin therapy in the first trimester with propylthiouracil in doses high enough to bring the free T_4 index into the mildly hyperthyroid range and then to taper the dose gradually. Despite its risk of aplasia cutis, switching to methimazole for the second and third trimester is recommended. Propranolol has been used to control maternal cardiovascular symptoms but may result in fetal bradycardia, growth restriction, preterm labor, and neonatal respiratory depression. Partial or total thyroidectomy, especially in the second trimester, is a reasonably safe procedure except for the risk of preterm labor.

B. Management of the newborn   Newborns should be observed carefully. In infants of mothers given propylthiouracil, even equivocal evidence of hypothyroidism is an indication for thyroxine replacement therapy. Neonatal Graves disease, which may present as late as 2 weeks after delivery, requires intensive therapy (see Chapter 7).

Hypothyroidism in Pregnancy

Clinical hypothyroidism is uncommon in pregnancy because most women with the untreated disorder are anovulatory. As a practical matter, women taking thyroid medication at the time of conception should be maintained on a 30% higher dose throughout pregnancy. Physiologic doses of thyroid hormone replacement are innocuous, but maternal hypothyroidism is hazardous to the developing fetus. Women with a personal or family history of thyroid disease or with symptoms suggestive of hypothyroidism should have TSH tested prior to conception. The correlation between maternal and fetal thyroid status is poor, and hypothyroid mothers frequently deliver euthyroid infants. The strongest correlation between maternal and newborn hypothyroidism occurs in areas where endemic goiter due to iodide deficiency is common. In an iodine-deficient population, treatment with iodine in the first and second trimesters of pregnancy significantly reduces the incidence of cretinism (growth failure, mental retardation, and other neuropsychologic deficits). Even subclinical maternal hypothyroidism has been associated with fetal neurodevelopmental damage and reduced IQs in the offspring. This is thought to be due to inadequate transplacental supply of thyroxine T_4 in early pregnancy as the mother is the only source of T_4 for the developing first trimester fetal brain.

Pituitary Disorders in Pregnancy

In women of reproductive age, small tumors of the anterior pituitary are not uncommon (see also Chapter 4). Although many are nonfunctional and asymptomatic, the most common symptom of pituitary microadenomas is amenorrhea, frequently accompanied by galactorrhea. In the past, few affected women became pregnant, but now most can be made to ovulate and to conceive with the aid of clomiphene citrate, recombinant gonadotropins and

hCG, or bromocriptine. Before ovulation is induced in any patient, serum PRL should be determined. Modest elevations of PRL warrant checking IGF-I levels, because hyperprolactinemia occurs in 25% of patients with GH-producing adenomas. If PRL or IGF-1 is elevated, the sella turcica should be evaluated by magnetic resonance imaging. About 10% of women with secondary amenorrhea are found to have adenomas, and 20% to 50% of women with amenorrhea and galactorrhea have detectable tumors.

The effect of pregnancy on pituitary adenomas depends on their size. Microadenomas rarely (1%) lead to visual field defects. However, approximately 20% of macroadenomas may lead to abnormalities in visual fields or other neurologic signs, usually in the first half of pregnancy. These changes almost always revert to normal after delivery, so aggressive therapy for known pituitary adenomas is not indicated except in cases of rapidly progressive visual loss, where surgery is indicated. Monitoring of patients with known PRL-secreting adenomas during pregnancy is primarily based on clinical examination. The normal gestational increase in PRL may obscure an increase attributable to the adenoma, and radiographic procedures are undesirable in pregnancy.

A. Management

Management of the pregnant woman with a pituitary macroadenoma includes early ophthalmologic consultation for formal visual field mapping and repeat examinations every other month throughout pregnancy. If visual field disturbances are minimal, pregnancy may be allowed to proceed to term. If symptoms become progressively more severe and the fetus is mature, labor should be induced. If symptoms are severe and the fetus is immature, management may consist of transsphenoidal resection of the adenoma or medical treatment with bromocriptine. Although bromocriptine inhibits both fetal and maternal pituitary PRL secretion, it does not affect decidual PRL secretion. Bromocriptine appears not to be teratogenic, and no adverse fetal effects have been reported. In most cases, it is probably preferable to surgery. The newer, selective dopamine D_2 receptor agonist cabergoline has shown excellent results in normalizing PRL levels, inducing tumor shrinkage, and minimizing side effects. The data available on pregnancies in which cabergoline was used do not show adverse effects; however, because the data are limited compared with the large numbers for bromocriptine safety, the latter is recommended. Both have category B classification for pregnancy. Radiation therapy should not be used in pregnancy, however, focused gamma knife pituitary radiation, with abdominal shielding, is gaining popularity in this setting with less than 0.01% of the radiation dose reaching the uterus.

Lymphocytic hypophysitis is an autoimmune inflammation of the pituitary that classically occurs in women in late pregnancy or during the puerperium. The clinical presentation is difficult to distinguish from that of a large PRL-secreting adenoma. Expectant conservative medical management with corticosteroids is sometimes possible, with vigilant postpartum observation to prevent consequences of pituitary insufficiency.

B. Prognosis and follow-up

There appears to be no increase in obstetric complications associated with pituitary adenomas, and no fetal jeopardy. The rate of prematurity increases in women with tumors requiring therapy, but this is probably due to aggressive intervention rather than to direct effects on spontaneous preterm labor. The postpartum period is characterized by rapid relief of even severe symptoms, with less than 4% of untreated tumors developing permanent sequelae. In some cases, tumors improve following pregnancy, with normalization or lowering of PRL relative to prepregnancy values. Management should include imaging and assessment of PRL levels 4 to 6 weeks after delivery. There are no contraindications to breast-feeding.

Obesity and Pregnancy

Obesity is a complicated metabolic and endocrine condition that has been implicated in a number of pregnancy-related complications. Its prevalence has dramatically increased in the United States over the last 20 years. Currently approximately one-third of adult women are obese (body mass index [BMI] >30). This is a particular problem for non-Hispanic black women (49%) and Mexican American women (38%). Obese women are at increased risk for a number of adverse outcomes during pregnancy, including spontaneous abortion, stillbirth, preeclampsia, gestational diabetes, congenital anomalies, cesarean section, venous thromboembolism, and increased surgical morbidity. Complications in pregnancy are generally related to maternal pregravid obesity rather than excessive weight gain during pregnancy. In 2009, the Institute of Medicine updated its guidelines recommending weight gain of 25 to 35 lb for pregnant women with a normal BMI, 15 to 25 lb for overweight women, and 11 to 20 lb for obese women. These were initially designed to help prevent fetal growth restriction. However, most overweight/obese women have mean weight gain exceeding these guidelines. Because of the risks to the fetus, it is recommended that women attempt to lose weight prior to conception.

A. Early pregnancy risks associated with obesity

There is a well-documented increased risk of early miscarriage in obese women in both spontaneous pregnancies and after infertility treatments. Maternal obesity is also associated with an increased risk of a range of structural anomalies particularly neural tube defects, heart defects, and omphalocele. As these types of anomalies are also associated with diabetes, it has been suggested that some of these women may be undiagnosed diabetics. To complicate this further, obesity can affect accuracy of diagnostic testing for congenital anomalies. Heavier women have lower AFP levels likely from greater plasma volume and therefore adjustments have to be made for serum screening based on maternal weight. This group also is more likely to have uninterpretable cell-free fetal DNA testing due to a reduced fetal fraction DNA concentration. Ultrasound is the primary diagnostic tool for identifying structural abnormalities. Increasing maternal weight is associated with increasing impairment of adequate ultrasound visualization particularly of cardiac and craniospinal abnormalities. For these reasons, it is important to encourage preconception weight loss and perform early screening for diabetes.

B. Late pregnancy risks associated with obesity

Maternal obesity in pregnancy is associated with a significantly increased rate of gestational diabetes (GDM), preeclampsia, and stillbirths. In a large prospective study of 16,102 women, obese women and morbidly obese women were 2.5 and 3.2 more likely, respectively, to develop gestational hypertension, and 1.6 and 3.3 times more likely to develop preeclampsia. Given the potential increase in oxidative stress from maternal adipose tissue, antioxidants such as vitamin C and E have been studied in the prevention of preeclampsia in obese women; however, they have yet to show any benefit. Gestational diabetes occurs due to decreased insulin sensitivity and inadequate insulin secretory response. Obese women, in general, are more insulin resistant at baseline; therefore, it is not surprising that they are at higher risk of developing GDM. Overweight and obese women have a 2.0 to 2.4 fold increased risk of unexplained fetal death, respectively. The exact pathophysiology of unexplained intrauterine fetal death in obese women is currently unknown.

C. Peripartum risks associated with obesity

Overweight and obese women also have an increased rate of cesarean section and surgical complications, including risks of anesthesia, wound infection, excessive blood loss, endometritis, and deep venous thrombosis. In a recent report, the rate of cesarean section in overweight women was 33.8% and 47% in obese women, compared to only 20.7% in normal weight controls.

D. Long-term risks associated with obesity

Maternal obesity is a risk factor for fetal macrosomia. Accumulating evidence indicates fetal macrosomia is associated with adolescent and adult obesity and metabolic syndrome. A large retrospective study recently found that children born to obese mothers were twice as likely to be obese at 2 years of age. Both maternal obesity and maternal diabetes may independently affect the risk of adolescent obesity in children. Macrosomic infants are also at increased risk of subsequent development of diabetes. Thus, the epidemics of obesity and diabetes may continue to increase further as a result of fetal overgrowth and adiposity in utero.

Parathyroid Disease and Pregnancy

Pregnancy is associated with an approximately 25 to 30 g accumulation of calcium in the mother by term. Most of this calcium is used for fetal skeletal development. Elevated levels of 1,25-hydroxyvitamin D from the decidua leads to increased calcium absorption by the maternal gastrointestinal tract. The kidneys also work to conserve calcium during pregnancy by increasing reabsorption. Overall PTH levels are slightly lower throughout pregnancy and calcium is actively transported across the placenta to the fetus against a concentration gradient. The fetus is relatively hypercalcemic, hypercalcitonemic, and hypoparathyroid in comparison to the mother, but this resolves shortly after birth.

A. Hyperparathyroidism

Hyperparathyroidism can be either primary, from an overactive parathyroid gland(s), or a secondary physiologic response to low calcium or vitamin D deficiency. Primary hyperparathyroidism in pregnancy is rare and is due to a solitary or multiple parathyroid adenomas, hyperplasia, or carcinoma. Symptoms of hyperparathyroidism are nonspecific including fatigue, anorexia, nausea, vomiting, constipation, mental status changes, and depression and are generally present when serum calcium levels are over 12 mg/dL. Interestingly, women with hyperparathyroidism typically experience improvement in their symptoms and calcium levels during pregnancy, due to the large amount of calcium taken up by the placenta for the fetus. Complications during pregnancy from uncontrolled hyperparathyroidism include nephrolithiasis, pancreatitis, hyperemesis gravidarum, and hypercalcemic crisis. There is an increased incidence of these complications during the postpartum period when the fetal/placental drain of calcium has been removed if the hyperparathyroidism persists after birth of the infant. Fetal complications have been reported to be as high as 80% and include increased risk of spontaneous abortions, intrauterine growth restriction, low birth weight, intrauterine demise, and postpartum neonatal hypocalcemia/tetany due to suppression of the fetal parathyroid glands. In general, neonates do well if supplemental calcium and vitamin D are started promptly and serum biochemistries are closely monitored. If possible, delivery should be delayed until eucalcemia is achieved in order to allow for normal development of the fetal parathyroid glands. Surgical excision of a symptomatic adenoma is generally recommended in pregnancy during the second trimester. Conservative management throughout pregnancy is, however, possible with close maternal and fetal surveillance, if the patient is asymptomatic and only mild elevations in serum calcium are present.

B. Hypoparathyroidism

Hypoparathyroidism in pregnancy is even rarer than hyperparathyroidism and is most commonly due to incidental resection of or damage to the parathyroid glands during thyroidectomy. Symptoms from hypocalcemia include numbness and tingling of fingers and perioral area. If serum calcium levels are maintained within normal limits, pregnancy outcome should not be negatively affected, but large amounts may be needed. If not treated, maternal hypocalcemia can lead to hyperparathyroidism in the fetus causing bone demineralization, and labor may be complicated by tetany. Treatment of hypoparathyroidism involves administration of supplemental calcium and vitamin D or its active metabolite 1,25-dihydroxyvitamin D.

PREECLAMPSIA/ECLAMPSIA

Preeclampsia is an idiopathic multisystem disease seen only in pregnancy and during the peripartum period. The incidence of preeclampsia is approximately 7%. Risk factors include nulliparity, African-American race, extremes of age, chronic hypertension, multiple gestation, prior history of preeclampsia, family history of preeclampsia, chronic renal disease, antiphospholipid antibody syndrome, hydramnios, diabetes, and obesity. Preeclampsia is characterized by onset of hypertension with proteinuria or end-organ dysfunction after 20 weeks of gestation. Other signs and symptoms can include proteinuria, headache, visual disturbances,

epigastric pain, nausea/vomiting, thrombocytopenia, abnormal liver and kidney function tests. Eclampsia is the occurrence of seizures that cannot be attributed to other causes in women with preeclampsia and is associated with a maternal mortality rate as high as 10%. Preeclampsia accounts for approximately 15% of maternal deaths in the United States. Deaths occur most frequently from cerebral hemorrhage, renal failure, disseminated intravascular coagulopathy, acute pulmonary edema, or hepatic failure. Preeclampsia is also associated with perinatal fetal death and morbidity, due most commonly to iatrogenic prematurity.

Pathophysiology

The exact pathogenesis of preeclampsia remains poorly understood despite a significant amount of research in the field. It likely involves both maternal and placental factors as it is also seen in molar pregnancies with only trophoblastic and no fetal tissue. Abnormalities in placental vasculature development are postulated to result in placental hypoxia, which leads to factors being released that cause hypertension and microangiopathy of target organs. Both epidemiologic and experimental data support the role of the placenta in the etiology of preeclampsia as placental tissue is necessary for the development of the disease and once the placenta is removed its signs and symptoms begin to abate.

In preeclampsia, cytotrophoblast invasion is shallow and only the decidual portion of the spiral arteries is remodeled. In contrast, in normal pregnancies the cytotrophoblasts infiltrate deeper into the muscular tunica media of the spiral arteries, transforming these small muscular arterioles into large vessels with low resistance that facilitate placental blow flow (see Figure 16–1). It is likely that environmental, immunologic, and genetic factors all play a role in this important process.

Hypoperfusion and hypoxia are likely both a cause and effect of abnormal placental vascularization and subsequent preeclampsia. Animal models support this theory as induced preeclampsia generally requires mechanically reduced uteroplacental perfusion. In addition, maternal medical conditions associated with vascular dysfunction such as hypertension, lupus, and renal disease increase the risk of preeclampsia, as do obstetric conditions that increase placental volume without increasing placental blood flow, such as twins and hydatidiform moles.

Generalized endothelial dysfunction may explain many of the multiple clinical features of preeclampsia. Evidence to support this includes enhanced vascular reactivity to angiotensin II, impaired flow-mediated vasodilation, decreased production of endothelial-derived vasodilators such as nitric oxide and prostacyclin, and increased production of vasoconstrictors like endothelins and thromboxanes.

Extensive placental angiogenesis is required to supply the necessary nutrients and oxygen to the fetus. Normal placental vessel development relies on a balance between proangiogenic factors such as VEGF and placental growth factor (PlGF) and antiangiogenic factors such as soluble fms-like tyrosine kinase 1 (sFlt-1) and soluble endoglin (sEng). It is proposed that free sFlt-1 in the maternal circulation antagonizes the angiogenic activities of VEGF and PlGF, leading to ischemia and vasospasm. sEng from

the placenta is elevated in preeclamptic women, and appears to inhibit TGF-beta-1-mediated vasodilation. A recent study indicates that a low ratio of sFlt-1:PlGF has a negative predictive value of greater than 99% for the development of preeclampsia in the ensuing week.

Despite extensive research and multiple hypotheses regarding its etiology and pathophysiology, there is still no unifying theory that explains all the features of preeclampsia. It is generally accepted that the basis for the development of preeclampsia occurs early in pregnancy.

Clinical Features

Preeclampsia is classified as having severe features if any of the following signs or symptoms are present: headache, blurred vision, scotomata, altered mental status, right upper quadrant or epigastric pain, severe hypertension (160/110 mm Hg), pulmonary edema, oliguria (<500 cc/24 h), renal failure (creatinine >1 mg/dL over baseline), elevated liver function tests (>2× normal), thrombocytopenia (platelets <100,000), coagulopathy or HELLP syndrome (hemolysis, elevated liver enzymes, low platelets). Despite knowledge of the many risk factors described above, it is still not possible to determine which mothers will ultimately develop preeclampsia and there are no effective preventative treatments. Large clinical trials using calcium and antioxidant vitamin supplementation revealed minimal to no benefit in preventing the development of preeclampsia. Although some clinical trials of low dose (81 mg/d) aspirin failed to show benefit, several meta-analyses support its use for prophylaxis.

Treatment/Management of Preeclampsia

The only definitive therapy for preeclampsia is delivery of fetus and placenta. This is straightforward for pregnancies near term. However, pregnancies between 24 and 34 weeks are more complicated as the obstetrician must balance the significant perinatal morbidity and mortality associated with preterm delivery versus the maternal and fetal risk of prolonging these high-risk pregnancies. Antihypertensive medications should be used in setting of severe hypertension to prevent a maternal stroke; however, their use in mild to moderate hypertension has not been shown to improve maternal or fetal outcome. Magnesium sulfate therapy is initiated as the anticonvulsant of choice for preeclamptics during labor, while administering corticosteroids prior to a planned preterm delivery, and for 24 hours postpartum.

Pancreatic Hormones and Diabetes Mellitus

Umesh Masharani, MB, BS, MRCP (UK) and
Michael S. German, MD

ABCC8	ATP-binding cassette transporter sub-family C member 8
ACE	Angiotensin-converting enzyme
ADA	American Diabetes Association
ADH	Antidiuretic hormone (vasopressin)
AGE	Advanced glycation end product
AGPAT	1-acylglycerol-3-phosphate-*O*-acyltransferase 2
AKT/PKB	AKR mouse tumor 8 kinase/protein kinase B
AIRE	Autoimmune regulator
ALT	Alanine aminotransferase
AMPK	Adenosine monophosphate-activated protein kinase
APS1	Autoimmune polyendocrinopathy syndrome type 1
ATF6	Activating transcription factor 6
BMI	Body mass index
cAMP	Cyclic adenosine monophosphate
CCK	Cholecystokinin
CEL	Carboxyl-ester lipase
cGMP	Cyclic 3′,5′-guanosine monophosphate
CIDEC	Cell death-inducing DFFA-like effector C
CSII	Continuous subcutaneous insulin infusion
CST	Contraction stress test
CTLA4	Cytotoxic T-lymphocyte-associated protein 4
DCCT	Diabetes Control and Complications Trial
DIDMOAD	Diabetes insipidus, diabetes mellitus, optic atrophy, deafness (Wolfram syndrome)
DPP	Diabetes Prevention Program
DPP-4	Dipeptidyl peptidase 4
DPT-1	Diabetes Prevention Trial-1
EIF2AK3	Eukaryotic translation initiation factor 2-α kinase 3

ER	Endoplasmic reticulum
FDA	Food and Drug Administration
FFA	Free fatty acid
FHR	Fetal heart rate
Foxo1	Forkhead box, subfamily O, member 1
FOXP3	Forkhead box, subfamily P, member 3
GABA	Gamma-aminobutyric acid
GAD	Glutamic acid decarboxylase
GCK	Glucokinase
GH	Growth hormone
GHb	Glycohemoglobin
GHSR	Growth hormone-secretagogue receptor
GI	Glycemic index
GIP	Gastric inhibitory polypeptide
GLIS3	Glioma-associated oncogene homolog—similar 3
GLP-1	Glucagon-like peptide-1
GLP-2	Glucagon-like peptide-2
GLUT	Glucose transporter
GPCR	G protein–coupled receptor
GRPP	Glicentin-related polypeptide
GWAS	Genome-wide association study
HDL	High-density lipoprotein
HLA	Human leukocyte antigen
HNF	Hepatocyte nuclear factor
hPL	Human placental lactogen
IA2	Insulinoma antigen 2
IAA	Insulin autoantibody
IAPP	Islet amyloid polypeptide
ICA	Islet cell antibody
IFG	Impaired fasting glucose
IGF-1	Insulin-like growth factor 1
IGT	Impaired glucose tolerance

IL-6	Interleukin-6
INS	Insulin
IP3	Inositol 1,4,5-triphosphate
IPEX	Immunodysregulation polyendocrinopathy enteropathy, X-linked
IPF-1	Insulin promoter factor-1
IRE1	Inositol-requiring enzyme 1
IRS	Insulin receptor substrate
ISL1	Islet transcription factor 1
IUGR	Intrauterine growth restriction
KPD	Ketosis-prone diabetes
KCNJ11	Potassium inwardly-rectifying channel, subfamily J, member 11
Kir6.2	Potassium channel, inwardly-rectifying 6.2
LADA	Latent autoimmune diabetes of adulthood
LKB1	Liver kinase B1
LDL	Low-density lipoprotein
MAPK	Mitogen-activated protein kinase
MODY	Maturity-onset diabetes of the young
MHC	Major histocompatibility complex
mTOR	Mammalian target of rapamycin
NeuroD1	Neural differentiation factor 1
Neurog3	Neural genesis factor 3
NIH	National Institutes of Health
NPH	Neutral protamine hagedorn
NST	Nonstress test
PAI-1	Plasminogen activator inhibitor-1
PAX4	Paired homeobox 4
PCSK	Proprotein convertase, subtilisin/kexin
PD-1	Programmed death 1
PD-L1	Programmed death ligand 1
PDE5	Phosphodiesterase type 5
PDX1	Pancreatic duodenal homeobox-1

PERK	Protein kinase R-like endoplasmic reticulum kinase
PGC1α	PPAR gamma coactivator-1α
PNDM	Permanent neonatal diabetes mellitus
POEMS	Polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes
PP	Pancreatic polypeptide
PPAR	Peroxisome proliferator-activated receptor
PTF1A	Pancreatic transcription factor 1α
PTP1b	Protein tyrosine phosphatase 1b
RFX6	Regulatory factor X-6
RXR	9-*cis*-retinoic acid receptor
SCL19A2	Solute carrier family 19 (thiamine transporter), member 2
SOCS	Suppressor of cytokine signaling
SREBP1c	Sterol regulatory element-binding protein 1c
SSTR	Somatostatin receptor
SUR1	Sulfonylurea receptor 1
TCF7L2	Transcription factor 7-like 2
TGF-β	Transforming growth factor-β
TNDM	Transient neonatal diabetes mellitus
TNF-α	Tumor necrosis factor-α
Ucn3	Urocortin3
UGDP	University Group Diabetes Program
UKPDS	United Kingdom Prospective Diabetes Study
VEGF	Vascular endothelial growth factor
VLDL	Very low density lipoprotein
VNTR	Variable number of tandem repeats
WFS1	Wolfram syndrome protein 1
ZAC	Zinc finger protein-inducing apoptosis and cell cycle arrest
ZnT8	Zinc transporter 8
ZFP57	Zinc finger protein 57

THE ENDOCRINE PANCREAS

The pancreas comprises two functionally distinct organs: the **exocrine pancreas**, the major digestive gland of the body; and the **endocrine pancreas**, the source of insulin, glucagon, somatostatin, pancreatic polypeptide (PP), and ghrelin. Whereas the major role of the products of the exocrine pancreas (the digestive enzymes) is the processing of ingested foodstuffs so that they become available for absorption, the hormones of the endocrine pancreas modulate every other aspect of cellular nutrition from rate of adsorption of foodstuffs to cellular storage or metabolism of nutrients. Dysfunction of the endocrine pancreas or abnormal responses to its hormones by target tissues cause serious disturbances in nutrient homeostasis, including the important clinical syndromes grouped under the name **diabetes mellitus**.

ANATOMY AND HISTOLOGY

The endocrine pancreas consists of approximately 1 million small endocrine glands—the islets of Langerhans—scattered throughout the glandular substance of the exocrine pancreas. The exocrine pancreas consists of the enzyme-producing cells organized into acini, and the duct system that delivers those enzymes to the lumen of the duodenum. The islet volume comprises 1% to 1.5% of the total mass of the pancreas and weighs about 1 to 2 g in adult humans. At least five cell types—α, β, δ, ε, and PP—have been identified in the islets (Table 17–1). Each of these islet cell types produces a distinguishing peptide hormone: glucagon, insulin, somatostatin, ghrelin, and PP, respectively. Within individual islets, the different cell types are scattered throughout. A typical human islet is depicted in Figure 17–1.

TABLE 17–1   Cell types in adult human pancreatic islets of Langerhans.

Cell Types	Approximate Percentage of Islet Volume	Secretory Products
α Cell	25	Glucagon, proglucagon
β Cell	55	Insulin, C peptide, proinsulin, IAPP, Ucn3, γ-aminobutyric acid (GABA)
δ Cell	10	Somatostatin-14
ε Cell	3	Ghrelin
PP cell	5	Pancreatic polypeptide

These cell types are not distributed uniformly throughout the pancreas. The PP cells reside primarily in islets in the posterior portion (posterior lobe) of the head, a discrete lobe of the pancreas separated from the anterior portion by a fascial partition. This lobe originates in the primordial ventral bud as opposed to the dorsal bud. The posterior lobe receives its blood supply from the superior mesenteric artery; the remainder of the pancreas derives most of its blood flow from the celiac artery. The islets themselves are richly vascularized, receiving five to ten times the blood flow
FIGURE 17–1   Human islet of Langerhans. Staining for insulin (red), glucagon (green), and somatostatin (blue) was performed by immunofluorescence and imaged by confocal microscopy. The unique cytoarchitecture of human pancreatic islets has implications for islet cell function. *Proc Natl Acad Sci U S A.* 2006 Feb 14;103(7):2334-2339.)

of the surrounding exocrine pancreatic tissue. Each islet is surrounded by a lattice of astroglial cells and innervated by sympathetic, parasympathetic, and sensory neurons.

HORMONES OF THE ENDOCRINE PANCREAS

1. INSULIN

Biosynthesis

The human insulin gene resides on the short arm of chromosome 11. A unique set of transcription factors found in the β cell nucleus activates the transcription of the preproinsulin mRNA from the *insulin* gene (Figure 17–2). A precursor molecule, **preproinsulin**, a peptide of MW 11,500, is translated from the preproinsulin messenger RNA in the rough endoplasmic reticulum of pancreatic β cells (see Figure 17–2). Microsomal enzymes cleave preproinsulin to proinsulin (MW ~9000) almost immediately after synthesis. Proinsulin is transported to the Golgi apparatus, where packaging into clathrin-coated secretory granules takes place. Maturation of the secretory granule is associated with loss of the clathrin coating and conversion of proinsulin into insulin and a smaller connecting peptide, or C peptide, by proteolytic cleavage at two sites along the peptide chain. Mature secretory granules contain insulin and C peptide in equimolar amounts and only small quantities of proinsulin, a small portion of which consists of partially cleaved intermediates.

Biochemistry

Proinsulin (Figure 17–3) consists of a single chain of 86 amino acids, which includes the A and B chains of the insulin molecule plus a connecting segment of 35 amino acids. Two proteins—the prohormone-converting enzymes type 1 and 2 (PCSK1 and PCSK2)—are packaged with proinsulin in the immature secretory granules. These enzymes recognize and cut at pairs of basic amino acids, thereby removing the intervening sequence. After the two pairs of basic amino acids are removed by carboxypeptidase E, the result is a 51 amino acid insulin molecule and a 31 amino acid residue, the C peptide, as shown in Figure 17–3.

A small amount of proinsulin produced by the pancreas escapes cleavage and is secreted intact into the bloodstream, along with insulin and C peptide. Most anti-insulin sera used in the standard immunoassay for insulin cross-react with proinsulin; about 3% to 5% of immunoreactive insulin extracted from human pancreas is actually proinsulin. Because proinsulin is not removed by the liver, it has a half-life three to four times that of insulin. Its long half-life allows proinsulin to accumulate in the blood, where it accounts for 12% to 20% of the circulating immunoreactive insulin in the basal state in humans. Human proinsulin has about 7% to 8% of the biologic activity of insulin. The kidney is the principal site of proinsulin degradation.

Of the two major proinsulin split products present in plasma, the one split at arginine 32-33 far exceeds in amount the barely detectable 65-66 split product. In control subjects, concentrations

FIGURE 17–2 Structural components of the pancreatic β cell involved in glucose-induced biosynthesis and release of insulin. (Modified with permission from Junqueira LC, Carneiro J, Long JA. *Basic Histology*, 5th ed. New York: McGraw-Hill Education; 1986.)

FIGURE 17–3 Structure of human proinsulin C peptides and insulin molecules connected at two sites by dipeptide links.

of proinsulin and 32-33 split proinsulin after an overnight fast averaged 2.3 and 2.2 pmol/L, respectively, with corresponding postprandial rises to 10 and 20 pmol/L.

C peptide, the 31 amino acid peptide (MW 3000) released during cleavage of insulin from proinsulin, has no known biologic activity. β Cells release C peptide in equimolar amounts with insulin. It is not removed by the liver but is degraded or excreted chiefly by the kidney. It has a half-life three to four times that of insulin. In the basal state after an overnight fast, the average concentration of C peptide may remain as high as 1000 pmol/L.

Insulin is a protein consisting of 51 amino acids contained within two peptide chains: an A chain, with 21 amino acids; and a B chain, with 30 amino acids. The chains are connected by two disulfide bridges as shown in Figure 17–3. In addition, an intra-chain disulfide bridge links positions 6 and 11 in the A chain. Human insulin has a molecular weight of 5808.

Endogenous insulin has a circulatory half-life of 3 to 5 minutes. It is degraded chiefly by insulinases in liver, kidney, and placenta. A single pass through the liver removes approximately 50% of the plasma insulin.

Secretion

The human pancreas secretes about 30 units of insulin per day into the portal circulation of normal adults in distinct pulses with a period of approximately 5 minutes. The basal concentration of insulin in the peripheral blood of fasting humans averages 10 μU/mL (0.4 ng/mL, or 61 pmol/L). In normal control subjects, insulin seldom rises above 100 μU/mL (610 pmol/L) after standard meals. After ingestion of food, peripheral insulin concentration increases within 8 to 10 minutes, reaches peak concentrations by

30 to 45 minutes, and then rapidly declines to baseline values by 90 to 120 minutes postprandially.

Basal insulin secretion occurs in the absence of exogenous stimuli, in the fasting state. Plasma glucose levels below 80 to 100 mg/dL (4.4-5.6 mmol/L) do not stimulate insulin release, and most other physiologic regulators of insulin secretion only function in the presence of stimulatory levels of glucose. Stimulated insulin secretion occurs in response to exogenous stimuli. *In vivo*, ingested meals provide the major stimuli for insulin secretion. Glucose is the most potent stimulant of insulin release. The perfused pancreas releases insulin in two phases in response to glucose stimulation (Figure 17–4). When the glucose concentration increases suddenly, an initial short-lived burst of insulin release occurs (the **first phase**); if the glucose elevation persists, the insulin release gradually falls off and then begins to rise again to a steady level (the **second phase**). However, sustained levels of high glucose stimulation (~4 hours *in vitro* or >24 hours *in vivo*) result in a reversible desensitization of the β cell response to glucose but not to other stimuli.

The β cell senses glucose through its metabolism (Figure 17–5). Indeed, agents such as 2-deoxyglucose that inhibit the metabolism of glucose block the release of insulin. Glucose enters the pancreatic β cell by passive diffusion, facilitated by membrane proteins termed glucose transporters (GLUTs) (discussed later). Because the transporters function in both directions, and the β cell has an excess of GLUTs, the glucose concentration inside the β cell is in equilibrium with the extracellular glucose concentration. The low-affinity enzyme glucokinase catalyzes the subsequent, and rate-limiting, step in glucose metabolism by the pancreatic β cell, the phosphorylation of glucose to glucose-6-phosphate. Glucose catabolism in the β cell causes a rise in the intracellular ATP-ADP ratio. Acting through the sulfonylurea receptor (SUR1), the
FIGURE 17–4 Multiphasic response of the *in vitro* perfused rat pancreas during constant stimulation with glucose. (Modified with permission from Grodsky GM, Curry D, Landahl H, et al. Further studies on the dynamic aspects of insulin release *in vitro* with evidence for a two-compartmental storage system. *Acta Diabetol Lat*. 1969 Sep;6 Suppl 1:554-578.)
FIGURE 17–5   A simplified outline of glucose-sensing and regulated insulin secretion from the β cell. The blue arrows indicate stimulation, and the red lines indicate inhibition. Glucose enters the β cell through facultative glucose transporters, is phosphorylated to glucose-6-phosphate by glucokinse, and enters glycolysis. This results in the production of pyruvate, which enters the mitochondria, is converted to acetyl-CoA, and feeds the tricarboxylic acid (TCA) cycle and oxidative phosphorylation to produce ATP. When ATP levels rise or sulfonylureas bind to the regulatory subunit (SUR1/ABCC8) of the ATP-sensitive K^+ channels, the channel subunit (Kir6.2/KCNJ11) closes. This block of the K^+ current depolarizes the cell, allowing the voltage-gated calcium channels to open. The entry of calcium drives the fusion of insulin granules with the cell surface membrane and exocytosis of insulin. Glucose metabolism and extracellular signals modulate this pathway through release of Ca^{2+} from intracellular stores and changes in diacylglycerol (DAG), cAMP, and other intracellular signaling pathways.

nucleotide-sensing subunit of the ATP-sensitive potassium channels on the surface of the β cell, the rise in ATP-ADP ratio closes the potassium channels and depolarizes the cell, thereby activating the voltage-sensitive calcium channels and allowing the entry of calcium ions into the cell.

Insulin release requires calcium ion signaling. In addition to the voltage-dependent entry of extracellular Ca^{2+} into the β cell as described earlier, glucose also retards Ca^{2+} efflux from the β cell and releases Ca^{2+} from intracellular compartments (predominantly the endoplasmic reticulum) into the cytosol. Some nonglucose stimuli of insulin release also function through increases in cytoplasmic Ca^{2+}. The sulfonylurea and meglitinide (such as repaglinide) medications act by closing the ATP-sensitive potassium channels. Secretagogues such as acetylcholine that act through G protein–coupled receptors (GPCRs) of the $G\alpha_q$ class stimulate the release of intracellular Ca^{2+} stored in the endoplasmic reticulum by activating phospholipase C and releasing the intracellular signaling molecule inositol 1,4,5-triphosphate (IP3).

Glucose metabolism in the β cell also generates additional signals that amplify the secretory response to elevations in cytoplasmic Ca^{2+} concentration. The exact mechanisms of these amplifying signals remains unknown but involve multiple pathways and include increases in the intracellular signaling molecules diacylglycerol and cAMP. Secretagogues such as the gut hormones glucagon-like peptide-1 (GLP-1) and gastric inhibitory polypeptide (also known as glucose-dependent insulinotropic peptide, GIP) that act via GPCRs of the $G\alpha_s$ class also stimulate insulin secretion through elevations in cAMP.

Other factors involved in the regulation of insulin secretion are summarized in Table 17–2. These factors can be divided into three categories: **direct stimulants**, which directly raise cytoplasmic calcium ion concentrations and thus can act in the absence of stimulatory glucose concentrations; **amplifiers**, which potentiate the response of the β cell to glucose; and **inhibitors**. Many of the amplifiers are **incretins**: gastrointestinal hormones that are released in response to the ingestion of meals and stimulate insulin secretion. The action of the incretins explains the observation that orally ingested glucose provokes a greater insulin secretory response than does the same amount of intravenously administered glucose.

TABLE 17–2 Regulation of insulin release.

Stimulants of Insulin Release	Glucose Amino acids: Leucine Neural: Vagal stimulation, acetylcholine Drugs: Sulfonylureas, meglitinides

Amplifiers of Glucose-Induced Insulin Release	Enteric hormones:
	  Glucagon-like peptide 1 (7-37) (GLP1)
	  Gastric inhibitory peptide (GIP)
	  Cholecystokinin, gastrin
	  Secretin
	Neural: β-adrenergic effect of
	  catecholamines
	Amino acids: arginine
	Drugs: GLP1 agonists

Inhibitors of Insulin Release	Neural: α-adrenergic effect of
	  catecholamines
	Humoral: somatostatin
	Drugs: diazoxide, thiazides, β-blockers,
	  clonidine, phenytoin, vinblastine,
	  colchicine

Insulin Receptors and Insulin Action

Insulin action begins with the binding of insulin to a receptor on the surface of the target cell membrane. Most cells of the body have specific cell surface insulin receptors. In fat, liver, and muscle cells, binding of insulin to these receptors is associated with the biologic response of these tissues to the hormone. These receptors bind insulin rapidly, with high specificity and with an affinity high enough to bind picomolar amounts.

Insulin receptors, members of the growth factor receptor family (see Chapter 1), are membrane glycoproteins composed of two protein subunits encoded by a single gene. The larger alpha subunit (MW 135,000) resides entirely extracellularly, where it binds the insulin molecule. The alpha subunit is tethered by disulfide linkage to the smaller beta subunit (MW 95,000). The beta subunit crosses the membrane, and its cytoplasmic domain contains a tyrosine kinase activity that initiates specific intracellular signaling pathways.

Downstream signaling   On binding of insulin to the alpha subunit, the beta subunit activates itself by autophosphorylation. The activated beta subunit then recruits additional proteins to the complex and phosphorylates a network of intracellular substrates, including insulin receptor substrate-1 (IRS-1), insulin receptor substrate-2 (IRS-2), and others (Figure 17–6). These activated substrates each lead to subsequent recruitment and activation of additional kinases, phosphatases, and other signaling molecules in a complex pathway that generally contains two arms: the mitogenic pathway, which mediates the growth effects of insulin and the metabolic pathway, which regulates nutrient metabolism.
FIGURE 17–6 A simplified outline of insulin signaling. A minimal diagram of the mitogenic and metabolic arms of the insulin-signaling pathway is shown. GLUT 4, glucose transporter 4; GRB2, growth factor receptor–binding protein 2; GS, glycogen synthase (P indicates the inactive phosphorylated form); GSK3, glycogen synthase kinase 3; IRS, insulin receptor substrate (four different proteins); MAP kinase, mitogen-activated protein kinase; mTOR, mammalian target of rapamycin; PDK, phospholipid-dependent kinase; PI3 kinase, phosphatidylinositol 3 kinase; PKB/AKT, protein kinase B/AKR mouse tumor 8 kinase; PP-1, glycogen-associated protein phosphatase-1; Ras, rat sarcoma protein; SHC, Src and collagen homology protein; SOS, son-of-sevenless related protein; TK, tyrosine kinase.

In the metabolic signaling pathway, activation of phosphatidylinositol-3-kinase leads to the activation of serine/threonine kinase AKT/PKB. AKT activation drives the movement of GLUT 4–containing vesicles to the cell membrane, increases glycogen and lipid synthesis, and stimulates protein synthesis through the activation of mTOR. In the mitogenic signaling pathway, activation of Ras initiates a cascade of activating phosphorylations via the MAP kinase pathway, leading to cell growth and proliferation.

Transcriptional regulation   In addition, the insulin-signaling pathway regulates the activity of several nuclear transcription factors that in turn control the expression of genes involved in metabolism and growth. These include members of the forkhead family of transcription factors, including Foxo1, which is inactivated by phosphorylation by AKT downstream of insulin signaling. Foxo1 coordinates the expression of gene networks involved in nutrient metabolism in multiple tissues, generally activating genes involved in the response to fasting. In this process, Foxo1 works with several other transcriptional regulators including the lipogenic transcription factor SREBP1c, members of the PPAR family of nuclear receptors and the PPAR coactivator PGC1α (Figure 17–7). Foxo1 also inhibits β cell proliferation and survival.

The three members of the PPAR family of nuclear hormone receptors play pleiotropic roles in regulating genes involved in metabolism in many tissues. They may function as targets of insulin signaling, modulators of insulin signaling, or both. Despite overlap in the tissue expression and gene targets of the three PPARs, some general conclusions can be drawn about the function of each. PPARα regulates genes involved in fatty acid catabolism and gluconeogenesis and is most highly expressed in brown fat, heart, liver, kidney, and intestine. PPARβ/δ is broadly expressed and activates gene programs involved in fatty acid oxidation. PPARγ is most highly expressed in adipose tissue, intestine, and immune cells, but also at lower levels in many other tissues. PPARγ drives white adipocyte differentiation and lipid storage and inhibits production of many of the pro-resistance adipokines and pro-inflammatory cytokines in adipose tissue (see section on insulin resistance later). In macrophages, PPARγ acts to promote their alternative activation to the anti-inflammatory M2 state, rather than the pro-inflammatory M1 state.

The PPARs bind to DNA as heterodimers with the 9-*cis*-retinoic acid receptor (RXR), and recruit a variety of coactivators and corepressors. PGC1α was originally identified as a coactivator interacting with PPARγ, but the interaction is not exclusive. On different genes PPARγ works with different coactivators, and PGC1α interacts with the other PPARs and many other transcription factors. In collaboration with a variety of different transcription factors in various tissues, PGC1α orchestrates the expression of a set of genes involved in metabolism. PGC1α itself is highly regulated by several signaling pathways including insulin signaling, which inhibits PGC1α activity via phosphorylation by AKT.

A number of natural and synthetic lipids and related compounds can act as PPAR ligands, but the endogenous ligands acting *in vivo* remain a mystery. The fibrate class of lipid-lowering drugs, used clinically to lower circulating triglyceride levels, act as PPARα ligands. The thiazolidinedione class of insulin-sensitizing drugs, used for the treatment of type 2 diabetes (discussed later), act as PPARγ ligands.

Deactivation of insulin signaling   Once activated by binding to insulin, the insulin receptor and downstream signaling cascades rapidly deactivate again by several mechanisms. Insulin can simply disengage from the receptor, or the receptor can be internalized and degraded. The receptor and its tyrosine-phosphorylated substrates can be deactivated by specific protein tyrosine phosphatases such as PTP1b. In addition, inhibitory SOCS (suppressor of cytokine signaling) proteins block interactions between the phosphorylated receptor and interacting IRS proteins, direct the ubiquitination and degradation of the IRS proteins, and terminate the activation of downstream components of the signaling pathway. Finally, serine phosphorylation of the insulin receptor and its active substrates by several different serine/threonine kinases, including components of the insulin-signaling pathway such as AKT, blocks insulin signaling. Many of these mechanisms may play a role in the development of insulin resistance (discussed later).

Metabolic Effects of Insulin

The major function of insulin is to promote storage of ingested nutrients. Although insulin directly or indirectly affects the

FIGURE 17–7 Regulation and function of Foxo1. The blue arrows indicate stimulation, and the red lines indicate inhibition. Processes activated by Foxo1 are labeled in blue, while the processes inhibited by Foxo1 are shown in red. (ACC, acetyl-CoA carboxylase; ACLY, ATP-citrate lyase; AKT, AKR mouse tumor 8 kinase; FAS, fatty acid synthase; G6P, glucose-6-phosphatase; GK, glucokinase; LPK, liver pyruvate kinase; MTTP, microsomal triglyceride transfer protein; PDH, pyruvate dehydrogenase; PEPCK, phosphoenolpyruvate carboxykinase; PGC1α, peroxisome proliferator-activated receptor gamma coactivator-1; SREBP1c, sterol regulatory element-binding protein 1c).

function of almost every tissue in the body, the discussion here will be limited to a brief overview of the effects of insulin on the major tissues specialized for energy metabolism: liver, muscle, adipose tissue, and brain. In addition, the paracrine effects of insulin will be discussed briefly.

A. Paracrine effects   The effects of the products of endocrine cells on surrounding cells are termed *paracrine effects*, in contrast to actions that take place at sites distant from the secreting cells, which are termed *endocrine effects* (see Chapter 1). Paracrine effects of the β and δ cells on the nearby α cells (see Figure 17–1) are of considerable importance in the endocrine pancreas. Insulin directly inhibits α cell secretion of glucagon. In addition, somatostatin, which δ cells release in response to most of the same stimuli that provoke insulin release, also inhibits glucagon secretion.

Because glucose stimulates only β and δ cells (whose products then inhibit α cells) whereas amino acids stimulate glucagon as well as insulin, the type and amounts of islet hormones released during a meal depend on the ratio of ingested carbohydrate to protein. The higher the carbohydrate content of a meal, the lower the amount of glucagon released by any amino acids absorbed. In contrast, a predominantly protein meal results in relatively greater glucagon secretion, because amino acids are less effective at stimulating insulin release in the absence of concurrent hyperglycemia but are potent stimulators of α cells.

B. Endocrine effects (Table 17–3)

1. **Liver**—The first major organ reached by insulin via the bloodstream is the liver. Insulin exerts its action on the liver in two major ways:
   a. **Insulin promotes anabolism**—Insulin promotes glycogen synthesis and storage while inhibiting glycogen breakdown. These effects are mediated by changes in the activity of enzymes in the glycogen synthesis pathway (discussed later). The liver has a maximum storage capacity of 100 to 110 g of glycogen, or approximately 440 kcal of energy.

   Insulin increases both protein and triglyceride synthesis and very low density lipoprotein (VLDL) formation by the liver. It also inhibits gluconeogenesis and promotes glycolysis through its effects on the function and expression of key enzymes of both pathways.
   b. **Insulin inhibits catabolism**—Insulin acts to reverse the catabolic events of the postabsorptive state by inhibiting hepatic glycogenolysis, ketogenesis, and gluconeogenesis.
2. **Muscle**—Insulin promotes protein synthesis in muscle by increasing amino acid transport, as well as by stimulating ribosomal protein synthesis. In addition, insulin promotes glycogen synthesis to replace glycogen stores expended by muscle activity. This is accomplished by increasing glucose transport into the muscle cell, enhancing the activity of glycogen synthase, and inhibiting the activity of glycogen phosphorylase. Approximately 500 to 600 g of glycogen are stored in the muscle tissue of a 70-kg man, but because of the lack of glucose 6-phosphatase in this tissue, it cannot be used as a source of blood glucose, except for a small amount produced when the debranching enzyme releases unphosphorylated glucose from branch points in the glycogen polymer, and the

TABLE 17–3 Endocrine effects of insulin.

Tissue	Effect of Insulin
Liver	**Catabolic Pathways** Inhibits glycogen breakdown (inhibits glycogen phosphorylase) Inhibits conversion of fatty acids and amino acids to keto acids Inhibits conversion of amino acids to glucose (gluconeogenesis) **Anabolic Pathways** Promotes glucose storage as glycogen (induces glucokinase and glycogen synthase) Increases triglyceride synthesis and VLDL formation
Muscle	**Protein Synthesis** Increases amino acid transport Increases ribosomal protein synthesis **Glycogen Synthesis** Increases glucose transport Induces glycogen synthase Inhibits glycogen phosphorylase
Adipose Tissue	**Triglyceride Storage** Lipoprotein lipase is induced by insulin to hydrolyze triglycerides in circulating lipoproteins for delivery of fatty acids to the adipocytes Glucose transport into cell provides glycerol phosphate to permit esterification of fatty acids supplied by lipoprotein transport Intracellular lipase is inhibited by insulin
Brain	**Decreased appetite** **Increased energy expenditure**

glucose indirectly produced via the liver from lactate generated by muscle.
3. **Adipose tissue**—Fat, in the form of triglyceride, is the most efficient means of storing energy. It provides 9 kcal/g of stored substrate, as opposed to the 4 kcal/g generally provided by protein or carbohydrate. In the typical 70-kg man, the energy content of adipose tissue is about 100,000 kcal.

   Insulin acts to promote triglyceride storage in adipocytes by a number of mechanisms. (1) It induces the production of lipoprotein lipase in adipose tissue (this is the lipoprotein lipase that is bound to endothelial cells in adipose tissue and other vascular beds), which leads to hydrolysis of triglycerides from circulating lipoproteins, thereby yielding fatty acids for uptake by adipocytes. (2) By increasing glucose transport into fat cells, insulin increases the availability of α-glycerol phosphate, a substance used in the esterification of free fatty acids into triglycerides. (3) Insulin inhibits intracellular lipolysis of stored triglyceride by inhibiting intracellular lipase (also called **hormone-sensitive lipase**). This reduction of fatty acid flux to the liver is a key regulatory factor in the action of insulin to lower hepatic gluconeogenesis and ketogenesis.
4. **Central nervous system**—Although the brain is traditionally not considered an insulin-sensitive tissue, and overall glucose utilization by the brain is not acutely regulated by insulin, key regions of the brain can respond to insulin. Insulin signaling via PI3 kinase in key cells in the hypothalamus functions with leptin signaling to decrease appetite and increase energy expenditure (see Chapter 20).

C. AMPK and insulin-independent regulation of nutrient metabolism

Insulin, along with the counter-regulatory hormones and other circulating enhancers and inhibitors of their actions, coordinates nutrient metabolism in response to the overall needs of the organism. At the level of the individual cell, however, additional mechanisms sense and respond to the local energy state. Among these mechanisms, adenosine monophosphate protein kinase (AMPK) plays a central role. When energy availability falls, the drop in cellular ATP concentration and rise in AMP trigger a conformational change in the trimeric AMPK complex and the subsequent activation of the catalytic domain by the serine/threonine kinase LBK1/STK11. AMPK then drives the production of ATP by activating catabolic pathways and inhibiting synthetic pathways in the cell (Figure 17–8). In muscle, in response to the rise in AMP during exercise, AMPK increases fatty acid oxidation and insulin-independent glucose uptake while inhibiting mTOR and protein synthesis. In the long term, AMPK also drives mitochondrial biogenesis. In liver cells, AMPK blocks fatty acid and triglyceride synthesis while activating fatty acid oxidation, and also inhibits the gluconeogenic program by blocking cAMP activation of gene expression and inhibiting Foxo1/PGC1α-driven expression of the gluconeogenic genes. In brain, AMPK also functions as an energy sensor and plays a role in the regulation of appetite and energy expenditure by the hypothalamus. AMPK has also been implicated in the regulation of insulin secretion by β cells.

While predominantly an intracellular energy sensor, AMPK increases the sensitivity of cells to insulin, although the mechanisms remain uncertain. AMPK also responds to extracellular signals, and contributes to the regulation of metabolism by many of the adipokines and cytokines (discussed later) as well as cannabinoids. The biguanide drugs, including metformin, which is used in the treatment of type 2 diabetes, activate AMPK by reducing mitochondrial production of ATP and raising intracellular levels of AMP, and thereby lower blood glucose levels by inhibiting gluconeogenesis.

Glucose Transporter Proteins

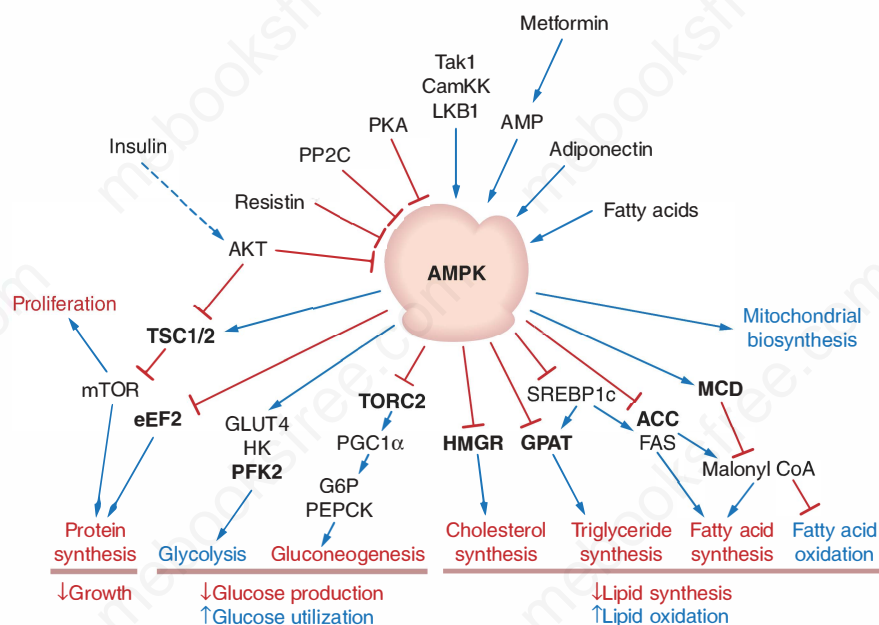
Glucose oxidation provides energy for most cells and is critical for brain function. Because cell membranes are impermeable to hydrophilic molecules such as glucose, all cells require carrier proteins to transport glucose across the lipid bilayers into the cytosol. All cells utilize non-energy-dependent transporters that facilitate diffusion of glucose from a higher concentration to a lower concentration across cell membranes. Facilitative GLUTs comprise a large family including at least 13 members, although some of the recently identified members of the family have not yet been shown to transport glucose. The first four members of the family are the best characterized, and they have distinct affinities for glucose and distinct patterns of expression.


FIGURE 17–8 Regulation and function of AMPK. Proteins that are directly phosphorylated by AMPK are shown in bold font. The blue arrows indicate stimulation, and the red lines indicate inhibition. Processes activated by AMPK are labeled in blue, while the processes inhibited by AMPK are shown in red. (ACC, acetyl-CoA carboxylase; AKT, AKR mouse tumor 8 kinase; CamKK, calcium/calmodulin-dependent protein kinase kinase; eEF2, eukaryotic translation elongation factor 2; FAS, fatty acid synthase; G6P, glucose-6-phosphatase; GPAT, glycerol-3-phosphate acyltransferase, mitochondrial; HK, hexokinase; HMGR, HMG-CoA reductase; LKB1, liver kinase B1; MCD, malonyl-CoA decarboxylase; mTOR, mammalian target of rapamycin; PEPCK, phosphoenolpyruvate carboxykinase; PFK2, 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase; PGC1α, peroxisome proliferator-activated receptor gamma coactivator-1; PKA, protein kinase A; PP2C, protein phosphatase 2C; SREBP1c, sterol regulatory element–binding protein 1c; Tak1, TGF-β-activated kinase 1; TORC2, transducer of regulated cAMP response element-binding protein 2; TSC1/2, tuberous sclerosis 1).

GLUT 1 is present in all human tissues. It mediates basal glucose uptake, because it has a very high affinity for glucose and, therefore, can transport glucose at the relatively low concentrations found in the fasted state. For this reason, its presence on the surface of the endothelial cells of the brain vascular system (blood–brain barrier) ensures adequate transport of plasma glucose into the central nervous system.

GLUT 3, which is also found in all tissues, is the major GLUT on neurons. It also has a very high affinity for glucose and is responsible for transferring glucose into neuronal cells at the lower concentrations found in the central nervous system.

In contrast, GLUT 2 has a lower affinity for glucose and thus increases glucose transport when plasma glucose levels rise, such as postprandially. It is a major transporter of glucose in hepatic, intestinal, and renal tubular cells. The low affinity of GLUT 2 for glucose reduces hepatic uptake of glucose during fasting, while its ability to transport glucose equally efficiently in both directions assists in the export of glucose from hepatocytes. GLUT 2 is also expressed on the surface of the β cells in rodents, but it is not detected at significant levels on human β cells.

GLUT 4 is found in two major insulin target tissues: skeletal muscle and adipose tissue. It is sequestered mainly within an intracellular compartment of these cells and thus does not function as a GLUT until insulin signaling causes translocation of GLUT 4 to the cell membrane, where it facilitates glucose entry into these tissues after a meal (see Figure 17–6). In muscle, exercise also drives GLUT 4 translocation to the cell surface by activating AMPK.

The intestine and kidney also have energy-dependent Na^+-glucose cotransporters capable of transporting glucose against its concentration gradient. SGLT1 transports glucose from the gut lumen into the absorptive enterocytes lining the lumen and is also found in the proximal tubules of the kidney. SGLT2, however, which is found in the proximal convoluted tubules in the kidney, performs the majority of the renal glucose reabsorption.

Islet Amyloid Polypeptide

Islet amyloid polypeptide (IAPP), or amylin, is a 37 amino acid peptide produced and stored with insulin in pancreatic β cells but only at a low ratio of approximately one molecule of IAPP to 100 of insulin. β cells cosecrete IAPP with insulin in response to glucose and other β cell secretagogues. Although it plays a role in regulating gut physiology by decreasing gastric emptying and gut motility after meals, the full physiologic functions of IAPP remain uncertain. A soluble analog of IAPP called pramlintide has been approved for use in patients with type 1 diabetes and insulin-treated type 2 diabetes (discussed later).

IAPP produces amyloid deposits in pancreatic islets of most patients with type 2 diabetes of long duration. These amyloid deposits are insoluble fibrillar proteins generated from IAPP oligomers that encroach on and may even occur within pancreatic β cells. Islets of nondiabetic elderly persons may contain less extensive amyloid deposits. Whether amyloid fibrils and deposition contribute to the islet dysfunction and β cell loss seen in type 2 diabetes or are simply a consequence of disordered and hyperstimulated islet function remains an unresolved question.

2. GLUCAGON
Biochemistry

Pancreatic glucagon, along with several other biologically active peptides, derives from the large proglucagon peptide encoded by the preproglucagon gene located on human chromosome 2. Tissue-specific proteases (the prohormone convertases) cleave different sets of peptide products from the proglucagon molecule in the endocrine L-cells of the gut and the α cells in the islet (Figure 17–9). The activity of prohormone convertase 2 in α cells generates the glucagon peptide, along with the amino-terminal glicentin-related peptide, a small central hexapeptide, and a large carboxyl-terminal fragment.

Glucagon consists of 29 amino acids in a single-chain polypeptide with a molecular weight of 3485. In healthy humans, the average fasting plasma immunoreactive glucagon level is 75 pg/mL (25 pmol/L). Only 30% to 40% of this is actually pancreatic glucagon, the remainder being a heterogeneous composite of higher-molecular-weight molecules with glucagon immunoreactivity such as proglucagon, glicentin, and oxyntomodulin. Circulating glucagon has a half-life of 3 to 6 minutes due to removal by the liver and kidney.

Secretion

In contrast to its stimulation of insulin secretion, glucose inhibits glucagon secretion. Conflicting data surround the question of whether glucose directly inhibits secretion from the α cell or whether it only acts via release of insulin and somatostatin from the β and δ cells, both of which inhibit the α cell directly. In addition, because β cells release gamma-aminobutyric acid (GABA) and α cells express inhibitory GABA receptors, GABA also may participate in the inhibition of α cells during β cell stimulation.

Many amino acids stimulate glucagon release, although they differ in their ability to do so. Some, such as arginine, release both glucagon and insulin; others (eg, alanine) stimulate primarily glucagon release. Leucine, an effective stimulant of insulin release, does not stimulate glucagon. Other substances that promote glucagon release include catecholamines, gastrointestinal hormones (cholecystokinin [CCK], gastrin, and gastric inhibitory polypeptide [GIP]), and glucocorticoids. Both sympathetic and parasympathetic (vagal) stimulation promote glucagon release, especially in response to hypoglycemia. High levels of circulating fatty acids suppress glucagon secretion.

Action of Glucagon

In contrast to insulin, which promotes energy storage in a variety of tissues in response to feeding, glucagon provides a humoral mechanism for delivering energy from the liver to the other tissues between meals. The ratio of insulin to glucagon affects key target tissues by regulating the expression and activity of key enzymes controlling nutrient metabolism and, thereby, controlling the flux of these nutrients into or out of storage.

The liver, because of its connection to the pancreas via the portal vein, represents the major target organ for glucagon, with
FIGURE 17–9 Tissue-specific secretory products of human proglucagon (GLP-1, glucagon-like peptide-1; GLP-2, glucagon-like peptide-2; GRPP, glicentin-related polypeptide).

portal vein glucagon concentrations reaching as high as 300 to 500 pg/mL (100-166 pmol/L) during fasting. It is unclear whether physiologic levels of glucagon affect tissues other than the liver. Glucagon signals through the glucagon receptor, a GPCR of the $G\alpha_s$ class found predominantly on the surface of hepatocytes. Binding of glucagon to its receptor in the liver activates adenylyl cyclase and the generation of cAMP, which in turn mediates the phosphorylation or dephosphorylation of key enzymes regulating nutrient metabolism. In addition, like insulin, glucagon receptor signaling modifies the activity of a set of cAMP responsive transcriptional regulators that in turn control the expression of the genes encoding these same enzymes.

Glucagon signaling in the liver stimulates the breakdown of stored glycogen, maintains hepatic output of glucose from amino acid precursors (gluconeogenesis), and promotes hepatic output of ketones generated from fatty acid precursors (ketogenesis). Glucagon facilitates the uptake of the gluconeogenic substrate alanine by liver, and directs fatty acids away from reesterification to triglycerides and toward ketogenic pathways. In sum, glucagon signaling results in the net release of readily available energy stores from the liver in the form of glucose and ketones.

Glucagon-Related Peptides

In the intestinal ʟ-cells, found predominantly in the distal ileum and colon, prohormone convertase 1 generates a different set of peptides from the proglucagon molecule, including glicentin, glicentin-related polypeptide (GRPP), oxyntomodulin, and the two glucagon-like peptides **GLP-1** and **GLP-2** (see Figure 17–9). Several biological activities have been attributed to glicentin and oxyntomodulin based on studies using high concentrations of the peptides, but all these actions can be explained by low-affinity interactions with the receptors for glucagon, GLP-1 and GLP-2. Specific receptors for glicentin and oxyntomodulin have not been identified, and it remains uncertain whether these peptides play any biological role at physiologic concentrations. GRPP also has no clearly established biological activity. The other two gut-derived glucagon-related peptides, GLP-1 and GLP-2, however, play important roles in nutrient metabolism and gastrointestinal physiology (Table 17–4).

There are two active forms of GLP-1: GLP-1(7-36) amide, and GLP-1(7-37). The intestinal ʟ-cells secrete GLP-1 in response to meals, through dietary glucose and lipids and parasympathetic stimulation. The ʟ-cells sense dietary fat in the gut lumen in part through the GPR119 receptor, which binds the long chain fatty acid derivative oleoylethanolamide. GPR119 is also expressed on the surface of the β cells. GLP-1 binds to the GLP-1 receptor, a GPCR similar to the glucagon receptor. The ubiquitous protease dipeptidyl peptidase 4 (**DPP-4**) rapidly inactivates circulating GLP-1 (half-life <2 min) by removing the two amino-terminal amino acids. Pancreatic islets are major targets of GLP-1 action. GLP-1 directly stimulates the production and secretion of insulin and somatostatin, and thereby indirectly inhibits the secretion of glucagon. In addition, GLP-1 protects the β cells from destruction and stimulates β cell growth. Other targets of GLP-1 include the stomach, where the peptide inhibits gastric emptying and gastric acid secretion; the brain, where it inhibits appetite and induces weight loss; and the heart, where it has some protective effects.

Along with GLP-1, intestinal ʟ-cells cosecrete GLP-2 in response to eating; and like GLP-1, GLP-2 binds to a specific GPCR closely related to the glucagon and GLP-1 receptors. DPP-4 also inactivates GLP-2. GLP-2 signaling predominantly targets the intestine, where it stimulates mucosal growth and nutrient absorption and inhibits motility.

TABLE 17–4 **Biologic roles of glucagon-related peptides.**

Target Tissue	Glucagon	GLP-1	GLP-2	GIP
Islet	**Stimulates** insulin secretion	**Stimulates** insulin and soma-tostatin secretion **Inhibits** glucagon secretion (indirectly) **Inhibits** β cell death		**Stimulates** insulin, somatosta-tin, and glucagon secretion **Inhibits** glucagon secretion (indirectly) **Inhibits** β cell death
Liver	**Stimulates** glycogenolysis, gluconeogenesis, fatty acid oxidation, and ketogenesis **Inhibits** glycogen synthesis and fatty acid synthesis			
Stomach		**Inhibits** gastric acid secretion **Inhibits** gastric emptying		**Inhibits** gastric acid secretion and gastric emptying
Intestine			**Stimulates** mucosal growth and nutri-ent absorption **Inhibits** motility	**Stimulates** GLP-1 secretion by L-cells
Adipose tissue				**Stimulates** adipogenesis, lipogenesis, and adipokine production
Brain (hypothalamus)		**Inhibits** appetite		

The K cells in the duodenum and jejunum produce a related 42 amino acid incretin peptide, **GIP**, that has both functional and sequential similarity to GLP-1, but is the product of a distinct gene and binds to a distinct receptor, GIPR, which also belongs to the family of glucagon-related $G\alpha_s$-linked receptors. The K cells secrete GIP in response to glucose—via the same pathway used by the β cell (see Figure 17–5)—and lipids. Interestingly, the GIP prepropeptide is also expressed in α cells, but prohormone conver-tase 2 in α cells produces a shorter peptide, GIP_{1-30}, which lacks the 12 carboxyl amino acids present in intestinal GIP_{1-42}. The two forms of GIP appear to function identically. GIP signaling through its receptor has similar effects to those of GLP-1 on the stomach and β cells. α Cells also express the GIP receptor, through which GIP directly stimulates glucagon secretion; but GIP concomitantly suppresses glucagon secretion indirectly

through its stimulation of insulin secretion. The GIP receptor is also expressed in adipose tissue and bone. In adipose tissue, GIP plays an important role in the differentiation of new adipocytes, and also drives lipogenesis and adipokine production in mature adipocytes. In bone, GIP stimulates the osteoblasts and increases bone density.

3. SOMATOSTATIN

The pancreatic δ cells transcribe the gene for somatostatin on the long arm of chromosome 3. It codes for a 116 amino acid peptide, preprosomatostatin, from whose carboxyl end is cleaved the hor-mone somatostatin, a 14 amino acid cyclic polypeptide with a molecular weight of 1640 (Figure 17–10). First identified in the hypothalamus, it owes its name to its ability to inhibit the release
FIGURE 17–10 Amino acid sequence of somatostatin and its cleavage from dibasic amino acid residue in prosomatostatin and preprosomatostatin.

of growth hormone (GH; pituitary somatotropin). Since that time, somatostatin has been found in a number of tissues, including many areas of the brain and peripheral nervous system, the endocrine D cells in the epithelial lining of the stomach and intestine, and the δ cells in the pancreatic islets. In neurons, gastric D cells and the islet, somatostatin-14 predominates, but approximately 5% to 10% of the somatostatin-like immunoreactivity in the brain consists of a 28 amino acid peptide, somatostatin-28. Somatostatin-28 consists of an amino terminal region of 14 amino acids and a carboxyl terminal segment containing somatostatin-14. In small intestine, the larger molecule predominates, with 70% to 75% of the hormone in the 28 amino acid form and only 25% to 30% as somatostatin-14. Somatostatin-28 is 10 times more potent than somatostatin-14 in inhibiting growth hormone and insulin secretion, whereas somatostatin-14 is more effective in inhibiting glucagon release.

Most known stimulators of insulin release also promote somatostatin release from δ cells. These include glucose, arginine, gastrointestinal hormones, and sulfonylureas. The peptide hormone Urocortin3 (Ucn3), which is secreted by the β cells, also stimulates somatostatin secretion. The importance of circulating somatostatin is unclear; the major action of this peptide appears to be paracrine regulation of the pancreatic islet and the gastrointestinal tract. Physiologic levels of somatostatin in humans seldom exceed 80 pg/mL (49 pmol/L). The metabolic clearance of exogenously infused somatostatin in humans is extremely rapid; the half-life of the hormone is less than 3 minutes.

Molecular cloning has identified five somatostatin receptors (SSTR1-5), all of which are GPCRs. They vary in size from 364 to 418 amino acids (with 105 amino acids invariant) and function in the central nervous system and a wide variety of peripheral tissues, including the pituitary gland, the small intestine, and the pancreas. All five receptors belong to the $G\alpha_i$ class and inhibit the activity of adenylate cyclase, thereby lowering intracellular levels of cAMP and inhibiting cAMP-activated secretion. In addition, however, each of the different somatostatin receptors interacts with additional distinct downstream effectors that modify the cellular consequences of receptor activation. Binding of ligand to SSTR5 on β cells mediates the inhibition of insulin secretion, whereas inhibition of GH release from pituitary somatotrophs as well as glucagon release from α cells of the pancreas works through SSTR2. This explains why an analog of somatostatin, octreotide, which has a much greater affinity for SSTR2 than for SSTR5, is effective in correcting GH excess without having much effect on carbohydrate tolerance when used to treat acromegaly.

Somatostatin acts in several ways to restrain the movement of nutrients from the intestinal tract into the circulation. It prolongs gastric emptying time, decreases gastric acid and gastrin production, diminishes pancreatic exocrine secretion, decreases splanchnic blood flow, and retards xylose absorption.

4. PANCREATIC POLYPEPTIDE

PP is found in PP cells located chiefly in islets in the posterior portion of the head of the pancreas. Similar to the other islet hormones, PP derives from a larger prepropeptide of 85 amino acids that is cleaved to a single 36 amino acid peptide with a molecular weight of 4200. Circulating levels of the peptide increase in response to a mixed meal; however, intravenous infusion of glucose or lipid does not produce such a rise, and intravenous amino acids induce only a small increase. In contrast, vagotomy abolishes the response to an ingested meal, demonstrating that PP secretion responds predominantly to neural, rather than nutrient signals.

In healthy subjects, basal levels of PP average 24 ± 4 pmol/L and may become elevated owing to a variety of factors including old age, alcohol abuse, diarrhea, chronic renal failure, hypoglycemia, or inflammatory disorders. Values above 300 pmol/L are found in most patients with pancreatic endocrine tumors such as glucagonoma or vasoactive intestinal polypeptide-secreting tumor and in all patients with tumors of the pancreatic PP cell. As many as 20% of patients with insulinoma and one-third of those with gastrinomas also have plasma concentrations of PP that are greater than 300 pmol/L.

Although it has been implicated in the regulation of exocrine pancreatic secretion and gall bladder contraction, the physiologic actions of PP remain uncertain.

5. GHRELIN

The peptide hormone ghrelin was originally identified in extracts from the stomach based on its ability to bind to and activate the growth hormone secretagogue receptor (GHSR) and stimulate growth hormone release from the pituitary (thus the basis of its name: **g**rowth **h**ormone-**rel**easing peptide). The P/D1 endocrine cells in the gastric mucosa and the ε cells in the islet make ghrelin, as do a few cells in the heart, lung, kidney, immune system, hypothalamus, and pituitary. The human *GHRELIN* gene comprises four exons, and the major splice product encodes the 117 amino acid preproghrelin peptide. Processing in the ε cells yields the active form of ghrelin: a 28 amino acid peptide (amino acids 24-51 of preproghrelin) with the serine in position 3 modified by the attachment of an octanoyl side chain by Ghrelin O-acyltransferase (GOAT). Full biological activity requires the *n*-octanoyl modification. In addition, protease cleavage generates a second peptide, obestatin (amino acids 76-98 of preproghrelin) of less certain biological function.

Initially identified as a stimulator of growth hormone secretion, ghrelin signals through its receptor, the previously identified GHSR, which is a GPCR found in a variety of tissues, including the hypothalamus, pituitary, intestine, and islet. Ghrelin signaling stimulates growth hormone secretion directly through its receptor on pituitary somatotrophs, and also through its stimulation of hypothalamic GHRH secretion. In addition, ghrelin induces gastric emptying and acid secretion and regulates appetite and energy balance via neurons in the arcuate nucleus of the hypothalamus (see Chapter 20). Recent evidence from rodents suggests that ghrelin plays an essential role in conserving energy and maintaining blood glucose levels during starvation. The role of ghrelin signaling in the pancreas, and the relative contribution of islet-derived ghrelin to the overall actions of ghrelin remains unresolved.

DIABETES MELLITUS

Clinical diabetes mellitus is a syndrome of disordered metabolism with inappropriate hyperglycemia due to an absolute or relative deficiency of insulin. There may also be a defect in insulin action (insulin resistance).

CLASSIFICATION

Diabetes is classified into five main groups based on known pathological and etiologic mechanisms—type 1, type 2, monogenic, secondary, and gestational diabetes (Table 17–5). Type 1 diabetes (previously referred to as juvenile-onset or insulin dependent diabetes mellitus [IDDM]) results from pancreatic islet β cell destruction most commonly by an autoimmune process. These patients are prone to developing ketoacidosis and require insulin replacement. Type 2 diabetes (previously referred to as adult-onset or non-insulin-dependent diabetes mellitus [NIDDM]), the most prevalent form of diabetes, is a heterogeneous disorder most commonly associated with insulin resistance combined with an impairment in compensatory insulin secretion.

TYPE 1 DIABETES MELLITUS

Type 1 diabetes is immune-mediated in more than 95% of cases (type 1a) and idiopathic in less than 5% (type 1b). The rate of pancreatic β cell destruction may vary, but in most cases the process is prolonged, extending over months or years, since evidence for an immune response can be detected long in advance of hyperglycemia in patients that eventually develop type 1 diabetes. It is a catabolic disorder in which circulating insulin is virtually absent, plasma glucagon is elevated, and the pancreatic β cells fail to respond to all known insulinogenic stimuli. In the absence of insulin, the three main target tissues of insulin (liver, muscle, and fat)

TABLE 17–5 Etiologic classification of diabetes mellitus.

I. Type 1 Diabetes[a] (β cell destruction, usually leading to absolute insulin deficiency)
   A. Immune-mediated, type 1a
   B. Idiopathic, type 1b

II. Type 2 Diabetes[a] (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with minimal insulin resistance)

III. Monogenic Diabetes
   A. Autosomal dominant genetic defects of pancreatic β cells
       1. Maturity onset diabetes of the young (MODY)
       2. Insulin gene (*INS*)
       3. ATP-sensitive potassium channel (*KCNJ11* and *ABCC8*)
   B. Other genetic defects of pancreatic β cells
       1. Autosomal recessive genetic defects
       2. Mitochondrial DNA
       3. Ketosis-prone diabetes (KPD)
   C. Genetic defects in insulin action
       1. Insulin receptor mutations
       2. Lipoatrophic diabetes
   D. Neonatal diabetes (overlaps with categories A, B, C, E, and F)
       1. Transient
       2. Permanent
   E. Monogenic autoimmune syndromes
       1. IPEX: Immunodysregulation polyendocrinopathy enteropathy, X-linked
       2. Autoimmune polyendocrinopathy syndrome type 1
       3. Other autosomal recessive autoimmune polyendocrinopathies (*IL2RA*, *ITCH*, and *LRBA*)
       4. Other autosomal dominant autoimmune polyendocrinopathies (*STAT1*, *STAT3*, and *SIRT1*)
   F. Other genetic syndromes sometimes associated with diabetes
       1. Chromosomal defects: Down, Klinefelter, and Turner syndromes
       2. Neuromuscular syndromes: Friedreich ataxia, Huntington chorea, myotonic dystrophy, porphyria, and others
       3. Obesity syndromes: Laurence-Moon-Biedl, Bardet-Biedl, Prader-Willi syndromes, and others
       4. Wolfram syndrome

IV. Secondary Diabetes
   A. Diseases of the exocrine pancreas
       1. Pancreatitis
       2. Trauma, pancreatectomy
       3. Neoplasia
       4. Cystic fibrosis
       5. Hemochromatosis
       6. Fibrocalculous pancreatopathy
   B. Endocrinopathies
       1. Acromegaly
       2. Cushing syndrome
       3. Glucagonoma
       4. Pheochromocytoma
       5. Hyperthyroidism
       6. Somatostatinoma
       7. Aldosteronoma
   C. Drug- or chemical-induced
       1. β cell toxicity: vacor, pentamidine, cyclosporine
       2. β cell autoimmunity: α-interferon, anti-PD-1, anti-PD-L1, anti-CTLA-4
       3. β cell dysfunction: thiazide and loop diuretics, diazoxide, α agonists, β blockers, phenytoin, opiates
       4. Insulin resistance: glucocorticoids, progesterone, nicotinic acid, thyroid hormone, β blockers, atypical antipsychotic drugs, antiretroviral protease inhibitors
   D. Infections
       1. Congenital rubella
       2. Other viruses: cytomegalovirus, coxsackievirus B, adenovirus, mumps
   E. Uncommon forms of immune-mediated diabetes

       3. POEMS syndrome

V. Gestational Diabetes Mellitus (GDM)

[a]Patients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not, of itself, classify the patient.

Data from American Diabetes Association. Classification and Diagnosis of Diabetes. *Diabetes Care*. 2016 Jan;39 Suppl 1:S13-22.

not only fail to appropriately take up absorbed nutrients but continue to deliver glucose, amino acids, and fatty acids into the bloodstream from their respective storage depots. Furthermore, alterations in fat metabolism lead to the production and accumulation of ketones. This inappropriate persistence of the fasted state postprandially can be reversed by the administration of insulin.

The incidence of type 1 diabetes varies widely in different populations. Scandinavia and northern Europe have the highest incidence of type 1 diabetes: the yearly incidence per 100,000 youngsters 14 years of age or less is as high as 40 in Finland, 31 in Sweden, 22 in Norway, 27 in Scotland, and 20 in England. The incidence of type 1 diabetes generally decreases across the rest of Europe to 11 in Greece and 9 in France. Surprisingly, the island of Sardinia has as high an incidence as Finland, even though in the rest of Italy, including the island of Sicily, the incidence is only 11 per 100,000 per year. The United States averages 16 per 100,000. The lowest incidence of type 1 diabetes worldwide is less than 1 per 100,000 per year in China and parts of South America.

Worldwide incidence of type 1 diabetes continues to increase steadily. In Finland, the incidence has more than tripled since 1953, when it was 12/100,000/year, with an average increase of 2.4% per year. The EURODIAB study group reported recently 0.6% to 9.3% annual increases in incidence of type 1 diabetes in children younger than 15 years in various European countries. The most rapid increases have occurred in low-prevalence countries and in younger patients. Changes in environmental factors most likely explain this increased incidence.

Latent autoimmune diabetes of adulthood (LADA)   Type 1 diabetes can present at any age, although peaks in incidence occur before school age and around puberty. Older adults often present with a more indolent onset that sometimes leads to misdiagnosis and has led to the use of the term **latent autoimmune diabetes of adulthood (LADA)** to distinguish these patients. These initially unrecognized patients may retain enough β cell function at the outset to avoid ketosis, but develop increasing dependence on insulin therapy over time as their β cell mass diminishes. Islet cell antibody surveys among northern Europeans indicate that up to 15% of patients previously diagnosed with type 2 diabetes may actually have LADA.

Autoimmunity and Type 1 Diabetes

Most patients with type 1 diabetes at diagnosis have circulating antibodies against β cell proteins: islet cell antibodies (ICA), insulin autoantibodies (IAA), and antibodies to glutamic acid decarboxylase 65 (GAD), tyrosine phosphatase IA2 (ICA512), and zinc transporter 8 (ZnT8) (Table 17–6). These autoreactive antibodies can often be detected well before the onset of frank hyperglycemia, even decades earlier, providing evidence that the autoimmune process may be prolonged. After diagnosis, autoantibody levels often decline with increasing duration of the disease. Also, once patients are treated with insulin, low levels of IAA develop, even in patients that do not have an autoimmune etiology for their diabetes.

Although useful for diagnosing and predicting type 1 diabetes, antibodies against β cell proteins do not directly cause the

TABLE 17–6 Diagnostic sensitivity and specificity of autoimmune markers in newly diagnosed patients with type 1 diabetes mellitus.

	Sensitivity (%)	Specificity (%)
Glutamic acid decarboxylase (GAD65)	70-90	99
Insulin (IAA)	40-70	99
Tyrosine phosphatase IA2 (ICA512)	50-70	99
Zinc transporter 8 (ZnT8)	50-70	99

destruction of β cells in type 1 diabetes. Instead, it is the cellular immune system, the T lymphocytes that infiltrate the islets (a process called insulitis) and destroy the β cells. At the time of diagnosis, the islets of patients with type 1 diabetes are extensively infiltrated with T lymphocytes.

Normally, the thymus deletes autoreactive T cells during development so that the immune system becomes tolerant of self-antigens. In addition, certain specialized T cells, the regulatory T cells, further prevent attacks against healthy tissues by restraining the activity of any autoreactive T cells that escape the thymus. Type 1 diabetes results from a breakdown in these processes of self-tolerance in the immune system.

Type 1b diabetes   Approximately 5% of patients with the clinical features of type 1 diabetes lack serum evidence of autoimmunity. Some of these individuals have high-risk HLA haplotypes (discussed later) and may have T-cell–mediated β cell destruction in the absence of measurable levels of the known autoantibodies. Others in this group have low-risk HLA haplotypes, and appear to have a nonautoimmune cause for loss of β cell function. Such nonautoimmune type 1 diabetes has been referred to as type 1b diabetes, but a variety of terms has been used. This probably represents a heterogeneous group of disorders that lead to profound β cell dysfunction or loss, absolute insulin deficiency and a syndrome clinically similar to autoimmune type 1a diabetes. Under the accepted classification system, as specific disorders within this subgroup become defined and the genetic or environmental causes are identified, these disorders become reclassified within the monogenic or secondary forms of diabetes.

Included within this group are patients that present with a course of relapsing diabetic ketoacidosis with intervening normoglycemia that eventually progresses to permanent insulin-deficient diabetes. This disorder, ketosis prone diabetes (KPD, discussed later), has also been referred to as type 1b diabetes, and may result from unknown environmental insults combined with genetic defects in the β cell.

Autoimmune diabetes and stiff person syndrome   GAD antibodies, the first identified in type 1 diabetes, remain among the most clinically useful. Human pancreatic β cells produce GAD65, which functions as an enzyme that catalyzes the synthesis

of GABA from glutamate. GAD65 and the closely related isoform GAD67 are also found in central nervous system inhibitory neurons that secrete GABA. Some patients with GAD antibodies develop a rare neurologic condition, **stiff person syndrome**, caused by the depletion of GABA in the central nervous system and characterized by progressive rigidity and fluctuating muscle spasms. Approximately half of the patients with stiff person syndrome develop type 1 diabetes.

The vast majority of patients with type 1 diabetes do not develop symptoms of stiff person syndrome, despite the presence of GAD antibodies. The rare patients that develop the syndrome usually have much higher titers of GAD antibodies than typical patients with type 1 diabetes alone.

Genetics of Type 1 Diabetes

Family members of patients with type 1 diabetes have an increased lifetime risk of developing type 1 diabetes. The offspring of a mother with type 1 diabetes have a risk of 3%, whereas the risk is 6% for children of affected fathers. The risk in siblings of affected individuals is related to the number of human leukocyte antigen (HLA) haplotypes (discussed later) that the sibling shares. If one haplotype is shared, the risk is 6% and if two haplotypes are shared, the risk increases to 12% to 25%. For monozygotic twins, the concordance rate reaches 25% to 50%. Although these data demonstrate a strong genetic contribution to the risk of type 1 diabetes, genetics plays an even larger role in type 2 diabetes, and environment also clearly contributes substantially to the risk of type 1 diabetes.

Genes in the major histocompatibility (MHC) locus on the short arm of chromosome 6 explain at least half of the familial aggregation of type 1 diabetes. Within the MHC locus lie a number of closely packed genes involved in the function and regulation of the immune response. Although a number of genes within the MHC locus have been linked to the risk of developing type 1 diabetes, the most important of these are the genes encoding the HLA class II molecules DQ and DR. The professional antigen-presenting cells—dendritic cells, macrophages and B lymphocytes—use the class II molecules on their cell surface to present peptide antigens to T lymphocytes through the T-cell receptor. T cells activated by antigen-presenting cells carry out the β cell destruction that leads to type 1 diabetes. Although exact mechanisms remain uncertain, the variations in the amino acid sequence of individual HLA class II molecules may impact their ability to present specific self-peptides to T cells either in the process of central or peripheral tolerization or later during the development of the autoimmune response, thereby contributing to the risk of developing type 1 diabetes.

The DR haplotypes DR3 and DR4 are major susceptibility risk factors for type 1 diabetes. As many as 95% of type 1 diabetic patients have a DR3 or a DR4 haplotype—or both—compared with 45% to 50% of Caucasian nondiabetic controls. Individuals who express both a DR3 and a DR4 allele carry the highest risk for type 1 diabetes in the United States.

The high-risk *DR* genes are generally in linkage disequilibrium with *DQ* genes that themselves confer high risk, particularly DQA1*0501, DQB1*0201 (coupled with DR3), and DQA1*0301, DQB1*0302 (coupled with DR4). DQ alleles are associated not only with risk for type 1 diabetes but also with dominant protection, often in linkage with HLA-DR2. The most protective of these—and a quite common allele—is DQA1*0102, DQB1*0602. It occurs in over 20% of individuals in the United States but in less than 1% of children who develop type 1 diabetes.

An independent genetic link to chromosome 11 has also been identified in type 1 diabetes. Studies of a polymorphic DNA locus flanking the 5′ region of the *insulin* gene on chromosome 11 revealed a small but statistically significant linkage between type 1 diabetes and this genetic locus in a Caucasian population with type 1 diabetes. This polymorphic locus, which consists of a variable number of tandem repeats (VNTRs) with two common sizes in Caucasians, small (26-63 repeats) or large (140-243 repeats), does not encode a protein. An intriguing proposal to explain how the VNTR might influence susceptibility to type 1 diabetes was based on findings that *insulin* gene transcription is facilitated in the fetal thymus gland by the presence of the large allele of the VNTR locus flanking the *insulin* gene. The large VNTR allele might produce a dominant protective effect by promoting negative selection (deletion) by the thymus of insulin-specific T lymphocytes that play a critical role in the immune destruction of pancreatic β cells.

The established genetic association with the MHC region of chromosome 6 contributes much more (about 50%) to the genetic susceptibility to type 1 diabetes than does this locus flanking the *insulin* gene on chromosome 11, which contributes about 10%. Both candidate gene studies and genome-wide association studies (GWAS) have identified a number of additional risk loci that make smaller contributions to the genetic risk of type 1 diabetes. Many of the genes linked to these additional loci also play important roles in the function and regulation of the immune response.

Mutations in two genes involved in T-cell tolerance cause rare syndromes of monogenic autoimmune diabetes together with other autoimmune diseases. In the autosomal recessive disease autoimmune polyglandular syndrome type 1 (APS1; see Chapter 2), homozygous mutations in the gene encoding the autoimmune regulator (*AIRE*) prevent the expression of certain self-proteins in the thymus, thus allowing mature autoreactive T cells to leave the thymus. In addition to other autoimmune diseases and mucocutaneous candidiasis, approximately 20% of patients with APS1 develop type 1 diabetes. The second gene, *FOXP3*, found on the X chromosome, encodes a transcription factor required for the formation of regulatory T cells. Mutations in *FOXP3* cause immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome. IPEX presents in male patients with very early onset type 1 diabetes, often neonatal, combined with other autoimmune endocrinopathies, autoimmune skin disorders, diarrhea secondary to autoimmune enteropathy, and frequent severe infections.

Environmental Factors in Type 1 Diabetes

While genetic inheritance may play an important role in causing type 1 diabetes, the monozygotic twin studies demonstrate that

other causes, stochastic or environmental, are at least as important. Most individuals with type 1 diabetes do not have other family members with the disease. Environmental factors associated with increased risk of type 1 diabetes include viruses (mumps, congenital rubella, Coxsackie virus B4), toxic chemical agents such as vacor (a nitrophenylurea rat poison), and other destructive cytotoxins such as hydrogen cyanide from spoiled tapioca or cassava root. How these environmental insults lead to type 1 diabetes is unknown; they may directly damage β cells in some cases, or may act as initiators or accelerators of the autoimmune attack on the β cells. In some cases, molecular mimicry, wherein the immune system mistakenly targets β cell proteins that share homologies with certain viral or other foreign peptides may play a role.

Epidemiological studies have demonstrated an association between breast-feeding in the first 6 months of life and protection from type 1 diabetes. While it has been suggested that proteins in cow's milk may be the culprits, the strongest evidence supports the idea that human breast milk may reduce the risk of autoimmune disease.

Accumulating evidence shows that in the process of modernizing and improving public health, the risk of type 1 diabetes has increased, possibly due to the removal of some protective factors. Type 1 diabetes is almost unheard of in many third-world countries, and has its highest incidence in countries with the best public health systems, such as the Scandinavian countries. In addition, the incidence of the disease has been steadily increasing over the past century in western and westernizing countries and is especially high among the more affluent. This has led to the suggestion that a dirty environment, one with more infections (especially more parasitic diseases) and more antigen exposure, may reduce the risk of type 1 disease.

TYPE 2 DIABETES

Type 2 diabetes mellitus—previously called non-insulin-dependent diabetes or adult-onset diabetes mellitus—results from relative insulin deficiency, in contrast to the absolute insulin deficiency of patients with type 1 diabetes. Type 2 diabetes is a heterogeneous disorder and probably represents a large number of different primary genetic and environmental insults leading to relative insulin deficiency—a mismatch between insulin production and insulin requirements. Clinically, patients with type 2 diabetes can range from those with severe insulin resistance and minimal insulin secretory defects to those with a primary defect in insulin secretion.

Type 2 diabetes accounts for 80% to 90% of cases of diabetes in the United States. These patients commonly present as adults with some degree of obesity, although increasing rates of obesity are leading to earlier onset of the disease in adolescents and children. At onset, most patients with type 2 diabetes do not require insulin to survive, but over time their insulin secretory capacity tends to deteriorate, and many eventually need insulin treatment to achieve optimal glucose control. Ketosis seldom occurs spontaneously, and if present, it is a consequence of severe stress from trauma or infection.

TABLE 17–7 Factors reducing sensitivity to insulin.

Prereceptor	Insulin autoantibodies Reduced transendothelial transit
Primary defect in insulin signaling	Insulin receptor mutations Leprechaunism (complete) Rabson-Mendenhall syndrome (partial) Type A (mild) Defects in other genes involved in insulin signaling Insulin receptor autoantibodies (Type B) Ataxia telangiectasia syndrome
Secondary to other endocrine disorders	Cushing syndrome Acromegaly Pheochromocytoma Glucagonoma Hyperthyroidism Insulinoma
Secondary to other disorders	Visceral obesity Stress (infection, surgery, etc) Uremia Hyperglycemia (mild resistance seen in type 1 diabetes) Liver disease Cytogenetic disorders (Down, Turner, Klinefelter) Neuromuscular disorders (muscular dystrophies, ataxias, muscle inactivity) Congenital lipodystrophies/lipoatrophy Acquired lipodystrophy
Secondary to normal physiologic states	Puberty Pregnancy Starvation
Secondary to medications	Glucocorticoids Atypical antipsychotic drugs Antiretroviral protease inhibitors Nicotinic acid Thiazide diuretics Oral contraceptive Progesterone β blockers

Most patients with type 2 diabetes, irrespective of weight, have some degree of tissue insensitivity to insulin attributable to several interrelated factors (Table 17–7). These include putative (mostly as yet undefined) genetic factors, which are aggravated in time by further enhancers of insulin resistance such as aging, a sedentary lifestyle, and abdominal visceral obesity. Not all patients with obesity and insulin resistance develop hyperglycemia, however. An underlying defect in the ability of the β cells to compensate for the increased demand determines which patients will develop diabetes in the setting of insulin resistance. Furthermore, both the tissue resistance to insulin and the impaired β cell response to glucose appear to be further aggravated by sustained hyperglycemia, which may impede both insulin signaling and β cell function. Treatment that reduces the blood glucose levels toward normal reduces this acquired defect in insulin resistance and may also improve glucose-induced insulin release to some degree, although the long-term decline in β cell function continues.

Type 2 diabetes frequently goes undiagnosed for many years because the hyperglycemia may develop quite gradually and without initial symptoms. Despite this mild presentation, these patients develop microvascular, and, especially, macrovascular complications. Furthermore, as noted earlier, patients with type 2 diabetes suffer from a progressive decline in β cell capacity, leading to worsening hyperglycemia over time.

A. Obesity in type 2 diabetes The majority of people with type 2 diabetes have excess adiposity, although the prevalence of obesity in association with type 2 diabetes varies among different racial groups. Sixty to eighty percent of North Americans, Europeans, or Africans with type 2 diabetes and close to 100% of individuals with type 2 disease among Pima Indians or Pacific Islanders from Nauru or Samoa have obesity as defined by body mass index (BMI, see Chapter 20), while as few as 30% of Chinese and Japanese patients with type 2 diabetes are obese. However, many of those individuals with type 2 diabetes who do not meet BMI criteria for obesity have a predominantly abdominal distribution of fat, producing an abnormally high waist to hip ratio. Increases in visceral adiposity correlate with increased insulin resistance.

B. Insulin resistance in type 2 diabetes Insulin resistance can be broadly defined as a decrease in tissue responsiveness to insulin. Clinically it can be assessed directly by measuring the ability of a fixed dose of insulin to promote total body glucose disposal. It can be assessed indirectly by measuring fasting insulin levels. An increase in insulin levels with normal plasma glucose indicates insulin resistance.

As adiposity increases, especially abdominal visceral fat deposits, total body insulin sensitivity decreases. Since adipose tissue only removes a small fraction of plasma glucose, clearly the increased adipose fat stores impact total body insulin sensitivity through effects on other tissues, especially muscle and liver, causing them to decrease insulin-stimulated glucose disposal. The exact means by which fat storage in adipocytes affects the insulin sensitivity of other cells remains uncertain, but experimental evidence suggests several possible mechanisms.

Abnormalities of insulin receptors—in concentration, affinity, or both—affect insulin action. Target tissues downregulate the number of insulin receptors on the cell surface in response to chronically elevated circulating insulin levels, probably by increased intracellular degradation. When insulin levels are low, on the other hand, receptor binding is upregulated. Conditions associated with high insulin levels and lowered insulin binding to the receptor include obesity, high intake of carbohydrates, and chronic exogenous overinsulinization. Conditions associated with low insulin levels and increased insulin binding include exercise and fasting. The insulin receptor itself is probably not the major determinant of insulin sensitivity under most circumstances, however. Clinically relevant insulin resistance most commonly results from defects in postreceptor intracellular signaling pathways.

Adipokines Adipose tissue can affect the insulin sensitivity of other tissues through the secretion of signaling molecules, *adipokines*, that inhibit (TNF-α, IL-6, leptin, resistin, and others) or enhance (adiponectin) insulin signaling locally or in distal target tissues (see Chapter 20). Levels of fat storage in adipocytes, along with insulin signaling itself, regulate the production and secretion of many of the adipokines. Some of these mediators of insulin resistance may reduce insulin signaling by blocking access of insulin to target tissues through reduced transendothelial transit. However, most evidence suggests that the secreted adipokines influence insulin signaling in distant tissues through effects on postreceptor intracellular signaling pathways. Potential intracellular effectors include protein tyrosine phosphatases that dephosphorylate the receptor and pathway components, inhibitors such as the SOCS proteins that block receptor–IRS interactions, and serine/threonine kinases that inhibit the receptor and substrates through serine phosphorylation.

Free fatty acids and ectopic lipid storage The release of fatty acids by the engorged adipocytes (especially visceral adipocytes, from which fatty acids are more readily mobilized) may play a role in the development of insulin resistance as well. Oxidation of fatty acids by muscle and other tissues could inhibit glycolysis and reduce insulin-stimulated glucose removal (the Randle hypothesis, named after its original proponent). Increased fat storage in adipocytes and release of fatty acids may also eventually cause a shift in lipid storage, increasing lipid uptake and storage in nonadipose tissues such as muscle, liver, and β cells. Ectopic lipid storage in these tissues may lead to a decrease in their insulin sensitivity. In addition, free fatty acids may function directly in a signaling role both locally within the adipose tissue and systemically.

Inflammation In addition to adipocytes, adipose tissue contains a variety of other cell types including inflammatory/immune cells, such as macrophages and lymphocytes. Recent evidence implicates these cells in obesity-induced insulin resistance. As adipocyte lipid stores rise, the increased release of free fatty acids and proinflammatory adipokines recruits macrophages to the adipose tissue and activates them. The activated macrophages then release a variety of molecules (TNF-α, IL-6, nitric oxide, and others) that decrease the insulin sensitivity of the adipocytes and further increase their release of proinflammatory fatty acids and peptides, creating a positive feedback loop that maintains a chronic state of local inflammation and insulin resistance. Release of these adipokines and proinflammatory cytokines, along with the increased release of free fatty acids and the development of ectopic lipid accumulation, promotes the development of inflammation and insulin resistance in the other key insulin-target tissues, such as muscle and liver. Similar mechanisms could also lead to inflammation in the islets and contribute to β cell failure.

PPARγ activity in the adipose tissue generally has beneficial effects on systemic insulin signaling through several mechanisms: (1) Promotion of adipose lipid storage, which thereby decreases ectopic lipid storage in nonadipose tissues; (2) Inhibition of the production of adipokines and proinflammatory cytokines, which promote insulin resistance, by adipocytes; (3) Promotion of the alternative activation of macrophages to the anti-inflammatory

M2 state, rather than the proinflammatory M1 state; (4) Inhibition of the release of proinflammatory and proresistance cytokines by macrophages. Although it is expressed at much lower levels in muscle than in adipose tissue, PPARγ in myocytes might also have a direct role in controlling muscle insulin sensitivity; however, these findings remain controversial.

Tissue heterogeneity in insulin resistance   Finally, it must be kept in mind that not all tissues necessarily develop insulin resistance in parallel, and in many cases insulin resistance may be limited to specific tissues. The combination of local and systemic contributors to obesity-induced insulin resistance may explain the different levels of insulin resistance in different tissues of the same patient. Even in the same cell, insulin resistance may impact different arms of the insulin-signaling pathway discordantly. As insulin levels rise in response to insulin resistance, heterogeneity in insulin sensitivity could explain unique syndromes associated with insulin resistance like hepatic steatosis and polycystic ovary syndrome.

Other causes of insulin resistance   Visceral obesity is not the only cause of insulin resistance, although it is by far the most common cause in most populations. Other causes of insulin resistance include a variety of genetic and acquired defects that impact the insulin receptors or postreceptor signaling pathways (see Table 17–7).

Clinical consequences of insulin resistance   In addition to the impact on glucose metabolism, severe insulin resistance and the resulting elevation in circulating insulin levels can cause other clinical consequences including acanthosis nigricans, pseudoacromegaly, and hyperandrogenism. Acanthosis nigricans appears to be a consequence of very high circulating insulin levels that cross over to bind to IGF receptors on epidermal and melanin-containing cutaneous cells. This leads to local skin hyperplasia with papillomatosis, hyperkeratosis, and hyperpigmentation. The dark, velvety patches of skin most commonly appear on the back of the neck, axillae, and anticubital fossae. In extreme and prolonged cases of insulin resistance, the secondary increase in signaling through the IGF-1 receptor, or possibly residual signaling through the mitogenic arm of the insulin signaling pathway, can cause pseudoacromegaly, a syndrome with all of the bone and soft tissue changes of acromegaly (see Chapter 4), but no elevation in growth hormone or IGF-1. A similar action of extremely high insulin levels on ovarian hilar cells has been implicated in women with insulin resistance who develop hyperandrogenism and hirsutism associated with menstrual irregularities, enlarged cystic ovaries and infertility (polycystic ovary syndrome).

C. β Cell defects in type 2 diabetes   Although the majority of people with type 2 diabetes have insulin resistance, most people with insulin resistance do not have diabetes because their β cells compensate for the insulin resistance by producing and secreting more insulin. Those individuals with insulin resistance who develop type 2 diabetes have a defect in the compensatory response of their β cells to insulin resistance. Functionally, this defect is revealed by a reduction in first phase insulin secretion and the maximal insulin secretion stimulated by glucose.

While increased insulin secretion per β cell may contribute to the compensatory response to insulin resistance, increases in the number of β cells play a role as well. In the setting of obesity, hyperplasia of pancreatic β cells is often present and probably accounts for the normal or exaggerated insulin responses to glucose and other stimuli seen in obese individuals without type 2 diabetes. Assessment of total β cell mass at autopsy has revealed that β cell mass increases in obesity, but the individuals with type 2 diabetes have decreased β cell mass when compared to nondiabetic individuals with the same BMI.

Several possible defects could contribute to the failure of β cell mass compensation in people with type 2 diabetes. Underlying genetic differences in the pathways that drive β cell expansion appear to limit compensation in individuals with high genetic risk of diabetes. In susceptible individuals with obesity, ectopic fat deposition in the islets, local obesity-induced inflammation in the islets, and local and circulating adipokines and inflammatory cytokines may accelerate β cell loss. As β cell failure progresses, levels of glucose and free fatty acids start to rise, which in turn can cause further β cell toxicity. Increased demand on a decreased β cell mass may cause further damage through ER stress and the increased formation of toxic IAPP oligomers. Then, once diabetes is established, all of these mechanisms may further contribute to the progressive decline in β cell function that characterizes type 2 diabetes.

D. Metabolic syndrome   Patients with visceral obesity and insulin resistance often present with a cluster of abnormalities commonly termed the metabolic syndrome. Hyperglycemia in these patients is frequently associated with hyperinsulinemia, dyslipidemia, and hypertension, which together lead to coronary artery disease and stroke. It has been suggested that this aggregation results from a genetic defect producing insulin resistance, particularly when obesity aggravates the degree of insulin resistance. In this model, impaired action of insulin predisposes to hyperglycemia, which in turn induces hyperinsulinemia. If this hyperinsulinemia is of insufficient magnitude to correct the hyperglycemia, type 2 diabetes is manifested. The excessive insulin level could also increase sodium retention by renal tubules, thereby contributing to or causing hypertension. Increased VLDL production in the liver, leading to hypertriglyceridemia (and consequently a decreased high-density lipoprotein [HDL] cholesterol level), has also been attributed to hyperinsulinism. Moreover, it has been proposed that high insulin levels can stimulate endothelial and vascular smooth muscle cell proliferation—by virtue of the hormone's action on growth factor receptors—to promote atherosclerosis.

Although there is full agreement on an association of these disorders, the mechanism of their interrelationship remains speculative and open to experimental investigation. Controversy persists about whether or not hypertension is caused by the hyperinsulinism that results from insulin resistance. Moreover, patients with hyperinsulinism due to an insulinoma are generally normotensive,

and there is no reduction of blood pressure after surgical removal of the insulinoma restores normal insulin levels.

An alternative unifying hypothesis could be that visceral obesity directly induces the other components of this syndrome. Visceral obesity is an independent risk factor for all of the other components of the metabolic syndrome. In addition to the metabolic effects of visceral obesity, the adipokines and inflammatory cytokines generated from overloaded and inflamed adipose tissue may contribute to the pathophysiology of the syndrome. Although the full details of the role of these molecules in causation of the metabolic syndrome remain under investigation, the adipocytes and associated macrophages clearly are not just innocent bystanders but play active roles in the development of systemic insulin resistance, hypertension, and hyperlipidemia. Furthermore, thrombi in atheromatous vessels may be more hazardous in patients with visceral obesity because of an associated increase in plasminogen activator inhibitor-1 (PAI-1), a circulating factor produced by omental and visceral adipocytes that inhibits clot lysis. This model emphasizes the importance of measures such as diet and exercise that reduce visceral adiposity in the management of patients with metabolic syndrome and obese type 2 diabetes.

The main value of grouping these disorders as a syndrome, regardless of its nomenclature, is to remind physicians that the therapeutic goals in these patients must not only correct hyperglycemia but also manage the elevated blood pressure and hyperlipidemia that result in considerable cardiovascular morbidity as well as cardiovascular deaths. In addition, it reminds physicians that when choosing antihypertensive agents or lipid-lowering drugs to manage one of the components of this syndrome, their possible untoward effects on other components of the syndrome should be carefully considered. For example, physicians aware of this syndrome are less likely to prescribe antihypertensive drugs that raise lipids (diuretics, beta blockers) or that raise blood glucose (diuretics). Likewise, they may refrain from prescribing drugs that correct hyperlipidemia, but increase insulin resistance with aggravation of hyperglycemia (nicotinic acid).

E. Genetics of type 2 diabetes   Type 2 diabetes has a strong genetic link. Depending on the population studied, monozygotic twins have lifetime concordance rates for type 2 diabetes exceeding 90%. In contrast, concordance rates for type 1 diabetes in monozygotic twins are 25% to 50%. Most individuals with type 2 diabetes have other family members with the disease, but the inheritance rarely fits Mendelian patterns, supporting the conclusion that multiple genes with varying degrees of penetrance contribute. Because of the heterogeneous nature of type 2 diabetes, and its complex inheritance, efforts to identify the genes that contribute to the disease have had very limited success in the vast majority of affected patients. There has been considerable success, however, in identifying small subsets of patients with unique monogenic forms of the disease. When the etiologic defect has been defined, these patients have been reclassified within a group designated "Monogenic Diabetes" (see Table 17–5).

Efforts to identify the genes involved in polygenic type 2 diabetes have focused on two approaches: candidate gene testing and GWAS. To date candidate gene and GWAS approaches have identified 19 loci with common variants linked to type 2 diabetes. Although statistically significant and validated in additional populations, these loci independently make very small contributions to type 2 diabetes risk. The highest risk of these common variants is found at a locus adjacent to the gene encoding TCF7L2, a transcription factor involved in Wnt signaling and implicated in β cell turnover. Inheritance of the high-risk TCF7L2 allele increases the probability of developing diabetes by 1.5-fold.

Among the genes identified so far, most are involved in β cell function and turnover. When combined with the predominance of β cell genes implicated in mongenic forms of diabetes (see Table 17-5), these results reinforce the critical role of the β cell in controlling blood glucose and its involvement in the pathophysiology of type 2 diabetes. Hopefully, with the advent of high-throughput whole genome sequencing technologies, the identification of rarer, but higher risk, variants will further expand our understanding of the genetics of type 2 diabetes in the near future.

F. Environmental factors in type 2 diabetes   Despite the critical role of genetics in type 2 diabetes, environment contributes as well, especially in determining the age of onset and severity of the disease. There is generally a low incidence of type 2 diabetes in underdeveloped countries, especially in rural areas. Western countries and westernizing countries suffer from a much higher incidence. Over the past half-century, the incidence of type 2 diabetes has increased rapidly in almost all world populations but especially in emerging third-world countries. This increase correlates with increasing rates of obesity in the same populations and reflects increased access to food with high caloric content and decreased physical activity. This combination inevitably leads to increased adiposity, especially in the more readily mobilized fat stores surrounding the viscera in the abdomen.

One of the most dramatic recent changes in the epidemiology of diabetes has been the growing incidence of type 2 diabetes in children. While rarely seen in children a generation ago, type 2 diabetes is now as common as type 1 diabetes in teenagers in the United States and is seen with increasing frequency, even in younger children. Again, this increase is directly related to increasing visceral adiposity.

MONOGENIC DIABETES

Autosomal Dominant Genetic Defects of Pancreatic β Cells

MODY   This subgroup of monogenic disorders is characterized by the onset of diabetes in late childhood or before the age of 25 years as a result of a partial defect in glucose-induced insulin release and accounts for up to 5% of diabetes in North American and European populations. A strong family history of early-onset diabetes occurring in one parent and in one-half of the parent's offspring suggests autosomal dominant transmission. In contrast to most patients with type 2 diabetes, these patients are generally nonobese and lack

associated insulin resistance. Instead they exhibit predominantly a defect in glucose-stimulated insulin secretion. However, because they are not ketosis-prone and may initially achieve good glycemic control without insulin therapy, their disease has been called **maturity-onset diabetes of the young (MODY)**. Several distinct types have been described with single-gene defects, and all have been shown to produce a defect in glucose-induced insulin release. MODY 2 results from an abnormal glucokinase enzyme. Many of the other forms of MODY are due to mutations of nuclear transcription factors that control β cell function and formation by regulating the expression of genes in β cells or their developmental precursors (Figure 17–8 and Table 17–11).

MODY 1 includes multiple members of a large pedigree known as the R-W family, descendants of a German couple who immigrated to Michigan in 1861. They were studied prospectively since 1958, and in 1996 the genetic defect was shown to be a nonsense mutation of a nuclear transcription factor found in liver as well as in pancreatic β cells. This gene has been termed *hepatocyte nuclear factor 4α* (*HNF4α*) and is found on chromosome 20. Mutations of this gene are among the rarest of the MODY groups, with few reported in families outside the Michigan pedigree. These patients display a progressive decline in β cell function and eventually develop chronic complications of diabetes including microangiopathy at a rate approaching that of people with type 1 diabetes. They often fare better with insulin therapy.

MODY 2 was first described in French families but has now been found in racial groups from most parts of the world. Multiple different mutations of the *glucokinase* gene (*GCK*) on chromosome 7 have been identified and characterized. In pancreatic β cells, glucokinase controls the rate-limiting step in glycolysis and thereby determines the rate of ATP production from glucose and the insulin secretory response to glucose (see Figure 17–5). Reduced glucokinase activity resets the sensitivity of the β cell to

glucose so that it requires higher plasma glucose levels to stimulate insulin secretion, resulting in fasting hyperglycemia and mild diabetes. Although some of these mutations can completely block the enzyme's function, others interfere only slightly with its action. In contrast to all the other forms of MODY, most patients with one mutated *GCK* allele (heterozygotes) have a benign course with few or no chronic complications and respond well to diet therapy or oral antidiabetic drugs without the need for insulin treatment. On the other hand, rare individuals who inherit two mutated *GCK* alleles have permanent neonatal diabetes (discussed later), a nonimmune form of absolute insulin deficiency that presents at birth.

In contrast to the mutations that reduce glucokinase enzyme activity and cause MODY 2, rare mutations in *GCK* that increase the enzymatic activity of glucokinase can cause increased insulin secretion and hypoglycemia (see Chapter 18), demonstrating the key role of this enzyme in determining the sensitivity of the β cell to glucose.

MODY 3 is caused by mutations of *hepatocyte nuclear factor 1α* (*HNF1α*), whose gene is located on chromosome 12. This is the most common form of MODY in European populations, with many different mutations having been reported. Like *HNF4α*, the *HNF1α* transcription factor is expressed in pancreatic β cells as well as in liver. Also similar to *HNF4α*, mutations in *HNF1α* cause a progressive form of diabetes with declining β cell function that often leads to dependence on insulin therapy and high rates of microvascular complications. Patients carrying *HNF1α* mutations often have reduced circulating levels of C-reactive protein. Of note, early in the course of the disease, these patients may display an exaggerated response to sulfonylureas.

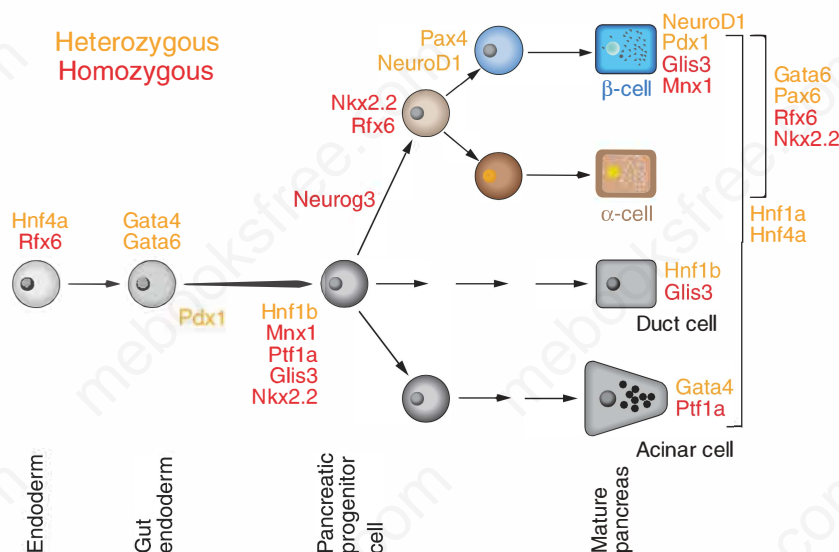
Together, *HNF1α* and *HNF4α*, along with several other β cell transcription factors including *PDX1* and *NEUROD1* (discussed later), form an interacting network of transcription factors (Figure 17–11). This transcriptional network regulates


FIGURE 17–11 A simplified model is shown for the differentiation of pancreatic cell types during the development of the pancreas, starting with the formation of the definitive endoderm. Transcription factors involved in this process and also implicated in human diabetes are shown at their major expression time points, and are labeled in orange if heterozygous mutations cause diabetes and in red if only homozygous mutations have been shown to cause diabetes.

genes involved in both the development of the β cell as well as mature β cell function, including glucose-sensing and insulin secretion. Target genes include *GCK*, as well as genes implicated in the formation, maturation and expansion of β cells. Impairment in β cell formation and regeneration may explain the progressive nature of the MODY transcription factor syndromes and reinforces the importance of β cell mass in preventing hyperglycemia.

MODY 4 results from mutation of a pancreatic nuclear transcription factor known as *pancreatic and duodenal homeobox-1* (*PDX1*), whose gene is on chromosome 13. It mediates *insulin* gene transcription and regulates expression of other β cell-specific genes including *GCK*. When both alleles of this gene are nonfunctioning, agenesis of the entire pancreas results; but in the presence of a heterozygous mutation of *PDX1*, a mild form of MODY has been described in which affected individuals developed diabetes at a later age (mean onset at 35 years) than occurs with the other forms of MODY, in whom onset generally occurs before the age of 25 years.

MODY 5 was initially reported in a Japanese family with a mutation of *HNF1*β, a hepatic nuclear transcription factor closely related in structure and molecular function to *HNF1*α. The two *HNF1* factors, however, are expressed by different cells. *HNF1*β is expressed early in the development of the liver, pancreas, kidneys, and genitourinary system, and is not found in mature β cells.

Mutations in this gene cause a moderately severe form of MODY with progression to insulin treatment and severe diabetic complications in those affected. Consistent with its expression pattern early in development, *HNF1*β mutations also frequently cause reduction in the overall size of the pancreas, decreased insulin production, and congenital defects in the kidney and urogenital tract. Patients may also suffer from varying degrees of cholestatic jaundice, hyperuricemia, nephropathy, and hypomagnesemia secondary to renal magnesium wasting.

MODY 6, a milder form of MODY similar to MODY 4, results from mutations in the gene encoding the islet transcription factor NeuroD1. Like PDX1, NeuroD1 plays an important role in the expression of insulin and other β *cell* genes, and in the formation and maintenance of β cells.

Other MODY genes   The six *MODY* genes listed earlier explain the majority of cases of MODY in patients of European ancestry, but less than half of those in non-European populations. Several rare variants in other genes have been implicated in autosomal dominant diabetes in a few families (see Table 17–8); however, a consensus has not yet been reached that these families fit the criteria for MODY and that the reported variants cause the disorder. The causative genes in most non-Europeans with MODY remain unknown.

The identification of mutations in multiple genes encoding pancreatic transcription factors in patients with MODY has led to the screening of other genes encoding pancreatic transcription factors in patients with diabetes. Heterozygous mutations in genes encoding several transcription factors have been identified in patients with earlier or later onset diabetes than in MODY patients, including *GATA6* and *GATA4* (neonatal diabetes) and

TABLE 17–8 Autosomal dominant genetic defects of pancreatic β cell function.

Syndrome	Mutated Protein	Gene	Function
MODY 1	Hepatocyte nuclear factor-4α	*HNF4A*	Transcription factor
MODY 2	Glucokinase	*GCK*	Glucose sensor
MODY 3	Hepatocyte nuclear factor-1α	*HNF1A*	Transcription factor
MODY 4	Pancreatic duodenal homeobox-1	*PDX1*	Transcription factor
MODY 5	Hepatocyte nuclear factor-1β	*HNF1B*	Transcription factor
MODY 6	NeuroD1	*NEUOROD1*	Transcription factor
MODY 7	Kruppel-like factor 11	*KLF11*	Transcription factor
MODY 8	Carboxyl-ester lipase	*CEL*	Exocrine enzyme
MODY 9	Paired homeobox 4	*PAX4*	Transcription factor
MODY 11	Tyrosine-protein kinase Blk	*BLK*	Intracellular signaling
MODY 14	Adaptor Protein APPL1	*APPL1*	Intracellular signaling
GATA4	GATA-binding protein 4	*GATA4*	Transcription factor
GATA6	GATA-binding protein 6	*GATA6*	Transcription factor
Mutant insulin or Proinsulin	Preproinsulin	*INS*	Hormone
KATP mutations	Inward-rectifying K⁺ channel 6.2	*KCNJ11*	Ion channel
	Sulfonylurea receptor 1	*ABBC8*	Ion channel

ISL1, *PAX6*, and *PAX4* (later onset diabetes). Heterozygous GATA4 and GATA6 mutations can also be associated with pancreatic agenesis and congenital cardiac defects. The association of diabetes with heterozygous mutations in so many β cell genes highlights the critical importance of optimal β cell function in metabolic regulation. Even modest defects in glucose-induced insulin secretion can result in hyperglycemia.

Insulin mutations   Sequencing of the *insulin* gene more than 30 years ago led to the first descriptions of heterozygous mutations in the coding sequence of the *insulin* gene that produce abnormal circulating forms of insulin. Most of these initial cases presented with high circulating levels of insulin, but normal insulin sensitivity and normal glucose levels. Because the abnormal insulins in these cases bind to receptors poorly, they have very low biologic activity and are cleared at a slower rate, leading to accumulation in the blood at higher levels than normal insulin and a subnormal

molar ratio of C peptide to immunoreactive insulin. They typically are not associated with hyperglycemia.

However, a mutation in the insulin B chain in one family was associated with decreased circulating levels of both the mutant and normal insulins, and diabetes. Subsequent extensive sequencing of the *INS* gene has identified many other mutant insulins that produce a similar heterozygous form of diabetes. Modeling of these dominant insulin mutations in mice demonstrates that they lead to the accumulation of aberrantly folded proteins in the endoplasmic reticulum, activation of the unfolded protein response in the ER, and β cell apoptosis. Patients with diabetes secondary to *INS* gene mutations usually present at a younger age than most patients with MODY, often developing the disease as neonates (see Neonatal Diabetes later). Because of the profound β cell loss, these patients follow a disease course similar to type 1 diabetes with absolute insulin deficiency and ketosis, and they require insulin therapy.

This syndrome highlights the sensitivity of the β cells to ER stress, which may explain why β cells often fail when presented with the increased insulin demands associated with insulin resistance, the toxicity of IAPP oligomers, or mutations in genes involved in the unfolded protein response pathway (discussed later).

Mutations in the subunits of the ATP-sensitive potassium channel

β cells sense rising blood glucose concentrations by increasing the production of ATP from glucose. The rising intracellular ATP levels cause the closure of ATP-sensitive potassium channels on the cell surface, which depolarizes the cell and sets off a cascade of events that leads to the secretion of insulin (see Figure 17–5). Rare dominant activating mutations in either of the two units of the channel, SUR1 and Kir6.2 (gene names *ABCC8* and *KCNJ11*, respectively), can cause the channels to remain open and prevent glucose-induced depolarization and insulin secretion. Children heterozygous for these mutations present with early-onset diabetes, commonly as neonates, and may have associated neurologic deficits implying a role for these channels in the central nervous system. Depending on the exact mutation, some of these children can still respond to treatment with sulfonylureas, which may also ameliorate the neurologic symptoms.

Other Genetic Defects of Pancreatic β Cells

Autosomal recessive genetic defects Although less common than the autosomal dominant β cell disorders, mutations in several genes causing autosomal recessive syndromes with defects in β cell function have been identified in patients with diabetes (Table 17–9). Due to the severity of the β cell defect, many of these present with neonatal diabetes. This group of disorders includes homozygous mutations in the MODY genes *GCK*, *PDX1,* and *NEUROD1*. Homozygous mutations in *GCK* cause a much more severe syndrome than the mild glucose-sensing defect seen in MODY 2. Patients with homozygous *GCK* mutations present at birth with severe hyperglycemia and require insulin therapy.

In patients with mutations in both alleles of *PDX1*, the pancreas fails to form, and they have pancreatic exocrine deficiency as well as diabetes. Homozygous mutations in several other pancreatic transcription factor genes have been described as well, including *PTF1A, NEUROG3, RFX6, NKX2-2, MNX1,* and *GLIS3*. Like *PDX1*, homozygous mutation of *PTF1A* causes diabetes and pancreatic agenesis, but it causes cerebellar atrophy as well. The transcription factor Neurog3 drives the formation of the endocrine cells in both the pancreas and gut. In addition to diabetes onset prior to puberty, infants born with homozygous *NEUROG3*

TABLE 17–9 Autosomal recessive genetic defects of pancreatic β cell function.

Function	Protein	Gene	Associated Defects
Glucose sensing	Glucokinase	GCK	
Transcription factors	Pancreatic duodenal homeodomain protein 1	PDX1	Pancreatic agenesis
	Pancreatic transcription factor 1a	PTF1A	Pancreatic and cerebellar agenesis
	Neurogenenin3	NEUROG3	Absence of gut endocrine cells, malabsorption
	Regulatory factor X-box 6	RFX6	Mitchell-Riley syndrome: absence of gut endocrine and islet α, β, and δ cells, pancreatic and gall bladder hypoplasia, intestinal atresia, malabsorption
	GLI Similar-3	GLIS3	Hypothyroidism, cholestasis, polycystic kidneys, hypoplastic pancreas
	NK homeodomain protein 2-2	NKX2-2	Severe developmental delay, hypotonia, cortical blindness, impaired visual tracking, and hearing impairment
	Motor neuron and pancreas homeodomain protein 1	MNX1	Severe developmental delay and neurological deficits, sacral agenesis
Unfolded protein response	Eukaryotic translation initiation factor 2-α kinase 3/PKR-like ER kinase (PERK)	EIF2AK3	Wolcott-Rallison syndrome: epiphyseal dysplasia and growth retardation; variable hepatic, renal, cardiac, and pancreatic exocrine defects
	Immediate early response 3 interacting protein 1	IER3IP1	MEDS syndrome: microcephaly, epilepsy
	Wolfram syndrome protein 1 (WFS1)	WFS1	Wolfram syndrome: diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (DIDMOAD)
Thiamine transport	Solute carrier family 19 (thiamine transporter), member 2	SLC19A2	Thiamine-responsive megaloblastic anemia: anemia, deafness

mutations have severe malabsorption associated with a lack of gut endocrine cells from birth.

Homozygous mutations in *RFX6*, which encodes a transcription factor that functions downstream of *NEUROG3* and upstream of *PDX1* in β cell development, cause **Mitchell–Riley syndrome** in which neonates present with diabetes in association with complete absence of all islet cell types except PP cells, hypoplasia of the pancreas and gall bladder, intestinal atresia, and severe malabsorption.

The zinc finger transcription factor GLIS3 is expressed broadly in many tissues and plays a role in the transcription of the *insulin* gene. Homozygous mutations in *GLIS3* cause congenital hypothyroidism in addition to neonatal diabetes.

In the autosomal recessive **Wolcott–Rallison syndrome**, affected children present with neonatal diabetes, epiphyseal dysplasia, and growth retardation together with a variety of progressive hepatic, renal, cardiac, and pancreatic exocrine defects and developmental delay. The causative gene, *EIF2AK3*, encodes a kinase (PKR-like ER kinase [PERK]) activated by the presence of unfolded proteins in the ER. PERK controls one of the three parallel arms of the unfolded protein response; inositol-requiring enzyme 1 (IRE1) and activating transcription factor 6 (ATF6) activate the other two arms. Together these three molecules activate signaling pathways that protect the cell from ER stress but lead to apoptosis when these protective mechanisms fail. Mice lacking PERK have an inadequate response to ER stress, which leads to accelerated β cell apoptosis. With the high load of insulin production in the ER, β cells are uniquely sensitive to ER stress, and this sensitivity probably underlies the damage caused by mutant insulins, IAPP oligomers, and Wolfram syndrome as well.

Wolfram syndrome is an autosomal recessive neurodegenerative disorder first evident in childhood. Patients present with diabetes insipidus, diabetes mellitus, optic atrophy, and deafness—hence the acronym DIDMOAD. Diabetes mellitus usually develops in the first decade together with the optic atrophy, followed by central diabetes insipidus and sensorineural deafness during the second decade in 60% to 75% of patients. Ureterohydronephrosis, neurogenic bladder, cerebellar ataxia, peripheral neuropathy, and psychiatric illness develop later in many patients. The diabetes mellitus is nonimmune and not linked to specific HLA haplotypes, but on autopsy these patients have selective loss of β cells in the pancreas. Genetic studies mapped the causative mutations to a gene called *WFS1*, which encodes a 100.3-kDa transmembrane protein localized to the endoplasmic reticulum membranes of all cells. *WFS1* is expressed at particularly high levels in β cells. Studies in mice have shown that the WFS1 protein forms part of the unfolded protein response downstream of PERK and IRE1 and helps protect the β cells from ER stress and apoptosis, especially during periods of high insulin demand.

Children with **thiamine-responsive megaloblastic anemia syndrome** carry mutations in the high-affinity thiamine transporter SLC19A2 found on cell and mitochondrial membranes. They develop megaloblastic anemia, diabetes, and sensorineuronal deafness. The diabetes usually presents in the first decade of life. In the absence of SLC19A2, cells and mitochondria can still transport thiamine through lower affinity transporters, and both the anemia and the diabetes respond to pharmacologic treatment with thiamine. However, all patients eventually require insulin replacement despite thiamine therapy. It remains unclear how partial defects in cellular and mitochondrial thiamine transport cause β cell failure.

Mitochondrial DNA mutations   Because sperm do not contain mitochondria, only the mother transmits mitochondrial genes to her offspring. Diabetes due to a mutation of mitochondrial DNA that impairs the transfer of leucine into mitochondrial proteins has now been described in a large number of families, and results from impaired β cell function. The incidence of this disorder is as high as 1% to 3% in patients with diabetes in Japan and Korea, but lower in European populations. Most patients have a mild form of maternally transmitted diabetes with insulin deficiency that responds to oral hypoglycemic agents; however, some patients have a more severe clinical picture similar to type 1a diabetes. As many as 63% of patients with this subtype of diabetes have hearing loss and a smaller proportion (15%) have a syndrome of myopathy, encephalopathy, lactic acidosis, and stroke-like episodes.

Ketosis-Prone Diabetes

First described in young adult African American males from the Flatbush neighborhood in New York City, but since described in a number of populations of both African and non-African ancestry, these patients typically present with diabetic ketoacidosis and absolute insulin deficiency, followed by extended clinical remission off insulin. When tested during remission, however, maximal insulin secretory capacity remains markedly reduced, and these patients follow a relapsing course of DKA and hyperglycemia with eventual permanent insulin-deficient diabetes. These patients do not have islet cell autoantibodies or increased frequencies of HLA haplotypes associated with risk of autoimmune type 1a diabetes. Although there is often a family history of similar diabetes, the inheritance is not clearly Mendelian. Although KPD patients have been distinguished based on the history of relapsing β cell dysfunction, it remains controversial as to whether KPD represents a clinical entity distinct from other forms of nonautoimmune type 1b diabetes.

In a study of KPD patients of West African ancestry, linkage was established with coding variants in the *PAX4* gene. *PAX4* encodes for a transcription factor that functions downstream of *NEUROG3* in the formation of β cells. Fourteen to twenty-one percent of individuals of West African ancestry carry a coding variant that substitutes tryptophan for arginine at position 133 in *PAX4* and reduces its ability to repress transcription of target genes. Interestingly, the R133W variant is unique to people of West African ancestry. The R133W allele is approximately twice as frequent in individuals with KPD, and all individuals homozygous for R133W have KPD. An additional *PAX4* coding variant with reduced ability to bind to DNA was identified in one patient with KPD. Different coding variants in *PAX4* have also been identified in Thai families with MODY (MODY 9) and in Japanese

patients (both heterozygous and homozygous) with early onset insulin-deficient diabetes similar to KPD. Taken together, these data suggest that coding variants in the *PAX4* gene predispose to insulin-deficient diabetes, but the clinical phenotype may depend on the exact nature of the variant and interactions with other genes and environmental factors.

Genetic Defects of Insulin Action

These are rare and unusual causes of diabetes that result from mutations of the insulin receptor or from other genetically determined postreceptor abnormalities of insulin action. Metabolic abnormalities associated with these disorders may range from hyperinsulinemia and modest hyperglycemia to severe diabetes. Many individuals have acanthosis nigricans, polycystic ovaries with hyperandrogenism, and, in exceptional cases, pseudoacromegaly (discussed earlier).

Familial forms of insulin resistance associated with acanthosis nigricans have been termed type A insulin resistance, and are often associated with heterozygous mutations in the **insulin receptor** or homozygous mutations that retain some insulin-signaling capacity. Because of the capacity of the β cell to compensate for insulin resistance, these patients often do not present with hyperglycemia, but have severely elevated levels of circulating insulin.

If both copies of the insulin receptor gene carry mutations that nearly or completely abrogate signaling, the affected children present at birth with a syndrome known as **Leprechaunism** (or **Donohue syndrome**) that includes growth retardation, multiple developmental defects, lipoatrophy, severely elevated insulin levels, and hyperglycemia that does not respond to insulin therapy. These patients generally do not survive beyond a few weeks. Patients with **Rabson–Mendenhall syndrome** also have homozygous or compound heterozygous mutations in the insulin receptor, but with some small amount of residual signaling that results in a slightly less severe syndrome associated with abnormalities in the nails, teeth, and pineal gland. They may survive into adolescence.

Familial forms of type A insulin resistance without mutations in the insulin receptor have been described, and some of these may result from mutations in downstream components of the insulin-signaling cascade, although to date few such mutations have been found in humans. Variants in IRS-1 have been identified in patients with diabetes, but also occur in people with normal insulin sensitivity. Rare coding mutations in the genes encoding the p85α subunit of PI3 kinase, in AKT2, and in PPARγ have been associated with severe insulin resistance in a very small number of patients. The one patient with homozygous mutation of *AKT2* also had mild atrophy of subcutaneous limb adipose tissue.

Congenital and acquired forms of lipodystrophy can cause severe insulin resistance. Except in newborns with lipoatrophy secondary to complete loss of insulin receptors (Leprechaunism), alterations in the structure and function of the insulin receptor cannot be demonstrated in patients with insulin-resistant lipodystrophic diabetes, suggesting that the cause of the insulin resistance in these patients must reside in postreceptor pathways. Replacement of the adipokines leptin and adiponectin can reverse insulin resistance in mouse models of severe lipoatrophy, and leptin has been helpful in human cases of generalized lipodystrophy, demonstrating the importance of the adipocyte in regulating insulin function. Also, the loss of adipose storage depots in lipoatrophy leads to very high levels of circulating triglyceride-rich lipoprotein particles and increased deposition of fat in nonadipose tissues such as liver and muscle, which may contribute to dysfunction and insulin resistance in these tissues. The increase in ectopic fat deposition leads to profound hepatic steatosis in affected patients and can progress to cirrhosis and liver failure.

The congenital syndromes can be divided into generalized and partial lipodystrophies with or without dystrophic features in other tissues. The generalized syndromes are often identified in neonates, have severe insulin resistance at diagnosis and rapidly develop hyperglycemia, acanthosis nigricans, hyperandrogenism, and pseudoacromegaly. Recessive mutations causing generalized congenital lipodystrophy have been identified in three genes encoding proteins involved in the formation of lipid droplets (seipin and caveolin-1) and triglyceride (1-acylglycerol-3-phosphate-*O*-acyltransferase 2 [AGPAT2]).

Two syndromes of familial partial lipodystrophy without associated dysmorphic defects have been described in which the lipoatrophy usually first appears late in childhood, but may be proceeded by evidence of insulin resistance. The type 1 syndrome consists of atrophy of limb, gluteal and subcutaneous abdominal fat with sparing or increases of the abdominal visceral, upper trunk, head, and neck fat. In the type 2 syndrome, truncal and visceral fat are also affected and only vulval and head and neck depots are spared.

To date no genetic causes of the type 1 syndrome have been identified. In the type 2 syndrome, dominant mutations have been found in *LMNA*, the gene encoding the nuclear intermediate filament lamin A/C. In addition, one individual with the type 2 syndrome has been identified with a homozygous nonsense mutation in the gene encoding the lipid droplet protein CIDEC, and one individual was identified with a homozygous truncation of the gene encoding lipase maturation factor 1, a protein required for the maturation of both lipoprotein lipase and hepatic lipase.

Consistent with its known role in adipocytes differentiation, dominant mutations in the gene encoding PPARγ have also been described in patients with familial partial lipodystrophy and insulin resistance. These patients have a pattern of lipoatrophy similar to the type 2 syndrome with *LMNA* mutations, but with less severe subcutaneous fat loss, and have been labeled type 3 familial partial lipodystrophy. Less commonly, mutations in the PLIN1, AKT2 and CIDEC genes have been associated with familial forms of partial lipodystrophy.

Several syndromes of lipodystrophy associated with other dysmorphic features have been described. Autosomal recessive mutations in *ZMPSTE24*, which encodes a metalloproteinase that cleaves prolamin A to produce mature lamin A, cause generalized lipodystrophy associated with mandibuloacral dysplasia. In patients with partial lipodystrophy combined with mandibuloacral dysplasia, autosomal recessive mutations have been identified in *LMNA*, but these mutations are distinct from those that cause familial partial lipodystrophy type 2. Remarkably, yet a different set of mutations in *LMNA* cause the autosomal recessive syndrome Hutchinson–Gilford progeria, which includes severe early

onset generalized lipodystrophy. Additional distinct mutations in *LMNA* cause several other congenital dysmorphic syndromes, including muscular dystrophies, familial dilated cardiomyopathy, and Charcot-Marie-Tooth disease.

Acquired forms of partial and generalized lipodystrophy with insulin resistance and diabetes can develop secondary to infections, autoimmunity, paraneoplastic syndromes, collagen vascular disorders, drugs, or unknown causes. One common form is seen in patients with HIV infection following treatment with protease inhibitors.

Neonatal Diabetes

Neonatal diabetes, defined as diabetes diagnosed before 6 months of age, is rare, occurring in fewer than 1 in 200,000 live births. Children with neonatal diabetes often present with decreased birth weight (intrauterine growth restriction, IUGR) and decreased fat stores in addition to hyperglycemia. Most commonly these children have reduced circulating insulin and C-peptide levels caused by inherited β cells defects, although rare inherited defects in insulin signaling can also present in neonates. In approximately half of cases, neonatal diabetes is transient: the diabetes goes into remission (normoglycemia with no therapy) before 18 months of age, although it usually returns at puberty. In the remainder of cases, the diabetes is permanent.

Transient neonatal diabetes (TNDM) Defects in imprinting underlie most cases of TNDM. The most common genetic defect is paternal uniparental isodysomy (replacement of the maternal copy of the region with the paternal copy) of an imprinted region at chromosome 6q24. In this region, the maternal copy of the chromosome is normally silenced by methylation. Simple duplication of the paternal copy of this region, or mutations in ZFP57, a zinc-finger protein required globally for the methylation of imprinted regions, can give the same TNDM phenotype. The affected region of 6q24 contains two genes of uncertain function, but one of them, *ZAC*, has been identified as a tumor suppressor gene and may activate the expression of an inhibitor of cell proliferation. An increase in hypomethylated copies of *ZAC* may lead to the inhibition of β cell proliferation and inadequate β cell mass.

Some autosomal dominant activating mutations in *KCNJ11* and *ABCC8*, the genes encoding the two subunits of the ATP-sensitive potassium channels in β cells (see Figure 17–5) and listed among autosomal dominant forms of heritable diabetes (discussed earlier) can cause TNDM. Autosomal dominant mutations in the MODY 5 gene, *HNF1*β, can also cause TNDM.

Permanent neonatal diabetes (PNDM) Autosomal dominant activating mutations in *KCNJ11* and *ABCC8* can also cause PNDM. Some of the autosomal dominant insulin mutations that cause rapid β cell apoptosis will result in permanent diabetes in neonates. In addition, most of the syndromes caused by autosomal recessive genetic defects in β cells (see Table 17–9) present in neonates. These include mutations in the MODY genes *GCK*, *PDX1*, and *NEUROD1*, the transcription factor genes *NKX2-2*, *MNX1*, *PTF1A*, *GLIS3*, and *RFX6*, and the Wolcott–Rallison

syndrome gene *EIF2AK3*. The IPEX syndrome (see Genetics of Type 1 Diabetes, discussed earlier), caused by mutations in *FOXP3*, can also present with accelerated autoimmune type 1 diabetes in neonates. Finally, mutations that cause complete, or nearly complete, loss of insulin signaling (Leprechaunism) also present with PNDM.

Several other syndromes of neonatal diabetes of unknown etiology associated with a variety of other developmental defects have been described. With the advent of rapid whole genome sequencing, the genetic defects that cause these syndromes, as well as later onset diabetes, may soon be identified, providing further insights into the pathogenesis of diabetes and identifying potential therapeutic targets.

Monogenic Autoimmune Syndromes

Several syndromes of altered immune function with multiple endocrine gland involvement caused by single gene mutations have been described. The APS1 and IPEX syndromes are described in the section on the genetics of type 1 diabetes and in Chapter 2. Recently several additional monogenic autoimmune syndromes that include type 1 diabetes have been identified with autosomal dominant (*STAT1*, *STAT3*, and *SIRT1*) or recessive (*IL2RA*, *ITCH*, and *LRBA*) inheritance.

Other Genetic Syndromes Sometimes Associated with Diabetes

More than 50 distinct genetic syndromes involve an increased incidence of diabetes mellitus. These include the chromosomal abnormalities of Down syndrome, Klinefelter syndrome, and Turner syndrome. In addition, a number of complex syndromes associated with neuromuscular pathologies (Freidriech ataxia, Huntington chorea, porphyria, muscular dystrophies) or severe obesity (Laurence–Moon–Biedl, Bardet–Biedl, and Prader–Willi syndromes) have been associated with diabetes.

SECONDARY DIABETES

Diabetes due to Diseases of the Exocrine Pancreas

Any process that diffusely damages or substantially displaces the pancreas can cause diabetes, although individuals with a predisposition to type 2 diabetes are probably more susceptible to developing diabetes with lesser degrees of pancreatic involvement. Because glucagon-secreting α cells are also damaged or removed by these processes, less insulin is usually required for replacement—as compared with most other forms of diabetes that leave α cells intact.

Acquired causes include pancreatitis, trauma, infection, pancreatic carcinoma, and pancreatectomy. Fibrocalculous pancreatopathy, a form of acquired pancreatitis with extensive fibrosis and ductal calculi seen commonly in tropical regions, may result from both dietary and genetic contributors, although the exact cause remains obscure. Like chronic pancreatitis from a variety of causes, fibrocalculous involvement of the pancreas may be accompanied

by abdominal pain radiating to the back and associated with pancreatic calcifications on x-ray. When extensive enough, hemochromatosis and cystic fibrosis can also displace β cells and reduce insulin secretion. Autosomal dominant mutations in carboxyl-ester lipase (CEL), an exocrine enzyme, cause accelerated exocrine pancreatic damage and diabetes at a young age, and have been designated as MODY 8 (see Table 17–8).

Endocrinopathies

Excess production of certain hormones—GH (acromegaly), glucocorticoids (Cushing syndrome or disease), catecholamines (pheochromocytoma), thyroid hormone (thyrotoxicosis), glucagon (glucagonoma), or pancreatic somatostatin (somatostatinoma)—can produce relative insulin deficiency and diabetes by a number of mechanisms. In all but the last instance (somatostatinoma), peripheral responsiveness to insulin is impaired. In addition, excess of catecholamines or somatostatin decreases insulin release from β cells. Diabetes mainly occurs in individuals with underlying defects in insulin secretion, and hyperglycemia typically resolves when the hormone excess is corrected.

Drug- or Chemical-Induced Diabetes

Many drugs are associated with carbohydrate intolerance or frank diabetes mellitus. Some act by interfering with insulin release from the β cells (thiazides, phenytoin, cyclosporine), some by inducing insulin resistance (glucocorticoids, oral contraceptive pills, niacin, and antiviral protease inhibitors), and some by causing β cell destruction (intravenous pentamidine). Atypical antipsychotic medications can provoke substantial weight gain and insulin resistance, but the high reported incidence of diabetic ketoacidosis in patients on these drugs suggests that they may also impair β cell function.

The increasing therapeutic use of drugs that block inhibitory immune system pathways that keep immune responses in check has led to the development of new syndromes of autoimmunity including autoimmune diabetes (essentially a secondary form of type 1 diabetes). Both α interferon used to treat Hepatitis C and immune checkpoint inhibitors such the monoclonal antibodies against PD-1 and CTLA-4 used to treat cancer have been associated with development of a fulminant form of autoimmune diabetes similar to type 1 diabetes, as well as other endocrine and non-endocrine autoimmune disorders.

Adrenergic drugs impact glucose metabolism in complex and often opposing ways because of differing effects on insulin secretion, glucagon secretion, hepatic glucose output, peripheral insulin sensitivity, and weight gain. In clinical practice, the first generation, nonselective β blockers such as propanolol tend to modestly increase glucose levels, at least in part due to increases in insulin resistance, but potentially by decreasing insulin secretion as well. The second generation, selective β1 blockers also tend to increase blood glucose, but the third generation drugs with combined α and β blockade have minimal effects on blood glucose. In contrast, nonselective α agonist and α2 agonists tend to raise blood glucose, probably due to their combined effects on insulin

secretion and hepatic glucose output. However, although β blockers and α2 agonists like clonidine, as well as calcium channel blockers, inhibit glucose-induced insulin release from *in vitro* preparations of pancreatic β cells, these drugs have minimal or modest effects on blood glucose control at the levels used in standard antihypertensive therapy in humans.

Finally it must be kept in mind that the most common toxin causing diabetes is ethanol. Chronic alcoholic pancreatitis with secondary loss of β cells accounts for approximately 1% of diabetes in the United States.

Infections Causing Diabetes

Certain viruses have been associated with direct pancreatic β cell destruction in animals. Diabetes is also known to develop frequently in humans who had congenital rubella, although most of these patients have HLA and immune markers characteristic of type 1 diabetes. In addition, coxsackievirus B, cytomegalovirus, adenovirus, and mumps have been implicated in inducing certain cases of diabetes.

Uncommon Forms of Immune-Mediated Diabetes

A severe form of insulin resistance has been reported in patients who developed high titers of antibodies that bind to the insulin receptor and block the action of insulin in its target tissues. As in other states of extreme insulin resistance, these patients often have acanthosis nigricans. In the past, this form of immune-mediated diabetes was termed type B insulin resistance. Most commonly these antibodies are of idiopathic origin, but they have also been described in monoclonal gamopathies and multiple myeloma and in patients with ataxia telangectasia syndrome.

Patients with POEMS, a syndrome of plasma cell dyscrasia associated with polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes, have an increased incidence of diabetes as well as other endocrine disorders. The cause of the diabetes in these patients has not been established.

CLINICAL FEATURES OF DIABETES MELLITUS

The principal clinical features of the two major types of diabetes mellitus are listed for comparison in Table 17–10.

Type 1 Diabetes

Patients with type 1 diabetes present with symptoms and signs related to hyperglycemia and hyperketonemia. The severity of the insulin deficiency and the acuteness with which the catabolic state develops determine the intensity of the osmotic and ketotic excess.

A. Symptoms   Increased urination is a consequence of osmotic diuresis secondary to sustained hyperglycemia. This results in a loss of glucose as well as free water and electrolytes in the urine. Nocturnal enuresis due to polyuria may signal the onset of

TABLE 17–10 Clinical features of diabetes at diagnosis.

	Diabetes Type 1	Diabetes Type 2
Polyuria and thirst	++	+
Weakness or fatigue	++	+
Polyphagia with weight loss	++	−
Recurrent blurred vision	+	++
Vulvovaginitis or pruritus	+	++
Peripheral neuropathy	+	++
Nocturnal enuresis	++	−
Often asymptomatic	−	++

diabetes in very young children. Thirst is a consequence of the hyperosmolar state, as is blurred vision, which often develops as the lenses and retinas are exposed to hyperosmolar fluids.

Weight loss, despite normal or increased appetite, is a common feature of type 1 diabetes when it develops subacutely over a period of weeks. The weight loss is initially due to depletion of water, glycogen, and triglyceride stores. Chronic weight loss due to reduced muscle mass occurs as amino acids are diverted to form glucose and ketone bodies.

Lowered plasma volume produces dizziness and weakness due to postural hypotension when sitting or standing. Total body potassium loss and the general catabolism of muscle protein contribute to the weakness.

Paresthesias may be present at the time of diagnosis of type 1 diabetes, particularly when the onset is subacute. They reflect a temporary dysfunction of peripheral sensory nerves and usually clear, as insulin replacement restores glycemic levels closer to normal; thus, their presence suggests neurotoxicity from sustained hyperglycemia.

When insulin deficiency is severe and of acute onset, the above symptoms progress in an accelerated manner. Ketoacidosis exacerbates the dehydration and hyperosmolality by producing anorexia, nausea, and vomiting, thus interfering with oral fluid replacement. As plasma osmolality exceeds 330 mOsm/kg (normal, 285-295 mOsm/kg), impaired consciousness ensues. With progression of acidosis to a pH of 7.1 or less, deep breathing with a rapid ventilatory rate (Kussmaul respiration) occurs as the body attempts to eliminate carbonic acid. With worsening acidosis (to pH 7.0 or less), the cardiovascular system may be unable to maintain compensatory vasoconstriction; severe circulatory collapse may result.

B. Signs   The patient's level of consciousness can vary depending on the degree of hyperosmolality. When insulin deficiency develops relatively slowly and sufficient water intake is maintained to permit renal excretion of glucose and appropriate dilution of extracellular sodium chloride concentration, patients remain relatively alert and physical findings may be minimal. When vomiting occurs in response to worsening ketoacidosis, dehydration progresses and compensatory mechanisms become inadequate to keep plasma osmolality below 330 mOsm/kg. Under these circumstances, stupor or even coma may occur. Evidence of dehydration

in a stuporous patient, with rapid deep breathing and the fruity breath odor of acetone, suggests the diagnosis of diabetic ketoacidosis.

Postural hypotension indicates a depleted plasma volume; hypotension in the recumbent position is a serious prognostic sign. Loss of subcutaneous fat and muscle wasting are features of more slowly developing insulin deficiency. In occasional patients with slow, insidious onset of insulin deficiency, subcutaneous fat may be considerably depleted. An enlarged liver, eruptive xanthomas on the flexor surface of the limbs and on the buttocks, and lipemia retinalis indicate that chronic insulin deficiency has resulted in chylomicronemia, with elevated circulating triglycerides, usually to over 2000 mg/dL (Chapter 19).

Type 2 Diabetes

Patients with type 2 diabetes usually have less severe insulin deficiency than type 1 patients and the symptoms and signs at presentation reflect this difference.

A. Symptoms   Many patients with type 2 diabetes have an insidious onset of hyperglycemia and may be relatively asymptomatic initially. The diagnosis may be made only after glycosuria or hyperglycemia is noted during routine laboratory studies. Chronic skin infections are common. Generalized pruritus and symptoms of candidal vaginitis are frequently the initial complaints of women with type 2 diabetes. Men may complain of an itchy rash of the prepuce. Some patients can remain undiagnosed for many years and the initial presentation may be due to complications such as visual disturbance due to retinopathy or foot pain or infection due to a peripheral neuropathy. Patients with a more severe insulin deficiency have the classical symptoms of polyuria, thirst, blurred vision, paresthesias, and fatigue. This is especially true in individuals who consume large amounts of carbohydrate-rich fluids in response to the thirst.

B. Signs   Many patients are obese or overweight. Even those patients who are not significantly overweight often have a characteristic fat distribution with more fat in the upper part of the body (particularly the abdomen, chest, neck, and face) and relatively less fat on the appendages, which may be quite muscular (the *metabolically obese*). This centripetal fat distribution has been termed **android** and is characterized by a high waist circumference. It differs from the more centrifugal **gynecoid** form of obesity, in which fat is localized more in the hips and thighs and less in the upper parts of the trunk. A larger waist circumference increases the risk for diabetes for any given BMI. Thus in patients with the metabolic syndrome, a waist circumference more than 40 in (102 cm) in men and more than 35 in (88 cm) in women is associated with an increased risk of diabetes. MRI and CT scans reveal that these patients with increased waist circumference have accumulation of fat in the omental and mesenteric distributions. This visceral fat correlates with insulin resistance, whereas fat predominantly in subcutaneous tissues of the abdomen has little, if any, association with insulin insensitivity.

Some patients, especially the obese, may have acanthosis nigricans—hyperpigmented, hyperkeratotic skin in the axilla, groin, and back of neck. This sign is associated with significant insulin resistance. Hypertension may be present especially in the obese patient. Eruptive xanthomata on the flexor surface of the limbs and on the buttocks and lipemia retinalis due to hyperchylomicronemia can occur in patients with uncontrolled type 2 diabetes who also have a familial form of hypertriglyceridemia. In women, candidal vaginitis with a reddened, inflamed vulvar area and a profuse whitish discharge may herald the presence of diabetes. In men, candidal infection of the penis may lead to reddish appearance of the penis and/or prepuce with eroded white papules and a white discharge. The occasional patient who has had undiagnosed diabetes for some time may present with retinopathy or peripheral neuropathy.

Patients can also present in hyperglycemic hyperosmolar coma—profoundly dehydrated, hypotensive, lethargic, or comatose without Kussmaul respirations.

Laboratory Testing in Diabetes Mellitus

Tests of urine glucose and ketone bodies, as well as whole blood or plasma glucose measured in samples obtained under basal conditions and after glucose administration, are very important in evaluation of the patient with diabetes. Tests for glycosylated hemoglobin have proved useful in both initial evaluation and in assessment of the effectiveness of therapeutic management. In certain circumstances, measurements of insulin or C-peptide levels and levels of other hormones involved in carbohydrate homeostasis (eg, glucagon, GH) may be useful. In view of the increased risk of atherosclerosis in patients with diabetes, determination of serum total cholesterol, HDL-cholesterol, triglycerides, and LDL-cholesterol may be helpful.

Urine Glucose

Several problems are associated with using urine glucose as an index of blood glucose, regardless of the method employed. First of all, the glucose concentration in bladder urine reflects the blood glucose at the time the urine was formed. Therefore, the first voided specimen in the morning contains glucose that was excreted throughout the night and does not reflect the morning blood glucose at all. Some improvement in the correlation of urine glucose to blood glucose can be obtained if the patient *double voids*—that is, empties the bladder completely, discards that sample, and then urinates again about one-half hour later, testing only the second specimen for glucose content. However, difficulty in completely emptying the bladder (large residual volumes), problems in understanding the instructions, and the inconvenience impair the usefulness of this test. Self-monitoring of blood glucose has replaced urine glucose testing in most patients with diabetes (particularly those receiving insulin therapy).

Several commercial products are available for determining the presence and amount of glucose in urine. The older and more cumbersome bedside assessment of glycosuria with Clinitest tablets has generally been replaced by the dipstick method, which is rapid, convenient, and glucose specific. This method consists of paper strips (Clinistix, Tes-Tape) impregnated with enzymes (glucose oxidase and hydrogen peroxidase) and a chromogenic dye that is colorless in the reduced state. Enzymatic generation of hydrogen peroxide oxidizes the dye to produce colors whose intensity depends on the glucose concentration. These dipsticks are sensitive to as little as 0.1% glucose (100 mg/dL) but do not react with the smaller amounts of glucose normally present in nondiabetic urine. The strips are subject to deterioration if exposed to air, moisture, and extreme heat and must be kept in tightly closed containers except when in use. False-negative results may be obtained in the presence of alkaptonuria and when certain substances such as salicylic acid or ascorbic acid are ingested in excess. All these false-negative results occur because of the interference of strong reducing agents with oxidation of the chromogen.

Although glycosuria reflects hyperglycemia in more than 90% of patients, two major classes of nondiabetic glycosuria must be considered:

A. Alterations in renal handing of glucose Disorders associated with abnormalities in renal glucose handling include Fanconi syndrome, a group of disorders characterized by combined renal wasting of multiple solutes including amino acids, uric acid, phosphate, and bicarbonate as well as glucose and caused by both genetic and acquired defects of the proximal renal tubule. Familial renal glycosuria, a benign inherited disorder manifest only by persistent glycosuria in the setting of euglycemia is caused by mutations in SGLT2, the sodium-glucose cotransporter responsible for the bulk of glucose reabsorption in the proximal tubule.

In addition, glycosuria is relatively common in pregnancy as a consequence of the increased load of glucose presented to the tubules by the elevated glomerular filtration rate during pregnancy. As many as 50% of pregnant women normally have demonstrable sugar in the urine, especially after the first trimester.

B. Excretion of sugars other than glucose in the urine Occasionally, a sugar other than glucose is excreted in the urine. Lactosuria during the late stages of pregnancy and the period of lactation is the most common example. Much rarer are other conditions in which inborn errors of metabolism allow fructose, galactose, or a pentose (1-xylose) to be excreted in the urine. Testing the urine with glucose-specific strips helps differentiate true glucosuria from other glycosurias.

Microalbuminuria and Proteinuria

Urinary albumin can now be detected in microgram concentrations using high-performance liquid chromatography or immunoassay methodology that is more sensitive than previous available tests. Conventional 24-hour urine collections, in addition to being inconvenient for patients, also show wide variability of albumin excretion, because several factors such as sustained upright posture, dietary protein, and exercise tend to increase albumin excretion rates. For these reasons, it is preferable to measure the albumin-creatinine ratio in an early morning spot urine collected

on awakening—prior to breakfast or exercise—and brought in by the patient for laboratory analysis. A ratio of albumin (μg/L) to creatinine (mg/L) of less than 30 is normal, and a ratio of 30 to 300 indicates abnormal microalbuminuria. Values greater than 300 are referred to as macroalbuminuria.

The minimal detection limit of protein on a standard urine dipstick is 10 to 20 mg/dL. If the dipstick is positive then it is likely that the patient has microalbuminuria and this should be specifically tested. The information from a spot urine sample is adequate for diagnosis and treatment and it is not usually necessary to perform a 24-hour urine collection for protein loss and creatinine clearance.

Blood Glucose Testing

A. Venous blood samples in the laboratory
Venous glucose samples should be collected in tubes containing sodium fluoride, which inhibits enolase and prevents glycolysis in the blood sample that would artifactually lower the measured glucose level. In the absence of fluoride, the rate of disappearance of glucose in the presence of blood cells has been reported to average 10 mg/dL/h—the rate increases with glucose concentration, temperature, and white blood cell count. Fluoride takes about 1 hour to effectively stop glycolysis. Therefore, the rate of decline during the first hour is the same in tubes with or without fluoride. A very high white blood cell count will lower glucose levels even in the presence of fluoride. Ideally the blood should be collected in a sodium fluoride/potassium oxalate tube, placed on ice and the plasma separated from the cells within 60 minutes.

Plasma or serum from venous blood samples has the advantage over whole blood of providing values for glucose that are independent of hematocrit and reflect levels in the interstitial spaces to which body tissues are exposed. For these reasons—and because plasma and serum lend themselves to automated analytic procedures—they are used in most laboratories. The glucose concentration is 10% to 15% higher in plasma or serum than in whole blood because structural components of blood cells are absent. Whole blood glucose determinations are seldom used in clinical laboratories, but are used by patients using home blood glucose monitors.

Glucose levels can be measured in the laboratory using enzymatic methods (such as glucose oxidase or hexokinase), condensation methods (such as *o*-toluidine), or reducing methods. The reducing methods take advantage of the reducing properties of glucose to change the redox state of a metal ion; however, the method is nonspecific and any strong reducing agent can cross-react to yield spuriously elevated glucose values. In condensation methods, the aldehyde group of glucose undergoes condensation with aromatic compounds to yield a colored product. In the most commonly used condensation reaction, *o*-toluidine reacts with glucose to form a glucosamine that has an intense green color. The color is measured spectrophotometrically to estimate the glucose concentration. *o*-Toluidine, however, has the drawback of being highly corrosive and toxic. In the enzymatic method, glucose oxidase reacts with glucose, water, and oxygen to form gluconic acid and hydrogen peroxide. The hydrogen peroxide can then be used

TABLE 17–11 Criteria for the diagnosis of diabetes.

	Normal Glucose Tolerance	Prediabetes	Diabetes Mellitus[a]
Fasting plasma glucose mg/dL(mmol/L)[b]	<100 (5.6)	100-125 (5.6-6.9) (impaired fasting glucose)	≥126 (7.0)
2 h after glucose load mg/dL (mmol/L)[c]	<140 (7.8)	≥140-199 (7.8-11.0) (impaired glucose tolerance)	≥200 (11.1)
HbA$_{1c}$ (%)[a]	<5.7	5.7-6.4	≥6.5
Symptoms and random glucose level (mg/dL)	–	–	≥200

[a]A fasting plasma glucose or HbA$_{1c}$ is diagnostic of diabetes if confirmed by repeat testing. HbA$_{1c}$ test should be performed using an assay certified by the National Glycohemoglobin Standardization program and standardized to the DCCT assay.

[b]A fasting plasma glucose ≥126 mg/dL is diagnostic of diabetes if confirmed on a subsequent day to be in the diabetic range after an overnight fast.

[c]Give 75 g of glucose dissolved in 300 mL of water after an overnight fast in subjects who have been receiving at least 150 to 200 g of carbohydrate daily for 3 days before the test. In the absence of unequivocal hyperglycemia, the result should be confirmed by repeat testing.

to oxidize a chromogen or the consumption of oxygen measured to estimate the amount of glucose present. Current laboratories use enzymatic methods to determine glucose levels.

The range of normal fasting plasma or serum glucose is 70 to 100 mg/dL (3.9-5.5 mmol/L). A plasma glucose level of 126 mg/dL (7.0 mmol/L) or higher on more than one occasion after at least 8 hours of fasting is diagnostic of diabetes mellitus (Table 17–11). Fasting plasma glucose levels of 100 mg/dL (5.6 mmol/L) to 125 mg/dL (6.9 mmol/L) are associated with increased risk for diabetes (impaired fasting glucose).

B. Self monitoring of blood glucose
Capillary blood glucose measurements performed by patients themselves, as outpatients, are extremely useful. In type 1 patients in whom tight metabolic control is attempted, they are indispensable. There are several paper strip (glucose oxidase; hexokinase; glucose dehydrogenase with nicotinamide adenine dinucleotide, glucose dehydrogenase with flavin-adenine dinucleotide, glucose dehydrogenase with pyrroloquinoline quinine) methods for measuring glucose on capillary blood samples. A reflectance photometer or an amperometric system is then used to measure the reaction that takes place on the reagent strip. A large number of blood glucose meters are now available. All are accurate, but they vary with regard to speed, convenience, size of blood samples required, and cost. Popular models include those manufactured by Life-Scan (One Touch), Bayer Corporation (Breeze, Contour), Roche Diagnostics (Accu-Chek), and Abbott Laboratories (Precision, FreeStyle). Various glucometers appeal to a particular consumer need and are relatively inexpensive, ranging from $50.00 to $100.00 (U.S.) each. Test strips remain a major expense, costing $0.25 to $1.50 (U.S.) each.

The meters have memories and can compute blood glucose averages. The data can be downloaded into a computer. Some meters are designed to communicate with a specific insulin pump. Contour Next Link meter, for example, communicates with the MiniMed Medtronic pump. In self-monitoring of blood glucose, patients must prick a finger with 26- to 33-gauge lancets. This can be facilitated by a small plastic trigger device such as an Accu-Chek multiclix (Roche Diagnostics), Microlet (Boehringer-Mannheim), or one touch lancing device (Lifescan, Inc.).

The clinician should be aware of the limitations of the self-glucose monitoring systems. The strips have limited lifespans and improper storage (high temperature; open vial) can affect their function. Patients should also be advised not to use expired strips. Some of the older meters require input of a code for each batch of strips and failure to enter the code can result in misleading results. Most meters no longer require this step. Increases or decreases in hematocrit can decrease or increase the measured glucose values, respectively. The mechanism underlying this effect is not known, but presumably it is due to the impact of red cells on the diffusion of plasma into the reagent layer. Meters and the test strips are calibrated over glucose concentrations ranging from 60 to 160 mg/dL, and the accuracy is not as good for higher and lower glucose levels. Thus, when the glucose is less than 60 mg/dL, the difference between the meter and the laboratory value may be as much as 20%. Glucose-oxidase-based amperometric systems underestimate glucose levels in the presence of high oxygen tension. This may be important in critically ill patients who are on supplemental oxygen, and under these circumstances, a glucose dehydrogenase-based system may be preferable. Glucose-dehydrogenase pyrroloquinoline quinone (GDH-PQQ) systems may report falsely high glucose levels in patients who are receiving parenteral products containing nonglucose sugars such as maltose, galactose, or xylose or their metabolites. Some meters have been approved for measuring glucose in blood samples obtained at alternative sites such as the forearm and thigh. There is, however, a 5- to 20-minute lag in the glucose response on the arm with respect to the glucose response on the finger. Forearm blood glucose measurements could therefore result in a delay in detection of rapidly developing hypoglycemia. Impaired circulation to the fingers (for example, in patients with Raynaud's disease) will artificially lower finger-stick glucose measurements (pseudohypoglycemia). The accuracy of data obtained by glucose monitoring requires education of the patient in sampling and measuring procedures as well as in proper calibration of the instruments. Bedside glucose monitoring in a hospital setting requires rigorous quality control programs and certification of personnel to avoid errors.

Continuous Glucose Monitoring Systems

A number of continuous glucose monitoring (CGM) systems are currently available for clinical use. The systems manufactured by Medtronic MiniMed, DexCom, Abbott Diagnostics involve inserting a subcutaneous biosensor (rather like an insulin pump cannula) that measures glucose concentrations in the interstitial fluid for 3 to 14 days. The glucose values are available for review by the patient at time of measurement. The systems differ in how the glucose data are displayed. The MiniMed system can only be used in conjunction with the MiniMed pump and the glucose data are displayed on the screen of the pump. The DexCom system wirelessly transmits glucose data to a separate pager-like device with a screen. The DexCom system also has the option of having the data appear on smart phones or smart watches or on the screens of several insulin pumps. The FreeStyle Libre (Abbott Diagnostics) sensor system requires the patient to hold a reading device close to the sensor patch for about a second to see the real time glucose value. The MiniMed and DexCom systems also display directional arrows indicating rate and direction of change and alarms can be set for dangerously low or high glucose values. Patients still have to calibrate the MiniMed and DexCom devices with periodic fingerstick glucose levels, and since there are concerns regarding reliability, it is still necessary to confirm the displayed glucose level with a fingerstick glucose before making interventions such as injecting extra insulin or eating extra carbohydrates. The FreeStyle Libre system does not require calibration and glucose readings are available 1 hour after insertion of sensors. The glucose data can be downloaded into computers for review by patients and their medical providers.

A 6-month randomized controlled study of type 1 patients showed that adults (25 years and older) using these systems had improved glycemic control without an increase in the incidence of hypoglycemia. A randomized controlled study of CGM during pregnancy showed improved glycemic control in the third trimester, lower birth weight, and reduced risk of macrosomia. The individual glucose values are not that critical—what matters is the direction and the rate at which the glucose is changing, allowing the user to take corrective action. The wearer also gains insight into the way particular foods and activities affect their glucose levels. The other main benefit is the low glucose alert warning. The MiniMed insulin pump can be programmed to automatically suspend insulin delivery for up to 2 hours when the glucose levels on its CGM device falls to a preset level and the patient does not respond to the alert. This insulin suspension feature has been shown to reduce the amount of time patients are in the hypoglycemic range at night. Many of these systems are covered by insurance. The initial cost is about $800 to $1000, and the sensor, which has to be changed every 3 to 14 days, costs $35 to $77; the out-of-pocket expense is about $4000 annually.

There is great interest in using the data obtained from these CGM systems to automatically deliver insulin by continuous subcutaneous insulin infusion pump. Algorithms have been devised to link CGM to insulin delivery. These closed loop systems (artificial pancreas) have been shown in short-term clinical studies to improve night time glucose control and reduce the risk of nocturnal hypoglycemia. The first of these closed loop systems (MiniMed system) has been approved for clinical use. With this system, the continuous glucose monitor readings are used to automatically adjust basal insulin rates by the insulin pump.

Urine and Serum Ketone Determinations

In the absence of adequate insulin, three major ketone bodies are formed and excreted into the urine: β-hydroxybutyrate (often the

most prevalent in diabetic ketoacidosis), acetoacetate, and acetone. Acetone and acetoacetate react with sodium nitroprusside (nitroferricyanide) in the presence of alkali to produce a purple-colored complex. Ketone test strips (ketostix; Keto-Diastix) utilize this nitroprusside reaction to quantify acetone and acetoacetate levels in urine and plasma. A strongly positive reaction in undiluted serum correlates with a serum ketone concentration of at least 4 mmol/L. Although these tests do not detect β-hydroxybutyric acid, which lacks a ketone group, the semiquantitative estimation of the other ketone bodies is nonetheless usually adequate for clinical assessment of ketonuria. Ketostix and Keto-Diastix have short shelf-lives (90 days) once the containers are opened and using expired strips can give false-negative results. It is better therefore to buy individually foil wrapped strips.

Many laboratories measure β-hydroxybutyrate levels and there are meters available (Precision Xtra, Nova Max Plus) for patients to measure β-hydroxybutyrate levels on capillary glucose samples. This technology uses hydroxybutyrate dehydrogenase to catalyse the oxidation of β-hydroxybutyrate to acetoacetate with concomitant reduction of NAD^+ to NADH. The NADH is reoxidized to NAD^+ by a redox mediator and a current is generated that is directly proportional to β-hydroxybutyrate concentration. β-Hydroxybutyrate levels more than 0.6 nmol/L require evaluation. Levels more than 3.0 nmol/L, which is equivalent to very large urine ketones, will require hospitalization.

Other conditions besides diabetic ketoacidosis may cause ketone bodies to appear in the urine; these include starvation, high-fat diets, alcoholic ketoacidosis, fever, and other conditions in which metabolic requirements are increased.

Glycated Hemoglobin Assays

Ketoamine reactions between glucose and other sugars and free amino groups on the alpha and beta chain lead to glycated forms of hemoglobin. Only glycation of the *N*-terminal valine of the beta chain imparts sufficient negative charge to the hemoglobin molecule to allow separation by charge-dependent techniques. The charge-separated hemoglobins are collectively referred to as hemoglobin A_1 (HbA_1). The major form of HbA_1 is hemoglobin A_{1c} (HbA_{1c}), where glucose is the carbohydrate. This form comprises 4% to 6% of total hemoglobin A. The remaining HbA_1 species contain fructose 1,6-diphosphate (HbA_{1a1}), glucose 6-phosphate (HbA_{1a2}), and an unknown carbohydrate moiety (HbA_{1b}). The hemoglobin A_{1c} fraction is abnormally elevated in diabetic patients with chronic hyperglycemia. Some laboratories measure the sum of these glycohemoglobins (GHbs) and report the total as hemoglobin A_1, but most laboratories have converted to the highly specific HbA_{1c} assay. Methods for measuring HbA_{1c} include electrophoresis, cation exchange chromatography, boronate affinity chromatography, and immunoassays Office-based immunoassays using capillary blood give a result in about 9 minutes, and this allows for immediate feedback to the patients regarding their glycemic control.

The red cell lifespan is about 120 days and so HbA_{1c} levels reflect glucose levels in the preceding 8 to 12 weeks. The value, however, is weighted to more recent glucose levels (previous month)

and this explains why significant changes in HbA_{1c} are observed with short-term (1 month) changes in mean plasma glucose levels. Measurements should be made in patients with either type of diabetes mellitus at 3- to 4-month intervals so that adjustments in therapy can be made if GHb is either subnormal or if it is more than 1% above the upper limits of normal for a particular laboratory. In patients monitoring their own blood glucose levels, GHb values provide a valuable check on the accuracy of monitoring. In patients who do not monitor their own blood glucose levels, GHb values are essential for adjusting therapy.

The various HbA_{1c} assays have been standardized to the assay used in the Diabetes Control and Complications Trial (DCCT) allowing the results to be related to the risks of developing microvascular complications. There is a linear relationship between the HbA_{1c} value and average glucose. The A_{1c}-Derived Average Glucose Study collected 3 months of blood glucose data on 507 subjects—normals, type 1 and type 2 diabetics. The estimated average glucose was calculated by combining weighted results from 2 days of CGM per month and seven point capillary blood glucose profiles (preprandial, postprandial, and bedtime) for at least 3 days/wk. The HbA_{1c} was measured at the end of the 3 months. The relationship between average glucose and HbA_{1c} based on linear regression analysis was Average glucose = (28.7 × HbA_{1c}) – 46.7. There is, however, substantial intra-individual variability. For HbA_{1c} values between 6.9% and 7.1%, the glucose levels ranged from 125 to 205 mg/dL (6.9-11.4 mmol/L; 95% CIs). For HbA_{1c} of 6%, the mean glucose levels ranged from 100 to 152 mg/dL (5.5-8.5 mmol/L); and for 8% they ranged from 147 to 217 mg/dL (8.1-12.1 mmol/L).

The accuracy of HbA_{1c} values can be affected by hemoglobin variants or derivatives, the effect depending on the specific hemoglobin variant or derivative and the specific assay used. Immunoassays that use an antibody to the glycated amino terminus of β globin do not recognize the terminus of the γ globin of hemoglobin F, and so in patients with high levels of hemoglobin F, immunoassays give falsely low estimates of HbA_{1c}. Cation exchange chromatography separates hemoglobin species by charge differences. Therefore, hemoglobin variants that coelute with HbA_{1c} can lead to an overestimation of the HbA_{1c} value. Chemically modified derivatives of hemoglobin such as carbamylated (in renal failure) or acetylated (high-dose aspirin therapy) hemoglobin can, in some methods, coelute with HbA_{1c}. Since many hemoglobin variants do not have a clinical phenotype, they should be considered if there is discordance between home blood glucose and HbA_{1c} measurements. The National Glycohemoglobin Standardization Program website (www.ngsp.org) has information on the impact of frequently encountered hemoglobin variants and traits on the results obtained with the commonly used HbA_{1c} assays.

Any condition that shortens erythrocyte survival or decreases mean erythrocyte age (eg, recovery from acute blood loss, hemolytic anemia) falsely lower HbA_{1c} irrespective of the assay method used. Alternative methods such as fructosamine (discussed later) should be considered for these patients. Vitamins C and E are reported to falsely lower test results, possibly by inhibiting glycation of hemoglobin. The American Diabetes Association (ADA)

has now endorsed using the HbA$_{1c}$ as a diagnostic test for diabetes (see Table 17–11). A cutoff value of 6.5% was chosen because the risk for retinopathy increases substantially above this value. The advantages of using the HbA$_{1c}$ to diagnose diabetes is that there is no need to fast; it has lower intra-individual variability than the fasting glucose test and the oral glucose tolerance test; and it gives a better picture of glucose control for 2 to 3 months. People with HbA$_{1c}$ levels of 5.7 % to 6.4% should be considered at high risk for developing diabetes (prediabetes). The diagnosis should be confirmed with a repeat HbA$_{1c}$ test, unless the patient is symptomatic with plasma glucose levels more than 200 mg/dL. This test would not be appropriate to use in populations with high prevalence of hemoglobinopathies or in conditions with increased red cell turnover. Also, the testing should be performed using a National Glycohemoglobin Standardization Program certified method and standardized to the Diabetes Control and Complications Trial assay. In the Europeon Union, the tests are standardized to the International Federation of Clinical Chemistry (IFCC) which defines HbA$_{1c}$ as mmol glycated hexapeptide per mol (glycated and nonglycated hexapeptides) and reported as mmol HbA$_{1c}$/mol Hb. The conversion factor for NGSP and IFCC results is: NGSP (USA) result = (0.09148 × IFCC result) + 2.152. Officially there is worldwide consensus that HbA$_{1c}$ should be reported in both NGSP (%) and IFCC (mmol/mol) units.

Serum Fructosamine

Serum fructosamine is formed by nonenzymatic glycosylation of serum proteins (predominantly albumin). Because serum albumin has a much shorter half-life (14-21 days) than hemoglobin, serum fructosamine generally reflects the state of glycemic control for the preceding 2 or 3 weeks. Reductions in serum albumin (eg, nephrotic state or hepatic disease) lower the serum fructosamine value. When abnormal hemoglobins or hemolytic states affect the interpretation of GHb or when a narrower time frame is required, such as for ascertaining glycemic control at the time of conception in a woman with diabetes who has recently become pregnant, serum fructosamine assays offer some advantage. Normal values vary in relation to the serum albumin concentration and are 200 to 285 umol/L when the serum albumin level is 5 g/dL. HbA$_{1c}$ values and fructosamine are highly correlated.

Thus fructosamine levels of 300, 367, and 430 approximate to HbA$_{1c}$ values of 7%, 8%, and 9%, respectively but there is substantial individual variability and caution should be exercised in estimating the likely HbA$_{1c}$ value from the fructosamine measurement.

In most circumstances, glycohemoglobin assays remain the preferred method for assessing long-term glycemic control in patients with diabetes.

Oral Glucose Tolerance Test

It is easy to screen for diabetes using an HbA$_{1c}$ or a fasting plasma glucose level (see Table 17–11). The oral glucose tolerance test, therefore, is mostly performed for research studies or when there is a suspicion of the diagnosis but the fasting plasma glucose is less than 126 mg/dL or the HBA$_{1c}$ level is below 6.5%. The test might

be considered, for example, in a woman with a history of delivering an infant above 9 lb (4.1 kg).

In order to optimize insulin secretion and effectiveness, especially when patients have been on a low-carbohydrate diet, a minimum of 150 to 200 g of carbohydrate per day should be included in the diet for 3 days preceding the test. The patient should eat nothing after midnight prior to the test day. Adults are given 75 g of glucose in 300 mL of water; children are given 1.75 g of glucose per kilogram of ideal body weight. The glucose load is consumed within 5 minutes. The test should be performed in the morning because there is some diurnal variation in oral glucose tolerance and patients should not smoke; drink coffee, tea, or alcohol; or be active during the test.

Blood samples for plasma glucose are obtained at 0 and 120 minutes after ingestion of glucose. A fasting plasma glucose value of 126 mg/dL (7 mmol/L) or higher or a 2-hour value of greater than 200 mg/dL (11.1 mmol/L) is diagnostic of diabetes mellitus (see Table 17–11). An oral glucose tolerance test is normal if the fasting venous plasma glucose value is less than 100 mg/dL (5.6 mmol/L) and the 2-hour value falls below 140 mg/dL (7.8 mmol/L). Patients with 2-hour values of 140 to 199 mg/dL have impaired glucose tolerance. False-positive results may occur in patients who are malnourished at test time, bedridden, or afflicted with an infection or severe emotional stress. Diuretics, oral contraceptives, glucocorticoids, excess thyroxine, phenytoin, nicotinic acid, and some of the psychotropic drugs may also cause false-positive results.

Insulin Levels

Normal immunoreactive insulin levels range from 5 to 20 μU/mL in the fasting state. During an oral glucose tolerance test, they reach 50 to 130 μU/mL at 1 hour, and usually return to levels below 30 μU/mL by 2 hours. Insulin measurements are rarely of clinical usefulness. They are principally used in research studies to determine insulin sensitivity.

The homeostasis model of insulin resistance (HOMA$_{IR}$) estimates insulin sensitivity using the following formula:

$$\text{HOMA}_{IR} \text{ (mmol/L} \times \mu\text{U/mL)} = \text{(fasting glucose [mmol/L]} \times \text{fasting insulin [μU/mL])}/22.5$$

The higher the HOMA$_{IR}$ value the more resistant the individual. Data from the oral glucose tolerance test can also be used to estimate insulin sensitivity. The Matsuda & DeFronzo Insulin Sensitivity Index is calculated as:

$$\text{Insulin sensitivity index (ISI)}$$
$$= 10,000/\text{square root of [fasting glucose} \times \text{fasting insulin]} \times \text{[mean glucose} \times \text{mean insulin during OGTT]}$$

The lower the ISI the more insulin resistant the subject.

Intravenous Glucose Tolerance Test

The intravenous glucose tolerance test (IVGTT) is performed by giving a bolus of 50 g of glucose per 1.7 m^2 body surface area

(or 0.5 g/kg of ideal body weight) as a 25% or 50% solution over 2 to 3 minutes after an overnight fast. Timing begins with injection and samples for plasma glucose determination are obtained from an indwelling needle in the opposite arm at 0, 10, 15, 20, and 30 minutes. The plasma glucose values are plotted on semilogarithmic paper against time. K, a rate constant that reflects the rate of fall of blood glucose in percent per minute, is calculated by determining the time necessary for the glucose concentration to fall by one-half ($t_{1/2}$) and using the following equation:

$$K(\text{glucose}) = \frac{0.693}{t_{1/2}} \times 100$$

The average K value for a nondiabetic patient is approximately 1.72% per minute; this value declines with age but remains above 1.3% per minute. Patients with diabetes almost always have a K value of less than 1% per minute. The disappearance rate reflects the patient's ability to dispose of a glucose load. Perhaps its most widespread present use is to screen siblings at risk for type 1 diabetes to determine if autoimmune destruction of β cells has reduced first phase insulin responses (at 1-5 minutes after the glucose bolus) to levels below the normal lower limit of 40 μU/mL.

The IVGTT has been modified by giving a glucose dose of 0.3 g/kg, with more frequent plasma sampling and extending the test to 3 to 4 hours. Also at 20 minutes, a 5-minute infusion of insulin is given (0.03 U/kg for the subject who is likely to be insulin sensitive and 0.06 U/kg for the likely resistant subject). Plasma glucose is sampled at 3, 4, 5, 6, 8, 10, 14, 19, 22, 25, 27, 30, 40, 50, 60, 80, 100, 140, and 180 minutes. Analysis of the time course of glucose and insulin during this frequently sampled IVGTT (FSIVGTT) allows for measurements of insulin sensitivity (S_i), that is, fractional glucose clearance per unit insulin concentration; the first phase insulin response ($AIR_{glucose}$); and glucose effectiveness (S_G), the ability of glucose itself to enhance its own disappearance independent of any change in insulin. The data analysis requires use of specific software (Minmod).

Lipoproteins in Diabetes

Levels of circulating lipoproteins are dependent on normal levels and action of insulin, just as is the plasma glucose. In type 1 diabetes, moderately deficient control of hyperglycemia is associated with only a slight elevation of low-density lipoprotein (LDL) cholesterol and serum triglycerides and little if any changes in HDL cholesterol. Once the hyperglycemia is corrected, lipoprotein levels are generally normal. However, patients with type 2 diabetes frequently have a dyslipidemia that is characteristic of the insulin resistance syndrome. Its features are a high serum triglyceride level (300-400 mg/dL), a low HDL cholesterol (<30 mg/dL), and a qualitative change in LDL particles producing a smaller dense LDL whose membrane carries supranormal amounts of free cholesterol. Because *low* HDL cholesterol is a major feature predisposing to macrovascular disease, the term *dyslipidemia* has preempted the previous label of *hyperlipidemia*, which mainly described the elevated triglycerides. Measures designed to correct obesity and hyperglycemia, such as exercise, diet, and

hypoglycemic therapy substantially correct the dyslipidemia but most patients require pharmacotherapy. Chapter 19 discusses these matters in detail.

Clinical Trials in Diabetes

Findings of the Diabetes Control and Complications Trial (DCCT) and of the United Kingdom Prospective Diabetes Study (UKPDS) have confirmed the beneficial effects of intensive therapy to achieve improved glycemic control in both type 1 and type 2 diabetes, respectively.

A. The Diabetes Control and Complications Trial (DCCT),

a long-term therapeutic study involving 1441 patients with type 1 diabetes mellitus, reported that "near" normalization of blood glucose resulted in a delay in the onset and a major slowing of the progression of established microvascular and neuropathic complications of diabetes during a follow-up period of up to 10 years. Multiple daily insulin injections (66%) or insulin pumps (34%) were used in the intensively treated group whereas the conventionally treated group used no more than two injections daily. The intensive group achieved a mean HbA_{1c} of 7.2% (normal: <6%) and a mean blood glucose of 155 mg/dL (8.6 mmol/L) while the conventionally treated group averaged an HbA_{1c} of 8.9% and mean blood glucose of 225 mg/dL (12.5 mmol/L). Over mean follow-up of 7 years, there was an approximately 60% reduction in risk between the two groups in regard to diabetic retinopathy, nephropathy, and neuropathy. The intensively treated group also had a nonsignificant reduction in the risk of macrovascular disease of 41% (95% CI, −10 to 68). Intensively treated patients had a threefold greater risk of serious hypoglycemia as well as a greater tendency toward weight gain. However, there were no deaths definitely attributable to hypoglycemia in any persons in the DCCT study, and no evidence of posthypoglycemic cognitive damage was detected.

Subjects participating in the DCCT study were subsequently enrolled in a follow-up observational study (Epidemiology of Diabetes Interventions and Complications [EDIC]). Even though the between group differences in HbA_{1c} narrowed within 4 years, the group assigned to intensive therapy had a lower risk for retinopathy at 4 years and microalbuminuria at 7 to 8 years of post study follow-up. Moreover, by the end of the 11 year follow-up period, the intensive therapy group had significantly reduced risk of any cardiovascular disease events by 42% (95% CI, 9%-23%; $p = 0.02$). Thus it seems that the benefits of good glucose control persist even if control deteriorates at a later date.

The general consensus of the ADA is that intensive insulin therapy associated with comprehensive self-management training should become standard therapy in most patients with type 1 diabetes after the age of puberty. Exceptions include those with advanced renal disease and the elderly, because the detrimental risks of hypoglycemia outweigh the benefit of tight glycemic control in these groups. In children under age 7 years, the risk of developing brain damage from hypoglycemia contraindicates attempts at tight glycemic control, particularly because diabetic complications do not seem to occur until some years after the onset of puberty.

B. The United Kingdom Prospective Diabetes Study (UKPDS) was a multicenter study designed to determine whether the risk of macrovascular or microvascular complications in patients with type 2 diabetes could be reduced by intensive blood glucose control with oral hypoglycemic agents or insulin and whether any particular therapy was better than the others. Patients aged 25 to 65 years who were newly diagnosed with type 2 diabetes were recruited between 1977 and 1991, and a total of 3867 were studied over 10 years. The median age at baseline was 54 years; 44% were overweight (>20% over ideal weight), and baseline HbA_{1c} was 9.1%. Therapies were randomized to include a control group on diet alone and separate groups intensively treated with insulin, chlorpropamide, glyburide, or glipizide. Metformin was included as a randomization option in a subgroup of 342 overweight patients, and—much later in the study—an additional subgroup of both normal-weight and overweight patients, who were responding unsatisfactorily to sulfonylurea therapy, were randomized to either continue on their sulfonylurea therapy alone or to have metformin combined with it.

After the study was initiated, a further modification was made to evaluate whether tight control of blood pressure with stepwise antihypertensive therapy would prevent macrovascular and microvascular complications in 758 hypertensive patients among this UKPDS population—compared with 390 patients whose blood pressure was treated less intensively. The tight control group was randomly assigned to treatment with either an angiotensin-converting enzyme (ACE) inhibitor (captopril) or a beta blocker (atenolol). Both drugs were stepped up to maximum doses of 100 mg/d, and then, if blood pressure remained higher than the target level of less than 150/85 mm Hg, more drugs were added in the following stepwise sequence—a diuretic, slow-release nifedipine, methyldopa, and prazosin—until the target level of tight control was achieved. In the control group, hypertension was conventionally treated to achieve target levels less than 180/105 mm Hg, but these patients were not given either ACE inhibitors or beta blockers.

Intensive glycemic therapy with either sulfonylureas, metformin, combinations of these, or insulin achieved mean HbA_{1c} levels of 7.0%. This level of glycemic control decreased the risk of microvascular complications in comparison with conventional therapy (mostly diet alone), which achieved mean levels of HbA_{1c} of 7.9%. Weight gain occurred in intensively treated patients except when metformin was used as monotherapy. There was a trend toward reduction in cardiovascular events (fatal or nonfatal MI; sudden death) with intensive treatment but this did not reach statistical significance (16% reduction, $p = 0.052$). Hypoglycemic reactions occurred in the intensive treatment groups, but only one death from hypoglycemia was documented over 27,000 patient years of intensive therapy.

Tight control of blood pressure (median value 144/82 mm Hg vs 154/87 mm Hg) substantially reduced the risk of microvascular disease and stroke but not myocardial infarction. The blood pressure lowering had substantially greater impact on microvascular outcomes than that achieved by lowering HbA_{1c} from 7.9% to 7%. More than half of the patients needed two or more drugs for adequate therapy of their hypertension, and there was no demonstrable advantage of ACE inhibitor therapy over beta blockers as regards diabetes endpoints. Use of a calcium channel blocker added to both treatment groups appeared to be safe over the long term in this population with diabetes, despite some controversy in the literature about its safety in such individuals.

The UKPDS researchers, like the DCCT group, performed posttrial monitoring to determine if there were long-term benefits of having been in the intensively treated glucose and blood pressure arms of the study. The between group differences in HbA_{1c} were lost within the first year of follow-up but the reduced risk of development or progression of microvascular complications in the intensively treated group persisted for 10 years (24%, $p = 0.001$). The intensively treated group also had significantly reduced risk for myocardial infarction (15%, $p = 0.01$) and death from any cause (13%, $p = 0.007$) during the follow-up period. The subgroup of overweight or obese subjects who were initially randomized to metformin therapy showed sustained reduction in risk of myocardial infarction and death from any cause in the follow-up period. The between group blood pressure differences disappeared within 2 years of the end of the trial. Unlike the sustained benefits seen with glucose control, there was no sustained benefit from having been in the more tightly controlled blood pressure group. Both blood pressure groups had similar risks for microvascular events and diabetes related endpoints in the follow-up period.

Thus, the follow-up of the UKPDS type 2 diabetes cohort showed that, as in type 1 diabetes, the benefits of good glucose control persist even if control deteriorates at a later date. Blood pressure benefits, however, last only as long as the blood pressure is well controlled.

C. Diabetes Prevention Program (DPP) was a randomized clinical trial in 3234 overweight men and women, aged 25 to 85 years, who showed impaired glucose tolerance. Results from this study indicated that intervention with a low-fat diet and 150 minutes of moderate exercise (equivalent to a brisk walk) per week reduces the risk of progression to type 2 diabetes by 58% as compared with a matched control group. Another arm of this trial demonstrated that use of 850 mg of metformin twice daily reduced the risk of developing type 2 diabetes by 31% but was relatively ineffective in those who were either less obese or in the older age group.

D. The Steno-2 Study This was designed in 1990 to validate the efficacy of targeting multiple concomitant risk factors for both microvascular and macrovascular disorders in type 2 diabetes. A prospective, randomized, open, blinded endpoint design was used in which 160 patients with type 2 diabetes and microalbuminuria were assigned to conventional therapy with their general practitioner or to intensive care at the Steno Diabetes Center. In the intensively treated group, stepwise introduction of lifestyle and pharmacologic interventions was aimed at keeping glycated hemoglobin less than 6.5%, blood pressure less than 130/80 mm Hg, total cholesterol less than 175 mg/dL, and triglycerides less than 150 mg/dL. All subjects in the intensively treated group received ACE inhibitors and if intolerant, an angiotensin II receptor blocker. The lifestyle component of intensive intervention

included reduction in dietary fat intake to less than 30% of total calories, a smoking cessation program, light to moderate exercise, and a daily vitamin-mineral supplement (vitamins C and E and chromium picolinate). Initially, aspirin was given as secondary prevention to patients with a history of ischemic cardiovascular disease, but later all patients received aspirin.

After a mean follow-up of 7.8 years, 44% of patients in the conventional arm and 24% in the intensive multifactorial arm developed cardiovascular events (myocardial infarction, angioplasties, coronary bypass grafts, strokes, amputations, vascular surgical interventions)—a 53% reduction. Rates of nephropathy, retinopathy, and autonomic neuropathy were also lower in the multifactorial intervention arm—61%, 58%, and 63% of rates in the conventional arm, respectively.

The subjects who participated in this trial were subsequently enrolled in an observational follow-up study for an average of 5.5 years. Even though the significant differences in glycemic control and levels of risk factors for cardiovascular disease between the groups had disappeared by the end of the follow-up period, the interventional group continued to have a lower risk for retinal photocoagulation, renal failure, cardiovascular endpoints, and cardiovascular mortality.

The data from the UKPDS and this study thus provide support for guidelines recommending vigorous treatment of concomitant microvascular and cardiovascular risk factors in patients with type 2 diabetes.

E. Accord, Advance, and VADT studies The ACCORD study was a randomized controlled study designed to determine whether normal HbA_{1c} levels would reduce the risk of cardiovascular events in middle-aged or older individuals with type 2 diabetes. About 35% of the 10,251 recruited subjects had established cardiovascular disease at study entry. The intensive arm of the study was discontinued after 3.5 years of follow-up because of more unexplained deaths in the intensive arm when compared to the conventional treatment arm (22%, $p = 0.020$). Analysis of the data at time of discontinuation showed that the intensively treated group (HbA_{1c} 6.4%) had a 10% reduction in cardiovascular event rate compared to the standard treated group (HbA_{1c} 7.5%), but this difference was not statistically significant. The ADVANCE trial randomly assigned 11,140 patients in their 60s with type 2 diabetes to standard or intensive glucose control. The primary outcomes were major macrovascular (nonfatal myocardial infarction or stroke or death from cardiovascular causes) or microvascular events. Thirty-two percent of the subjects had established cardiovascular disease at study entry. After a median follow-up of 5 years, there was a nonsignificant reduction (6%) in major macrovascular event rate in the intensively treated group (HbA_{1c} 6.5%) compared to the standard therapy group (HbA_{1c} 7.3%).

The Veteran Administration Diabetes Trial (VADT) randomly assigned 1791 patients in their 50s and 60s with type 2 diabetes to standard or intensive glucose control. Ninety-seven percent of the subjects were men. The primary outcome was a composite of myocardial infarction, death from cardiovascular causes, congestive heart failure, vascular surgery, inoperable coronary artery disease, and amputation for gangrene. All patients had optimized blood pressure and lipid levels. After a median follow-up of 5.6 years, there was no significant difference in the primary outcome in the intensively treated group (HbA_{1c} 6.9%) compared to the standard therapy (HbA_{1c} 8.4%). Within this larger study, there was an embedded study evaluating the impact of intensive therapy in patients who were categorized as having low, moderate, and high coronary calcium scores on CT scans. Patients with low coronary calcium score showed reduced number of cardiovascular events with intensive therapy.

Thus, the ACCORD, ADVANCE, and VADT results do not provide support for the hypothesis that near-normal glucose control in type 2 diabetes will reduce cardiovascular events. It is, however, important not to over-interpret the results of these three studies. The results do not exclude the possibility that cardiovascular benefits might accrue with longer duration of near-normal glucose control. In the UKPDS, risk reductions for myocardial infarction and death from any cause were only observed during 10 years of post-trial follow-up. Specific subgroups of type 2 diabetes patients may also have different outcomes. The ACCORD, ADVANCE, and VADT studies recruited patients who had diabetes for 8 to 10 years, and a third of them had established cardiovascular disease. Patients in the UKPDS, in contrast, had newly diagnosed diabetes, and only 7.5% had a history of macrovascular disease. It is possible that the benefits of tight glycemic control on macrovascular events are attenuated in patients with longer duration of diabetes or with established vascular disease. Specific therapies used to lower glucose may also affect cardiovascular event rate or mortality. Severe hypoglycemia occurred more frequently in the intensively treated groups of the ACCORD, ADVANCE, and VADT studies; and the ACCORD investigators were not able to exclude undiagnosed hypoglycemia as a potential cause for the increased death rate in their intensive arm group.

A formal meta-analysis performed on the raw trial data from the ACCORD, ADVANCE, VADT, and UKPDS studies found that allocation to more intensive glucose control reduced the risk of MI by 15% (hazard ratio 0.85, 95% CI 0.76-0.94). The benefit appeared to be in patients who did not have preexisting macrovascular disease.

TREATMENT OF DIABETES MELLITUS

Diet

A well-balanced, nutritious diet remains a fundamental element of therapy for diabetes. It is recommended that the macronutrient proportions (carbohydrate, protein, and fat) be individualized based on the patient's eating patterns, preferences and goals. Generally most patients with diabetes consume about 45% of their calories as carbohydrates; 25% to 35% fats; and 10% to 35% proteins. Limiting the carbohydrate intake and substituting some of the calories with monounsaturated fats, such as olive oil, rapeseed (canola) oil, or the oils in nuts and avocados, can lower triglycerides and increase HDL cholesterol. A Mediterranean-style eating pattern (a diet supplemented with walnuts, almonds, hazelnuts, and olive oil) has been shown to improve glycemic control and lower combined endpoints for cardiovascular events and

stroke. Caloric restriction and weight loss is an important goal for the obese patient with type 2 diabetes.

Patients with type 1 diabetes or type 2 diabetes on insulin should be taught *carbohydrate counting*, so they can administer their insulin bolus for each meal based on its carbohydrate content.

The current recommendations for saturated fats and dietary cholesterol intake for people with diabetes are the same as for the general population. Saturated fats should be limited to less than 10% of daily calories and dietary cholesterol intake should be less than 300 mg/d. For those patients with kidney disease, dietary protein should be maintained at the recommended daily allowance of 0.8 g/kg/d. Exchange lists for meal planning can be obtained from the American Diabetes Association and its affiliate associations or from the American Dietetic Association, 216 W. Jackson Blvd., Chicago, IL 60606 (312-899-0040 or http://www.eatright.org).

Special Considerations in Dietary Control

A. Dietary fiber   Plant components such as cellulose, gum, and pectin are indigestible by humans and are termed **dietary fiber**. Insoluble fibers such as cellulose or hemicellulose increase stool bulk and decrease transit time. Soluble fibers such as gums and pectins, found in beans, oatmeal, or apple skin, can delay glucose absorption and so diminish postprandial hyperglycemia. Although the ADA diet does not require insoluble fiber supplements such as added bran, it recommends foods such as oatmeal, cereals, and beans with relatively high soluble fiber content as stable components of the diet in patients with diabetes. High soluble fiber content in the diet may also have a favorable effect on blood cholesterol levels.

B. Glycemic index   Quantitation of the relative glycemic contribution of different carbohydrate foods has formed the basis of a **glycemic index** in which the area of blood glucose (plotted on a graph) generated over a 3-hour period following ingestion of a test food containing 50 g of carbohydrate is compared with the area plotted after giving a similar quantity of reference food such as glucose or white bread:

$$\frac{\text{Blood glucose area of test food}}{\text{Blood glucose area of reference food}} \times 100$$

White bread is preferred to glucose as a reference standard because it is more palatable and has less tendency to slow gastric emptying by high tonicity, as happens when glucose solution is used. Eating foods with low glycemic index will result in lower glucose levels after meals. Low glycemic index foods have values of 55 or less and include many fruits (apples, oranges) and vegetables, grainy breads, pasta, legumes, milk, and yoghurt. High glycemic index foods have values of 70 and over and include baked potato, white bread, and most white rice. Glycemic index is lowered by the presence of fats and protein when the food is consumed in a mixed meal. Cooking methods can also affect the glycemic index—thus mashed potatoes have a higher glycemic index than baked potato.

Since you have to have 50 g of available carbohydrate to measure the glycemic index, you cannot assign glycemic indices to foods which have very little carbohydrate. Even though it may not be possible to accurately predict the impact of the glycemic index of a particular food in the context of a meal, it is still reasonable to choose foods with low glycemic index.

C. Sweeteners   The nonnutritive sweetener **saccharin** is widely used as a sugar substitute (sweet and low). **Aspartame** (NutraSweet) consists of two major amino acids, aspartic acid, and phenylalanine, which combine to produce a nutritive sweetener 180 times as sweet as sucrose. A major limitation is its heat lability, which precludes its use in baking or cooking. Sucralose (Splenda) and acesulfame potassium (Sunett, Sweet One, DiabetiSweet) are two other nonnutritive sweeteners that are heat stable and can be used in cooking and baking.

Fructose represents a *natural* sugar substance that is a highly effective sweetener. It induces only slight increases in plasma glucose levels and does not require insulin for its utilization. However, because of potential adverse effects of large amounts of fructose (up to 20% of total calories) on raising serum cholesterol, triglycerides, and LDL cholesterol, it does not have any advantage as a sweetening agent in the diabetic diet. This does not preclude, however, ingestion of fructose-containing fruits and vegetables or fructose-sweetened foods in moderation.

Sugar alcohols, also known as polyols or polyalcohol, are commonly used as sweeteners and bulking agents. They occur naturally in a variety of fruits and vegetables but are also commercially made from sucrose, glucose, and starch. Examples are sorbitol, xylitol, mannitol, lactitol, isomalt, maltitol, and hydrogenated starch hydrolysates (HSH). They are not as easily absorbed as sugar, so they do not raise blood glucose levels as much as conventional sugars. Therefore, sugar alcohols are often used in food products that are labeled as *sugar free*, such as chewing gum, lozenges, hard candy, and sugar-free ice cream. However, if consumed in large quantities, they will raise blood glucose and can also cause bloating and diarrhea.

D. Fish oils and other oils   Omega-3 fatty acids in high doses have been shown to lower plasma triglycerides and VLDL cholesterol. They may also reduce platelet aggregation. In the Lyon Diet Heart Study in nondiabetic patients, a high intake of α-linolenic acid was beneficial in secondary prevention of coronary heart disease. This diet, which is rich in vegetables and fruits, also supplies a high intake of natural antioxidants. There is limited clinical information on the use of these oils in patients with diabetes.

AGENTS FOR THE TREATMENT OF HYPERGLYCEMIA

The drugs for treating type 2 diabetes (Table 17–12), other than insulin, fall into several categories. (1) **Drugs that act on the sulfonylurea receptor complex of the β cell**. Sulfonylureas remain the most widely prescribed drugs for treating hyperglycemia.

TABLE 17–12 Drugs for treatment of type 2 diabetes.

Drug	Tablet Size	Daily Dose	Duration of Action (h)
Sulfonylureas			
Acetohexamide (Dymelor)	250 and 500 mg	0.25-1.5 g as single dose or in two divided doses	8-24
Chlorpropamide (Diabinese)	100 and 250 mg	0.1-0.5 g as a single dose	24-72
Gliclazide (not available in United States)	80 mg	40-80 mg as single dose; 160-320 mg as divided dose	12
Glimepiride (Amaryl)	1, 2, and 4 mg	1-4 mg as single dose. 8 mg once a day is maximal dose	Up to 24
Glipizide			
(Glucotrol)	5 and 10 mg	2.5-40 mg as single dose or in two divided doses on an empty stomach	6-12
(Glucotrol XL)	2.5, 5, and 10 mg	Up to 20 mg daily as a single dose	Up to 24
Glyburide			
(DiaBeta, Micronase)	1.25, 2.5, and 5 mg	1.25-20 mg as single dose or in two divided doses	Up to 24
Glynase	1.5, 3, and 6 mg	1.5-19 mg as a single dose or in two divided doses	Up to 24
Tolazamide (Tolinase)	100, 250, and 500 mg	0.1-1 g as single dose or in two divided doses	Up to 24
Tolbutamide (Orinase)	250 and 500 mg	0.5-2 g in two or three divided doses	6-12
Meglitinide Analogs			
Repaglinide (Prandin)	0.5, 1, and 2 mg	0.5 to 4 mg three times a day before meals	3
Mitiglinide (available in Japan)	5 and 10 mg	5 or 10 mg three times a day before meals	2
D-Phenylalanine			
Nateglinide (Starlix)	60 and 120 mg	60 or 120 mg three times a day before meals	1.5
Biguanides			
Metformin (Glucophage)	500, 850, and 1000 mg	1-2.5 g; one tablet with meals two or thee times daily	7-12
Extended-release metformin (Glucophage XR)	500 and 750 mg	500-2000 mg once a day	Up to 24
Thiazolidinediones			
Pioglitazone (Actos)	15, 30, and 45 mg	15-45 mg daily	Up to 24
Rosiglitazone (Avandia)	2, 4, and 8 mg	4-8 mg daily (can be divided)	Up to 24
α-Glucosidase Inhibitors			
Acarbose (Precose)	50 and 100 mg	75-300 mg in three divided doses with first bite of food	4
Miglitol (Glyset)	25, 50, and 100 mg	75-300 mg in three divided doses with first bite of food	4
GLP-1 Receptor Agonists			
Albiglutide (Tanzeum)	30, 50 mg single dose pen (powder)	Mix with diluent and inject subcutaneously. 30 mg is usual dose. Can increase dose to 50 mg if necessary	1 week
Dulaglutide (Trulicity)	0.75, 1.5 mg single dose pen or prefilled syringe	0.75 mg subcutaneously. Dose can be increased to 1.5 mg if necessary	1 week
Exenatide (Byetta)	5 and 10 μg	5 μg by subcutaneous injection within 1 hour of breakfast and dinner. Increase to 10 μg twice a day after about a month. Do not use if calculated creatinine clearance is <30 mL/min	6
Exenatide long-acting release (Bydureon, Byetta LAR)	2 mg powder	Suspend in provided diluent and inject subcutaneously	1 week
Liraglutide (Victoza)	0.6, 1.2, and 1.8 mg	0.6 mg by subcutaneous injection once a day starting dose. Increase to 1.2 mg after a week if no adverse reactions. Dose can be further increased to 1.8 mg if necessary	24
Lixisenatide (Adlyxin)	10 and 10 μg	10 μg by subcutaneous injection daily. Increase to 20 μg after two weeks	24
DPP-4 Inhibitors			
Alogliptin (Nesina)	6.25, 12.5, and 25 mg	25 mg once daily; dose is 12.5 mg daily if calculated creatinine clearance is 30–59 mL/min and 6.25 mg daily if clearance <30 mL/min	24
Linagliptin (Tradjenta)	5 mg	5 mg daily	24
Saxagliptin	2.5 and 5 mg	2.5 or 5 mg once a day. Use 2.5 mg dose if calculated creatinine clearance is ≤50 mL/min or if also taking strong CYP 3A4/5 inhibitors like ketoconazole	24
Sitagliptin	25, 50, and 100 mg	100 mg orally once a day. Reduce dose to 50 mg if calculated creatinine clearance is 30-50 mL/min. Give 25 mg daily if creatinine clearance <30 mL/min	24

(Continued)

TABLE 17–12 Drugs for treatment of type 2 diabetes. (*Continued*)

Drug	Tablet Size	Daily Dose	Duration of Action (h)
Vildagliptin (not available in United States)	50 mg	50 mg once or twice a day. Contraindicated in patients with calculated creatinine clearance ≤60 mL/min or AST/ALT three times upper limit of normal	24
SGLT2 Inhibitors Canagliflozin (Invokana)	100 and 300 mg	100 mg daily is usual dose. Do not use if eGFR <45 mL/min/1.72 m^2 300 mg dose can be used if normal eGFR	24
Dapagliflozin (Farxiga)	5 and 10 mg	10 mg daily. Use 5 mg dose in hepatic failure	24
Empagliflozin (Jardiance)	10 and 25 mg	10 mg daily. 25 mg can be used if necessary	24
Others Bromocriptine (Cycloset)	0.8 mg	0.8 mg daily. Increase weekly by 1 tablet until maximal tolerated dose of 1.6-4.8 mg daily	24
Colesevelam (Welchol)	625 mg	3 tablets twice a day	24
Pramlintide	5-mL vial containing 0.6 mg/mL	For insulin-treated type 2 patients, start at 60-μg dose three times a day (10 U on U100 insulin syringe) and increase to 120 μg three times a day (20 U) if patient has no nausea for 3-7 days. Give immediately before meal. For type 1 patients, start at 15 μg three times a day (2.5 U on U100 insulin syringe) and increase by increments of 15 μg to a maximum of 60 μg three times a day as tolerated. Lower insulin dose by 50% on initiation of therapy to avoid hypoglycemia	2

The meglitinide analog repaglinide and the D-phenylalanine derivative nateglinide also bind the sulfonylurea receptor and stimulate insulin secretion. (2) **Drugs that principally lower glucose levels by their actions on liver, skeletal muscle, or adipose tissue**. Metformin works primarily in the liver. The peroxisome proliferator-activated receptor agonists (PPARs), rosiglitazone, and pioglitazone appear to have their main effects on skeletal muscle and adipose tissue. (3) **Drugs that principally affect absorption of glucose**. The α-glucosidase inhibitors acarbose and miglitol are currently available drugs in this class. (4) **Drugs that mimic incretin effects or prolong incretin action**. The GLP-1 receptor agonists and the DPP-4 inhibitors fall into this category. (5) **Drugs that inhibit reabsorption of filtered glucose in the kidney**. The sodium-glucose cotransporter inhibitors are such agents. (6) **Other drugs**. Pramlintide, lowers glucose by suppressing glucagon and slowing gastric emptying. The mechanisms by which bromocriptine and colesevelam lower glucose levels have not been defined.

1. DRUGS THAT ACT ON THE SULFONYLUREA RECEPTOR COMPLEX

Sulfonylureas

The sulfonylureas contain a sulfonic acid-urea nucleus that can be modified by chemical substitutions to produce agents that have similar qualitative actions but differ widely in potency. They bind the ATP-sensitive potassium channels (K_{ATP}) on the surface of pancreatic β cells, resulting in closure of the channel and depolarization of the β cell. This depolarized state permits calcium to enter the cell and actively promote insulin release (see Figure 17–5).

In β cells, the ATP-sensitive channels contain four copies each of two subunits, the regulatory subunit SUR1, which binds ATP, ADP, and sulfonylureas, and the potassium channel subunit Kir6.2. K_{ATP} channels composed of the same subunits are found in α cells, GLP-1 secreting intestinal L-cells, and the brain. The SUR1/Kir6.2 complexes are opened by diazoxide and closed by sulfonylureas at low concentrations (IC_{50} about 1 nM for glyburide). Inactivating mutations in SUR1 or Kir6.2 cause persistent depolarization of the β cells and have been identified in patients with hyperinsulinemic hypoglycemia of infancy (see Chapter 18). Activating mutations in SUR1 or Kir6.2 prevent depolarization of the β cells and have been identified in patients with neonatal diabetes (see section on Neonatal Diabetes earlier).

K_{ATP} channels with different subunit combinations are found in other tissues. The combination of SUR2A/Kir6.2 is found in cardiac and skeletal muscle, and SUR2B/Kir6.1 in vascular smooth muscle. Channel configurations containing SUR2 subunits are insensitive to diazoxide but sensitive to other potassium channel agonists such as pinacidil and cromakalim. Certain channel *closers* have much higher affinity for SUR1-containing channels than SUR2-containing channels (the sulfonylureas tolbutamide and gliclazide and the meglitinides nateglinide and mitiglinide), while others have similar affinities for both of them (glyburide, glimepiride, and repaglinide). It remains uncertain whether the different affinities of these drugs for the two classes of receptors have clinical relevance.

Sulfonylureas are not indicated for use in type 1 diabetes patients since these drugs require functioning pancreatic β cells to produce their effect on blood glucose. These drugs are used in patients with type 2 diabetes, in whom acute administration improves the early phase of insulin release that is refractory to acute glucose stimulation. Sulfonylureas are metabolized by the

liver and apart from acetohexamide, whose metabolite is more active than the parent compound, the metabolites of all the other sulfonylureas are weakly active or inactive. The metabolites are excreted by the kidney and, in the case of the second-generation sulfonylureas, partly excreted in the bile. Sulfonylureas are generally contraindicated in patients with severe liver or kidney impairment. Idiosyncratic reactions are rare, with skin rashes or hematologic toxicity (leukopenia, thrombocytopenia) occurring in less than 0.1% of users.

A. First-generation sulfonylureas (tolbutamide, tolazamide, acetohexamide, and chlorpropamide)
Tolbutamide is supplied in tablets of 500 mg. It is rapidly oxidized in the liver to an inactive form. Because its duration of effect is short (6-10 hours), it is usually administered in divided doses (eg, 500 mg before each meal and at bedtime). The usual daily dose is 1.5 to 3 g; some patients, however, require only 250 to 500 mg daily. Acute toxic reactions such as skin rashes are rare. Because of its short duration of action, which is independent of renal function, tolbutamide is probably the safest agent to use in elderly patients, in whom hypoglycemia would be a particularly serious risk. Prolonged hypoglycemia has been reported rarely, mainly in patients receiving certain drugs (eg, warfarin, phenylbutazone, or sulfonamides) that compete with sulfonylureas for hepatic oxidation, resulting in maintenance of high levels of unmetabolized active sulfonylureas in the circulation.

Tolazamide, acetohexamide, and chlorpropamide are rarely used. Chlorpropamide has a prolonged biologic effect, and severe hypoglycemia can occur especially in the elderly, because their renal clearance declines with aging. Its other side effects include alcohol-induced flushing and hyponatremia due to its effect on vasopressin secretion and action.

Second-generation sulfonylureas (glyburide, glipizide, gliclazide, and glimepiride)
These agents have similar chemical structures, with cyclic carbon rings at each end of the sulfonylurea nucleus; this causes them to be highly potent (100- to 200-fold more potent than tolbutamide). The drugs should be used with caution in patients with cardiovascular disease as well as in elderly patients, in whom hypoglycemia would be especially dangerous.

a. Glyburide (glibenclamide)—Glyburide is supplied in tablets containing 1.25, 2.5, and 5 mg. The usual starting dose is 2.5 mg/d, and the average maintenance dose is 5 to 10 mg/d given as a single morning dose. If patients are going to respond to glyburide, they generally do so at doses of 10 mg/d or less, given once daily. If they fail to respond to 10 mg/d, it is uncommon for an increase in dosage to result in improved glycemic control. Maintenance doses higher than 20 mg/d are not recommended and may even worsen hyperglycemia. Glyburide is metabolized in the liver into products with such low hypoglycemic activity that they are considered clinically unimportant unless renal excretion is compromised. Although assays specific for the unmetabolized compound suggest a plasma half-life of only 1 to 2 hours, the biologic effects of glyburide clearly persist for 24 hours after a single morning dose in diabetic patients. Glyburide is unique among sulfonylureas in that it not only binds to the pancreatic β cell membrane sulfonylurea receptor but also

becomes sequestered within the β cell. This may also contribute to its prolonged biologic effect despite its relatively short circulating half-life.

A formulation of micronized glyburide, which apparently increases its bioavailability, is available in easy to divide tablet sizes of 1.5, 3, and 6 mg.

Glyburide has few adverse effects other than its potential for causing hypoglycemia. It should not be used in patients with liver failure and renal failure because of the risk of hypoglycemia. Elderly patients are at particular risk of hypoglycemia even with relatively small daily doses. Glyburide does not cause water retention, as chlorpropamide does, and even slightly enhances free water clearance.

b. Glipizide (glydiazinamide)—Glipizide is supplied in tablets containing 5 and 10 mg. For maximum effect in reducing postprandial hyperglycemia, this agent should be ingested 30 minutes before breakfast, because rapid absorption is delayed when the drug is taken with food. The recommended starting dose is 5 mg daily but 2.5-mg dose may be sufficient in elderly patients with early diabetes. The dose can gradually be increased by 2.5 or 5-mg increments. Although as much as 15 mg can be given as a single daily dose before breakfast, most patients do better with divided dosing, taking 5 mg before each meal or taking 10 mg before breakfast and before dinner. The maximum recommended dose is 40 mg/d, although doses above 20 mg probably provide little additional benefit in poor responders. At least 90% of glipizide is metabolized in the liver to inactive products, and only a small fraction is excreted unchanged in the urine. Glipizide therapy is contraindicated in patients with liver failure. Because of its lower potency and shorter half-life, it is preferable to glyburide in elderly patients and for those patients with renal impairment.

Glipizide is also available as a slow-release preparation (Glucotrol-XL, 2.5, 5, and 10-mg tablets). The medication is enclosed in a nonabsorbable shell that contains an osmotic compartment that expands slowly, thereby slowly pumping out the glipizide in a sustained manner. It provides extended release during transit through the gastrointestinal tract, with greater effectiveness in lowering of prebreakfast hyperglycemia than the shorter duration, immediate-release standard glipizide tablets. However, this formulation appears to have sacrificed glipizide's reduced propensity for severe hypoglycemia compared with longer acting glyburide without showing any demonstrable therapeutic advantages over glyburide.

c. Gliclazide (not available in the United States)—This drug is another intermediate duration sulfonylurea with a duration of action of about 12 hours. It is available as 80-mg tablets. The recommended starting dose is 40 to 80 mg/d with a maximum dose of 320 mg. Doses of 160 mg and above are given as divided doses before breakfast and dinner. The drug is metabolized by the liver, and the metabolites and conjugates have no hypoglycemic effect. An extended-release preparation is also available.

d. Glimepiride—This sulfonylurea is supplied in tablets containing 1, 2, and 4 mg. It has a long duration of effect with a half-life of 5 hours, allowing once-daily administration. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound. A single daily dose of 1 mg/d has been shown to be effective, and the maximal recommended dose is 8 mg. It is completely metabolized by the liver to relatively inactive metabolic products.

Meglitinide Analogs

Repaglinide is supplied as 0.5, 1, and 2-mg tablets. Its structure is similar to that of glyburide but lacks the sulfonic acid-urea moiety. It also acts by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. It is rapidly absorbed from the intestine and then undergoes complete metabolism in the liver to inactive biliary products, giving it a plasma half-life of less than 1 hour. The drug therefore causes a brief but rapid pulse of insulin. The starting dose is 0.5 mg three times a day 15 minutes before each meal. The dose can be titrated to a maximum daily dose of 16 mg. Hypoglycemia is the main side effect. In clinical trials, when the drug was compared with glyburide, a long-acting sulfonylurea, there was a trend toward less hypoglycemia. Like the sulfonylureas, it causes weight gain. Metabolism is by the cytochrome P450 3A4 isoenzyme. Other drugs that induce or inhibit this isoenzyme may increase or inhibit the metabolism of repaglinide. The drug may be useful in patients with renal impairment or in the elderly.

Mitiglinide is a benzylsuccinic acid derivative that is very similar to repaglinide in its clinical effects. It binds to the sulfonylurea receptor causing a brief pulse of insulin. It is given as a 5- or 10-mg dose just before a meal and reduces the postprandial rise in blood glucose. It has been approved for use in Japan.

δ-Phenylalanine Derivative

Nateglinide is supplied in tablets of 60 and 120 mg. This drug binds the sulfonylurea receptor and closes the ATP-sensitive potassium channel. The drug is rapidly absorbed from the intestine, reaching peak plasma levels within 1 hour. It is metabolized in the liver and has a plasma half-life of about 1.5 hours. Like repaglinide, it causes a brief rapid pulse of insulin, and when given before a meal, it reduces the postprandial rise in blood glucose. The 60-mg dose is used in patients with mild elevations in HbA_{1c}. For most patients, the recommended starting and maintenance dosage is 120 mg three times a day before meals. Like the other insulin secretagogues, its main side effects are hypoglycemia and weight gain.

2. DRUGS THAT ACT ON INSULIN TARGET TISSUES

Metformin

Metformin (1,1-dimethylbiguanide hydrochloride) is used, either alone or in conjunction with other oral agents or insulin, in the treatment of patients with type 2 diabetes.

Metformin acts primarily through AMPK (see Figure 17–8), which it activates by uncoupling mitochondrial oxidative phosphorylation and increasing cellular AMP levels. Metformin's therapeutic effects primarily derive from its effects on the liver, where increased AMPK activity reduces hepatic gluconeogenesis and lipogenesis. Metformin is a substrate for organic cation transporter 1, which is abundantly expressed in hepatocytes and in the gut.

Metformin is the first-line therapy for patients with type 2 diabetes. It is ineffective in patients with type 1 diabetes. The current recommendation is to start this drug at diagnosis. A side benefit of metformin therapy is its tendency to improve both fasting and postprandial hyperglycemia and hypertriglyceridemia in obese patients with diabetes without the weight gain associated with insulin or sulfonylurea therapy. It is dispensed as 500-, 850-, and 1000-mg tablets. A 500- and 750-mg extended-release preparation is also available. Eighty-five percent of the maximal glucose-lowering effect is achieved by a daily dose of 1500 mg, and there is little benefit from giving more than 2000 mg daily. It is important to begin with a low dose and increase the dosage very gradually in divided doses—taken with meals—to reduce minor gastrointestinal upsets. A common schedule would be one 500-mg tablet three times a day with meals or one 850-mg or 1000-mg tablet twice daily at breakfast and dinner. The maximum recommended dose is 850 mg three times a day. Up to 2000 mg of the extended-release preparation can be given once a day.

The most frequent side effects of metformin are gastrointestinal symptoms (anorexia, nausea, vomiting, abdominal discomfort, diarrhea), which occur in up to 20% of patients. These effects are dose-related, tend to occur at onset of therapy, and often are transient. However, in 3% to 5% of patients, therapy may have to be discontinued because of persistent diarrheal discomfort. In a retrospective analysis, it has been reported that patients who switched from immediate-release metformin to a comparable dose of extended-release metformin experienced fewer gastrointestinal side effects.

Absorption of vitamin B_{12} appears to be reduced during chronic metformin therapy but usually the vitamin B_{12} levels remain in the normal range. Screening of serum vitamin B_{12} levels should be considered if the patient develops a macrocytic anemia or if the patient develops peripheral neuropathy symptoms. Screening may also be considered in patients who have been on the drug for many years. Increased intake of dietary calcium may prevent the metformin-induced B_{12} malabsorption. If pernicious anemia is suspected then measurements of methylmalonate, homocysteine and antibodies to intrinsic factor should be performed. Hypoglycemia does not occur with therapeutic doses of metformin, which permits its description as a euglycemic or antihyperglycemic drug rather than an oral hypoglycemic agent. Dermatologic or hematologic toxicity is rare.

Metformin both increases lactate production by uncoupling mitochondrial oxidative phosphorylation, especially in the gut, and reduces lactate removal by the liver by blocking gluconeogenesis. At therapeutic doses of metformin, serum lactate levels rise only minimally if at all, since other organs such as the kidney can remove the slight excess. However, if tissue hypoxia occurs, the metformin-treated patient is at higher risk for lactic acidosis due to compromised lactate removal. Metformin has a half-life of 1.5 to 3 hours, does not bind to plasma proteins, and is excreted unchanged by the kidneys. With renal failure, plasma levels of metformin can rise far above the therapeutic range and increase lactate production and block hepatic uptake sufficiently to provoke lactic acidosis even in the absence of other causes of increased lactic acid production. Metformin can be safely used in patients with estimated glomerular filtration rate (eGFR) between 45 and 60 mL/min/1.73 m^2. It can be used cautiously in patients with

eGFR between 30 and 45 mL/min/1.73 m^2. It is contraindicated if the eGFR is less than 30 mL/min/1.73 m^2. Acute kidney failure can occur rarely in certain patients receiving radiocontrast agents. Metformin therapy should therefore be temporarily halted on the day of radiocontrast administration and restarted a day or two later after confirmation that renal function has not deteriorated. Renal function should be checked at least annually in patients on metformin therapy; and lower doses should be used in the elderly who may have limited renal reserve and in those with eGFR between 30 and 45 mL/min/1.73 m^2.

Alcoholics and patients with liver failure should not take metformin—lactic acidosis can occur because of impaired hepatic clearance of lactate. The drug is relatively contraindicated in patients with cardiorespiratory insufficiency, because they have a propensity to develop hypoxia that would aggravate the lactic acid production already occurring from metformin therapy.

Peroxisome Proliferator–Activated Receptor Agonists

Thiazolidinediones are insulin sensitizers exerting their antidiabetic effects through the activation of PPARγ (see discussion on PPAR nuclear receptors in insulin action and insulin resistance earlier). Observed effects of thiazolidinediones include increased GLUT expression (GLUT 1 and GLUT 4); decreased free fatty acid levels; decreased hepatic glucose output; increased adiponectin and decreased resistin release from adipocytes; and increased differentiation of preadipocytes into adipocytes. They have also been demonstrated to decrease levels of plasminogen activator inhibitor type 1, matrix metalloproteinase 9, C-reactive protein, and interleukin-6. Like the biguanides, this class of drugs does not cause hypoglycemia.

Rosiglitazone and **pioglitazone** are available for clinical use. Both are effective as monotherapy and in combination with sulfonylureas, metformin, or insulin. When used as monotherapy, these drugs lower HbA$_{1c}$ by about 1 or 2 percentage points. When used in combination with insulin, they can result in a 30% to 50% reduction in insulin dosage, and some patients can come off insulin completely. The dosage of rosiglitazone is 4 to 8 mg daily and of pioglitazone 15 to 45 mg daily, and the drugs do not have to be taken with food. Rosiglitazone is primarily metabolized by the CYP 2C8 isoenzyme and pioglitazone is metabolized by CYP 2C8 and CYP 3A4.

The combination of a thiazolidinedione and metformin has the advantage of not causing hypoglycemia. Patients inadequately managed on sulfonylureas can do well on a combination of sulfonylurea and rosiglitazone or pioglitazone. About 25% of patients in clinical trials fail to respond to these drugs, presumably because they are significantly insulinopenic.

In addition to glucose-lowering, the thiazolidinediones have effects on lipids and other cardiovascular risk factors. Rosiglitazone therapy is associated with increases in total cholesterol, LDL cholesterol (15%), and HDL cholesterol (10%). There is a reduction in free fatty acids of about 8% to 15%. The changes in triglycerides were generally not different from placebo. Pioglitazone in clinical trials lowered triglycerides (9%) and increased

HDL cholesterol (15%) but did not cause a consistent change in total cholesterol and LDL cholesterol levels. A prospective randomized comparison of the metabolic effects of pioglitazone and rosiglitazone in patients showed similar effects on HbA$_{1c}$ and weight gain. Pioglitazone-treated subjects, however, had lower total cholesterol, LDL cholesterol, and triglyceride levels when compared with rosiglitazone. Small prospective studies have also shown that treatment with these drugs leads to improvement of biochemical and histological features of nonalcoholic fatty liver disease. The thiazolidinediones also may limit vascular smooth muscle proliferation after injury and there are reports that pioglitazone can reduce neointimal proliferation after coronary stent placement. Also, in one double-blind, placebo-controlled study, rosiglitazone was shown to be associated with a decrease in the ratio of urinary albumin to creatinine.

Safety concerns and some troublesome side effects have emerged over this class of drugs that limit their use. A meta-analysis of 42 randomized clinical trials with rosiglitazone suggested that this drug increases the risk of angina pectoris or myocardial infarction. A meta-analysis of clinical trials with pioglitazone did not show a similar finding. Although conclusive data are lacking, the European Medicines Agency suspended the use of rosiglitazone in Europe. In the United States, the FDA established a restricted distribution program for rosiglitazone. A subsequent large prospective clinical trial (the RECORD study) failed to confirm the meta-analysis finding and the restrictions were lifted in the United States.

Edema occurs in about 3% to 4% of patients receiving monotherapy with rosiglitazone or pioglitazone. The edema occurs more frequently (10%-15%) in patients receiving concomitant insulin therapy and may result in congestive heart failure. The drugs are contraindicated in diabetic individuals with New York Heart Association class III or IV heart failure. Thiazolidinediones have also rarely been reported as being associated with new onset or worsening macular edema which resolved or improved once the drug was discontinued.

In experimental animals, rosiglitazone stimulates bone marrow adipogenesis at the expense of osteoblastogenesis resulting in a decrease in bone mineral density. An increase in fracture risk in women (but not men) has been reported with both rosiglitazone and pioglitazone. The fracture risk is in the range of 1.9 per 100 patient years with the thiazolidinedione. In at least one study of rosiglitazone, the fracture risk was increased in premenopausal as well as postmenopausal women. Other side effects include anemia, which occurs in 4% of patients treated with these drugs; it may be due to a dilutional effect of increased plasma volume rather than a reduction in red cell mass. Weight gain occurs, especially when the drug is combined with a sulfonylurea or insulin. Some of the weight gain is fluid retention, but there is also an increase in total fat mass. In preclinical studies with pioglitazone, bladder tumors were observed in male rats receiving clinically relevant doses of the medication. Initial clinical reports indicated that this might also be true in humans. A 10-year observational cohort study of patients taking pioglitazone, however, failed to find an association with bladder cancer. A large multipopulation pooled analysis (1.01 million persons over 5.9 million person years)

also failed to find an association between cumulative exposure to pioglitazone or rosiglitazone and incidence of bladder cancer. Another population based study generating 689,616 person years of follow-up did find that pioglitazone but not rosiglitazone was associated with an increased risk of bladder cancer—hazard ratio 1.63 for pioglitazone, 95% confidence intervals 1.22 to 2.19. Troglitazone, the first drug in this class, was withdrawn from clinical use because of drug-associated fatal liver failure. The two currently available agents, rosiglitazone and pioglitazone, have thus far not caused hepatotoxicity. The FDA has, however, recommended that patients should not initiate drug therapy if there is clinical evidence of active liver disease or pretreatment elevation of the alanine aminotransferase (ALT) level that is 2.5 times greater than the upper limit of normal. Obviously, caution should be used in initiation of therapy in patients with even mild ALT elevations. Liver biochemical tests should be performed prior to initiation of treatment and periodically thereafter.

3. DRUGS THAT AFFECT GLUCOSE ABSORPTION

Alpha-Glucosidase Inhibitors

Drugs of this family are competitive inhibitors of intestinal brush border α glucosidases. Two of these drugs, acarbose and miglitol, are available for clinical use in the United States. Voglibose, another α glucosidase inhibitor, is available in Japan, Korea, and India. Acarbose and miglitol are potent inhibitors of glucoamylase, α-amylase, and sucrase. They are less effective on isomaltase and are ineffective on trehalase or lactase. Acarbose binds 1000 times more avidly to the intestinal disaccharidases than do products of carbohydrate digestion or sucrose. A fundamental difference exists between acarbose and miglitol in their absorption. Acarbose has the molecular mass and structural features of a tetrasaccharide, and very little (~2%) crosses the microvillar membrane. Miglitol, however, is structurally similar to glucose and is absorbable. Both drugs delay the absorption of carbohydrates and reduce postprandial glycemic excursion.

a. **Acarbose** is available as 50- and 100-mg tablets. The recommended starting dose is 50 mg twice daily, gradually increasing to 100 mg three times daily. For maximal benefit on postprandial hyperglycemia, acarbose should be given with the first mouthful of food ingested. In diabetic patients it reduces postprandial hyperglycemia by 30% to 50%, and its overall effect is to lower the HbA$_{1c}$ by 0.5% to 1%. The principal adverse effect, seen in 20% to 30% of patients, is flatulence. This is caused by undigested carbohydrate reaching the lower bowel, where gases are produced by bacterial flora. In 3% of cases, troublesome diarrhea occurs. This gastrointestinal discomfort tends to discourage excessive carbohydrate consumption and promotes improved compliance of patients with type 2 diabetes with their diet prescriptions.

When acarbose is given alone, there is no risk of hypoglycemia. However, if combined with insulin or sulfonylureas, it may increase risk of hypoglycemia from these agents. A slight rise in hepatic aminotransferases has been noted in clinical trials (5% vs 2% in placebo controls, and

particularly with doses >300 mg/d). This generally returns to normal on stopping this drug. In the UKPDS, approximately 2000 patients on diet, sulfonylurea, metformin, or insulin therapy were randomized to acarbose or placebo therapy. By 3 years, 60% of the patients had discontinued the drug, mostly because of gastrointestinal symptoms. In the 40% of patients who remained on the drug, acarbose was associated with a 0.5% lowering of HbA$_{1c}$ compared with placebo.

b. **Miglitol** is similar to acarbose in terms of its clinical effects. It is indicated for use in diet- or sulfonylurea-treated patients with type 2 diabetes. Therapy is initiated at the lowest effective dosage of 25 mg three times a day. The usual maintenance dose is 50 mg three times a day, although some patients may benefit from increasing the dose to 100 mg three times a day. Gastrointestinal side effects occur as with acarbose. The drug is not metabolized and is excreted unchanged by the kidney. Theoretically, absorbable α-glucosidase inhibitors could induce a deficiency of one or more of α-glucosidases involved in cellular glycogen metabolism and biosynthesis of glycoproteins. This does not occur in practice because—unlike the intestinal mucosa, which is exposed to a high concentration of the drug—circulating plasma levels are 200-fold to 1000-fold lower than those needed to inhibit intracellular α glucosidases. Miglitol should not be used in renal failure because its clearance is impaired in this setting.

4. INCRETINS

The gut makes several incretins, gut hormones that amplify postprandial insulin secretion, including glucagon-like peptide-1 (GLP-1, see Figure 17–9) and glucose-dependent insulinotropic polypeptide (GIP). Therapeutic drugs in this class include **GLP-1 receptor agonists** and **dipeptidyl peptidase 4** (DPP-4) inhibitors, which increase levels of both GLP-1 and GIP.

When GLP-1 is infused in patients with type 2 diabetes, it stimulates insulin secretion and lowers glucose levels. GLP-1, unlike the sulfonylureas, has only a modest insulin stimulatory effect under normoglycemic conditions. This means that GLP-1 administration has a lower risk of causing hypoglycemia than the sulfonylureas. GLP-1, in addition to its insulin stimulatory effect, also has a number of other pancreatic and extrapancreatic effects (see Table 17–4).

GLP-1 Receptor Agonists

GLP-1 is rapidly proteolyzed by DPP-4 and by other enzymes such as endopeptidase 24.11. It is also cleared rapidly by the kidney. As a result, the half-life of GLP-1 is only 1 to 2 minutes. The native peptide, therefore, cannot be used therapeutically. Instead, the approach taken has been to develop metabolically stable analogs or derivatives of GLP-1 that are not subject to the same enzymatic degradation or renal clearance. Five GLP-1 receptor agonists, exenatide, liraglutide, albiglutide, dulaglutide, and lixisenatide are available for clinical use.

a. **Exenatide (exendin 4)** is a GLP-1 receptor agonist isolated from the saliva of the Gila monster (a venomous lizard) that is resistant to DPP-4 action and is cleared by the kidney. Its half life is 2.4 hours and its glucose lowering effect is about 6 hours. Exenatide is dispensed as two fixed-dose pens

(5 and 10 μg). It is injected within the hour before breakfast and before dinner. Patients should be prescribed the 5-μg pen for the first month and then, if tolerated, the dose should be increased to 10 μg twice daily. The drug is not recommended in patients with glomerular filtration rate less than 30 mL/min.

In clinical trials, adding exenatide to the therapeutic regimen of patients with type 2 diabetes who are already taking metformin or a sulfonylurea (or both) further lowered the HbA_{1c} value by 0.4% to 0.6% over a 30-week period. These patients also lost 3 to 6 lb in weight. In an open-label extension study up to 80 weeks, the HbA_{1c} reduction was sustained, and there was further weight loss (to a total loss of ~10 lb). Exenatide LAR is a once weekly preparation that is dispensed as a powder (2 mg). It is suspended in the provided diluent just prior to injection. In comparative clinical trials, the long-acting drug lowers the HbA_{1c} level a little more than the twice daily drug. Low-titer antibodies against exenatide develop in over one-third (38%) of patients, but the clinical effects are not attenuated. High-titer antibodies develop in a subset of patients (~6%), and in about half of these cases, an attenuation of glycemic response has been seen.

b. Liraglutide is a soluble fatty acid acylated GLP-1 analog—with replacement of lysine with arginine at position 34 and the attachment of a C16 acyl chain to a lysine at position 26. The fatty-acyl GLP-1 retains affinity for GLP-1 receptors, but the addition of the C16 acyl chain allows for non-covalent binding to albumin, both hindering DPP-4 access to the molecule and contributing to a prolonged half-life and duration of action. The half-life is approximately 12 hours allowing the drug to be injected once a day. The dosing is initiated at 0.6 mg daily, increased after 1 week to 1.2 mg daily. Some patients may benefit from increasing the dose to 1.8 mg. In clinical trials lasting 26 and 52 weeks, adding liraglutide to the therapeutic regimen (metformin, sulfonyl-urea, thiazolidinedione) of patients with type 2 diabetes further lowered the HbA_{1c} value. Depending on the dose and design of the study, the HbA_{1c} decline was in the range of 0.6% to 1.5%. The patients had sustained weight loss of 1 to 6 lb. Liraglutide at a dose of 3 mg daily has been approved for weight loss.

c. Albiglutide is a human GLP-1 dimer fused to human albumin. It is rendered resistant to DPP-4 action by a glycine substitution for alanine at position 8. The half-life of albiglutide is about 5 days and a steady state is reached after 4-5 weeks of once weekly administration. The usual dose is 30 mg weekly by subcutaneous injection. The dose can be increased to 50 mg weekly, if necessary. The pen contains a lyophilized powder that is reconstituted just prior to administration. Albiglutide monotherapy and combination therapy lowers HbA_{1c} by about 0.8%. Weight loss is much less than with exenatide and liraglutide.

d. Dulaglutide consists of two GLP-1 analog molecules covalently linked to an Fc fragment of human IgG4. The GLP-1 molecule is 90% homologous to native human GLP-1. The amino acid substitutions improve solubility and resist DPP-4 action. The half-life of dulaglutide is about 5 days. The usual dose is 0.75 mg weekly by subcutaneous

injection. The maximum recommended dose is 1.5 mg weekly. Dulaglutide monotherapy and combination therapy lowers HbA_{1c} by about 0.7% to 1.6%. Weight loss ranges from 2 pounds to 7 pounds.

e. Lixisenatide is a modified exendin 5 (deletion of c-terminal proline and addition of 6 lysines) with high affinity for the GLP-1 receptor. Its half-life is about 2 to 4 hours. Dosing is initiated at 10 μg daily and increased to 20 μg daily after two weeks. Lixisenatide monotherapy and combination therapy lowers HbA_{1c} by about 0.7%.

The most frequent adverse reactions of the GLP-1 receptor agonists are nausea (11%-40%), vomiting (4%-13%), and diarrhea (9%-17%). The reactions are more frequent at the higher doses. Albiglutide tends to have the lowest rates of these reactions. In clinical trials about 1% to 5% of participants withdrew from the studies because of the gastrointestinal symptoms.

All the GLP-1 receptor agonists are associated with increased risk of pancreatitis. The FDA reported 30 postmarketing reports of acute pancreatitis in patients taking exenatide. The pancreatitis was severe (hemorrhagic or necrotizing) in 6 instances, and 2 of these patients died. In the liraglutide, albiglutide, and dulaglutide clinical trials, there were 13, 6, and 5 cases of pancreatitis in the drug-treated groups versus 1, 2, and 1 case(s) in the comparator groups, respectively. This translates to about 1.4-2.2 versus 0.6-0.9 cases of pancreatitis per 1000 patient years. Patients taking GLP-1 receptor agonists should be advised to seek immediate medical care if they experience unexplained persistent severe abdominal pain.

The FDA also reported 16 cases of kidney impairment and 62 cases of acute kidney injury taking exenatide. Some of these patients had preexisting kidney disease, and others had one or more risk factors for kidney disease. A number of the patients reported nausea, vomiting, and diarrhea, and it is possible that these side effects caused volume depletion and contributed to the development of renal injury. For this reason, the GLP-1 receptors agonists should be prescribed cautiously in patients with kidney impairment.

GLP-1 receptor agonists stimulate C-cell neoplasia and cause medullary thyroid carcinoma in rats. Human C-cells express very few GLP-1-receptors, and the relevance to human therapy is unclear. The medications, however, should not be used in patients with personal or family history of medullary thyroid carcinoma or multiple endocrine neoplasia (MEN) syndrome type 2.

DPP-4 Inhibitors

An alternative to the use of GLP-1 receptor agonists involves inhibition of the enzyme DPP-4 with prolongation of the action of endogenously released GLP-1 and GIP. Four oral DPP-4 inhibitors, sitagliptin, saxagliptin, linagliptin, and alogliptin are available for the treatment of type 2 diabetes in the United States. An additional DPP-4 inhibitor, vildagliptin, is available in Europe.

a. Sitagliptin when used alone or in combination with other diabetes medicines additionally lowers HbA_{1c} by approximately 0.5%. The usual dose of sitagliptin is 100 mg once daily, but the dose is reduced to 50 mg daily if the calculated creatinine clearance is 30 to 50 mL/min and to 25 mg for clearances less than 30 mL/min. Unlike exenatide, sitagliptin

does not cause nausea or vomiting. It also does not result in weight loss. The main adverse effect appears to be a predisposition to nasopharyngitis or upper respiratory tract infection. A small increase in neutrophil count of approximately 200 cells/mL has also occurred. Since its FDA approval and clinical use, there have been reports of serious allergic reactions to sitagliptin, including anaphylaxis, angioedema, and exfoliative skin conditions, including Stevens-Johnson syndrome. There have also been reports of pancreatitis (88 cases including two cases of hemorrhagic or necrotizing pancreatitis). The frequency of these events is unclear. DPP-4 is a pleiotropic enzyme that inactivates a variety of peptide hormones, neuropeptides, and chemokines and DPP-4 inhibitors have been shown to prolong the action of neuropeptide Y and substance P. Whether its inhibition over a long-term period will have negative consequences is not known.

b. Saxagliptin when added to the therapeutic regimen (metformin, sulfonylurea, thiazolidinedione) of patients with type 2 diabetes further lowered the HbA_{1c} value by about 0.7% to 0.9%. The dose is 2.5 or 5 mg once a day. The 2.5-mg dose should be used in patients with calculated creatinine clearance less than 50 mL/min. The drug is weight neutral. The main adverse reactions were upper respiratory tract infection, naspharyngitis, headache, and urinary tract infection. There is also small reversible dose-dependent reduction in absolute lymphocyte count which remains within normal limits. Hypersensitivity reactions such as urticaria and facial edema occurred in 1.5% of patients on the drug compared to 0.4% with placebo. The metabolism of saxagliptin is through CYP 3A4/5; so strong inhibitors or inducers of CYP 3A4/5 will affect the pharmacokinetics of saxagliptin and its active metabolite. Saxagliptin may increase the risk of heart failure. In a postmarketing study of 16,492 type 2 diabetes patients, there were 289 cases of heart failure in the saxagliptin group (3.5%) and 228 cases in the placebo group (2.8%)—a hazard ratio of 1.27. Patients at the highest risk for failure were those who had a history of heart failure, had elevated levels of plasma N-terminal pro-brain natriuretic peptide (NT-pBNP) or had renal impairment.

c. Alogliptin lowers HbA_{1c} by about 0.5% to 0.6% when added to metformin, sulfonylurea, or pioglitazone. The usual dose is 25 mg orally daily. The 12.5-mg dose is used in patients with calculated creatinine clearance of 30 to 60 mL/min, and 6.25 mg for clearance less than 30 mL/min. In clinical trials, pancreatitis occurred in 11 of 5902 patients on alogliptin (0.2%) and in 5 of 5183 patients receiving all comparators (<0.1%). There have been reports of hypersensitivity reactions (anaphylaxis, angioedema, Stevens-Johnson syndrome). Cases of hepatic failure have been reported but it is unclear if alogliptin was the cause. The medication, however, should be discontinued in the event of liver failure.

In a large postmarketing study, alogliptin, like saxagliptin, was associated with a slightly increased rate of heart failure.

d. Linagliptin lowers HbA_{1c} by about 0.4% to 0.6% when added to metformin, sulfonylurea, or pioglitazone. The dose is 5 mg orally daily, and since it is primarily excreted unmetabolized through the bile, no dose adjustment is needed in patients with renal failure. The adverse reactions include

nasopharyngitis and hypersensitivity reactions (urticaria, angioedema, localized skin exfoliation, bronchial hyperreactivity). In one study, there were eight cases of pancreatitis in 4687 patients exposed to drug (4311 patient years) with 0 cases in 1183 patients receiving placebo (433 patient years).

e. Vildagliptin, like the other DPP-4 inhibitors, lowers HbA_{1c} by about 0.5% to 1% when added to the therapeutic regimen of patients with type 2 diabetes. The dose is 50 mg once or twice a day. The adverse reactions include upper respiratory tract infections, nasopharyngitis, dizziness, and headache. Rare cases of hepatic dysfunction including hepatitis have been reported. Liver function testing is recommended, quarterly the first year, and periodically thereafter.

Animal studies using much higher doses of DPP-4 inhibitors and GLP-1-receptor agonists than are used in humans caused expansion of pancreatic ductal glands and generation of premalignant pancreatic intraepithelial (PanIN) lesions that have the potential to progress to pancreatic adenocarcinoma. There is, however, currently no evidence that these drugs cause pancreatic cancer in humans.

5. SODIUM-GLUCOSE COTRANSPORTER 2 INHIBITORS

Glucose is freely filtered by the renal glomeruli and is reabsorbed in the proximal tubules by the action of sodium-glucose cotransporters (SGLT). Sodium-glucose cotransporter 2 (SGLT2) accounts for about 90% of glucose reabsorption and its inhibition causes glycosuria in people with diabetes, lowering plasma glucose levels. The SGLT2 inhibitors canagliflozin, dapagliflozin, and empagliflozin are approved for clinical use in the United States.

a. Canagliflozin reduces the threshold for glycosuria from a plasma glucose threshold of ~180 mg/dL to 70–90 mg/dL. It has been shown to reduce HbA_{1c} by 0.6% to 1% when used alone or in combination with other oral agents or insulin. It also results in modest weight loss of 2–5 kg. The usual dose is 100 mg daily but up to 300 mg daily can be used in patients with normal kidney function.

b. Dapagliflozin is an SGLT2 inhibitor that has been shown to reduce HbA_{1c} levels by 0.5% to 0.8% when used alone or in combination with other oral agents or insulin. It also results in modest weight loss of about 2 to 4 kg. The usual dose is 10 mg daily but 5 mg daily is the recommended initial dose in patients with hepatic failure.

c. Empagliflozin reduces HbA_{1c} by 0.5% to 0.7% when used alone or in combination with other oral agents or insulin. It also results in modest weight loss of about 2 to 3 kg. The usual dosage is 10 mg daily but a higher dose of 25 mg daily can be used. In a postmarketing multinational study of 7020 type 2 patients with known cardiovascular disease, the addition of empagliflozin was associated with a lower primary composite outcome of death from cardiovascular causes, nonfatal myocardial infarction, or non-fatal stroke (hazard ratio 0.86, $p = 0.04$). The mechanism(s) regarding the benefit remains unclear. Weight loss, lower blood pressure, and diuresis may have played a role since there were fewer deaths from heart failure in the treated group whereas the rates of myocardial infarction were unaltered. Additional studies with empagliflozin and other SGLT2 inhibitors are needed to confirm this result.

As might be expected, the efficacy of the SGLT2 inhibitors is reduced in chronic kidney disease. They can also increase creatinine and decrease eGFR, especially in patients with kidney impairment. Canagliflozin is contraindicated in patients with eGFR less than 45 mL/min/1.73 m^2. The main side effects are increased incidence of genital mycotic infections and urinary tract infections affecting ~8% to 9% of patients. There have also been reports of cases of pyelonephritis and septicemia requiring hospitalization. The glycosuria can cause intravascular volume contraction and hypotension.

Canagliflozin has been reported to cause a decrease in bone mineral density at the lumbar spine and the hip. An increase in fractures by about 30% was observed in patients on canagliflozin in a pooled analysis of 8 clinical trial (mean duration 68 weeks). It is likely that the effect on the bones is a class effect and not restricted to canagliflozin. A modest increase in upper limb fractures was observed with canaglifloxin therapy. It is not known if this is due to an effect on bone strength or related to falls due to hypotension. All the SGLT2 inhibitors cause a modest increase in LDL cholesterol levels (3%-8%). Also, in clinical trials, patients taking dapagliflozin had higher rates of breast cancer (nine cases vs none in comparator arms) and bladder cancer (10 cases vs 1 in placebo arm). These cancer rates exceeded the expected rates in age-matched reference diabetes population.

Cases of diabetic ketoacidosis have been reported with off label use of SGLT2 inhibitors in patients with type 1 diabetes. Type 1 patients are taught to give less insulin if their glucose levels are not elevated. SGLT2 inhibitors lower glucose levels by changing the renal threshold for glucose reabsorption (ie, increased glucosuria) and not through insulin action. Type 1 patients on an SGLT2 inhibitor, because the glucose levels are not elevated, may either withhold or reduce their insulin doses to such a degree as to induce ketoacidoisis, SGLT2 inhibitors should not be used in patients with type 1 diabetes and in those patients labeled as having type 2 diabetes but who are very insulin deficient and ketosis-prone.

6. OTHERS

a. Pramlintide is a synthetic analog of islet amyloid polypeptide (IAPP) that when given subcutaneously (1) delays gastric emptying, (2) suppresses glucagon secretion, and (3) decreases appetite. It is approved for use both in type 1 and insulin-treated type 2 patients. In 6-month clinical studies with type 1 and insulin-treated type 2 patients, those on the drug had approximately a 0.4% reduction in HbA$_{1c}$ and lost about 1.7 kg compared to placebo. The HbA$_{1c}$ reduction was sustained for 2 years, but some of the weight was regained. The drug is given immediately before the meal by injection. Hypoglycemia is the most concerning adverse event, and it is recommended that the short-acting or premixed insulin doses be reduced by 50% when the drug is started. Since the drug slows gastric emptying, recovery from hypoglycemia can be a problem because of delay in absorption of the fast-acting carbohydrate. Nausea was the other main side effect, affecting 30% to 50% of subjects. It tended to improve with time. In patients with type 1 diabetes, pramlintide is initiated at the dose of 15 μg before each meal and titrated by 15 μg increments to a maintenance dose of 30 or 60 μg before each meal. In patients with type 2 diabetes, the initiation dose is 60 μg premeals increased to 120 μg in 3 to 7 days if no significant nausea occurs.

b. Bromocriptine, a dopamine 2 receptor agonist, has been shown to modestly lower HbA$_{1c}$ by 0.1% to 0.5% when compared to baseline and 0.4% to 0.5% compared to placebo. The tablet dose is 0.8 mg and the daily dose is 2 (1.6 g) to 6 (4.8 mg) tablets as tolerated. Common side effects are nausea, vomiting, dizziness, and headache.

c. Colesevelam, the bile acid sequestrant, when added to metformin or sulfonylurea or insulin lowered HbA$_{1c}$ 0.3% to 0.4% when compared to baseline and 0.5% to 0.6% compared to placebo. HbA$_{1c}$ lowering, however, was not observed in a single monotherapy clinical trial comparing colesevelam to placebo. Colesevelam use is associated with ~20% increase in triglyceride levels. Other adverse effects include constipation and dyspepsia.

With their modest glucose lowering and significant side effects, using bromocriptine or colesevelam to treat diabetes is not recommended.

Drug Combinations

Several drug combinations are available in different dose sizes including glyburide-metformin (Glucovance), glipizide-metformin (Metaglip), repaglinide-metformin (Prandi-Met), rosiglitazone-metformin (Avandamet), pioglitazone-metformin (ACTOplus Met), rosiglitazone and glimepiride (Avandaryl), pioglitazone and glimepiride (Duetact), sitagliptin-metformin (Janumet), saxagliptin-metformin extended release (kombiglyze XR), linagliptin and metformin (Jentadueto), alogliptin and metformin (Kazano), alogliptin and pioglitazone (Oseni), dapagliflozin and metformin (Xigduo), canagliflozin and metformin (Invokamet), empagliflozin and metformin (Synjardy), empagliflozin and linagliptin (Glyxambi), and lixisenatide and insulin glargine (Soliqua). These combinations, however, limit the clinician's ability to optimally adjust dosage of the individual drugs and for that reason are not recommended.

7. INSULIN

Insulin is indicated for individuals with type 1 diabetes as well as for those with type 2 diabetes whose hyperglycemia does not respond to diet therapy and other diabetes drugs.

Human insulin is dispensed as either regular (R) or Neutral Protamine Hagedorn (NPH) formulations. Animal insulins are no longer available in the United States. Six analogs of human insulin—three rapidly acting (insulin lispro, insulin aspart, and insulin glulisine) and three long-acting (insulin glargine, insulin detemir, and insulin degludec) are available for clinical use. All currently available insulins contain less than 10 ppm of proinsulin and are labeled as "purified." These purified insulins preserve their potency, so that refrigeration is recommended but not crucial. During travel, reserve supplies of insulin can be readily transported for weeks without losing potency if protected from extremes of heat or cold. All the insulins in the United States are available in a concentration of 100 U/mL (U100) and dispensed in 10 mL vials or 0.3 mL cartridges or prefilled disposable pens. Several insulins are now available at higher concentrations—insulin glargine 300 U/mL (U300), insulin degludec 200 U/mL (U200),
FIGURE 17–12 Extent and duration of action of various types of insulin (in a fasting diabetic). Duration of action may be extended considerably when the dose of a given insulin formulation increases above the average therapeutic doses depicted here.

insulin lispro 200 U/mL (U200), and regular insulin 500 U/mL (U500). (Figure 17–12; Tables 17–13 and 17–14).

It is important to recognize that values given for time of onset of action, peak effect, and duration of action are only approximate and that there is great variability in these parameters from patient to patient and even in a given patient depending on the size of the dose, the site of injection, the degree of exercise, the avidity of circulating anti-insulin antibodies, and other less well-defined variables.

Short-Acting Insulin Preparations

The short-acting preparations are regular insulin and the rapidly acting insulin analogs. They are dispensed as clear solutions at neutral pH and contain small amounts of zinc to improve their stability and shelf life.

A. Regular insulin   Regular insulin is a short-acting, soluble crystalline zinc insulin whose hypoglycemic effect appears within 30 minutes after subcutaneous injection, peaks at about 2 hours, and lasts for about 5 to 7 hours when usual quantities (ie, 5-15 U) are administered. Intravenous infusions of regular

TABLE 17–13 Summary of bioavailability characteristics of the insulins.

Insulin Preparations	Onset of Action	Peak Action	Effective Duration
Insulins lispro, aspart, glulisine	5-15 min	1-1.5 h	3-4 h
Human regular	30-60 min	2 h	6-8 h
Technosphere inhaled insulin	5-15 min	1 h	3 h
Human NPH	2-4 h	6-7 h	10-20 h
Insulin glargine	0.5-1 h	Flat	~24 h
Insulin detemir	0.5-1 h	Flat	17 h
Insulin degludec	0.5-1.5 h	Flat	>42 h

insulin are particularly useful in the treatment of diabetic keto-acidosis and during the perioperative management of insulin-requiring diabetics.

For very insulin-resistant subjects who would otherwise require large volumes of insulin solution, a U500 preparation of human regular insulin is available both in a vial form and a disposable pen. If the vial form is used, a U500 insulin syringe is available to measure doses. The disposable pen dispenses the regular insulin in 5 unit increments.

B. Rapidly acting insulin analogs   *Insulin lispro* (Humalog) is an insulin analog where the proline at position B28 is reversed with the lysine at B29. *Insulin aspart* (Novolog) is a single

TABLE 17–14 Insulin preparations available in the United States.[a]

Short Acting Insulin Preparations
Insulin lispro (Humalog, Lilly)
Insulin aspart (Novolog, Novo Nordisk)
Insulin glusisine (Apidra, Sanofi Aventis)
Regular insulin (Lilly, Novo Nordisk)

   75% insulin lispro/protamine (NPL) 25% insulin lispro
      (Humalog Mix 75/25, Lilly)
   50% NPL/50% insulin lispro (Humalog Mix 50/50, Lilly)
   70% insulin aspart/protamine/30% insulin aspart
      (Novolog Mix 70/30, Novo Nordisk)
   70% insulin degludec/30% insulin aspart
      (Ryzodeg, Novo Nordisk)

[a]All types of insulin available in the United States are recombinant human or human insulin analog origin. All the insulins are dispensed at U100 concentration. There is an additional U500 preparation of regular insulin; U300 preparation of insulin glargine; U200 preparations of insulin lispro and insulin degludec.

substitution of proline by aspartic acid at position B28. In *Insulin glulisine* (Apidra) the asparagine at position B3 is replaced by lysine and the lysine in position B29 by glutamic acid. These three analogs have less tendency to form hexamers compared to human insulin. When injected subcutaneously, the analogs quickly dissociate into monomers and are absorbed very rapidly, reaching peak serum values in as soon as 1 hour—in contrast to regular human insulin, whose hexamers require considerably more time to dissociate and become absorbed. The amino acid changes in these analogs do not interfere with their binding to the insulin receptor, with the circulating half-life, or with their immunogenicity, which are all identical to those of human regular insulin.

Clinical trials have demonstrated that the optimal times of preprandial subcutaneous injection of comparable doses of the rapid-acting insulin analogs and of regular human insulin are 20 minutes and 60 minutes before the meal, respectively. Although this more rapid onset of action has been welcomed as a great convenience by patients with diabetes who object to waiting as long as 60 minutes after injecting regular human insulin before they can begin their meal, patients must be taught to ingest adequate absorbable carbohydrate early in the meal to avoid hypoglycemia during the meal. Another desirable feature of rapidly acting insulin analogs is that their duration of action remains at about 4 hours irrespective of dosage. This contrasts with regular insulin, whose duration of action is prolonged when larger doses are used.

The rapidly acting analogs are also commonly used in pumps. In a double-blind crossover study comparing insulin lispro with regular insulin in insulin pumps, persons using insulin lispro had lower HbA_{1c} values and improved postprandial glucose control with the same frequency of hypoglycemia. In the event of pump failure, however, users of the rapidly acting insulin analogs will have more rapid onset of hyperglycemia and ketosis.

While insulin aspart has been approved for intravenous use (eg, in hyperglycemic emergencies), there is no advantage in using insulin aspart over regular insulin by this route. A U200 concentration of insulin lispro is available in a disposable prefilled pen. The only advantage of the U200 over the U100 insulin lispro preparation is that it delivers the same dose in half the volume.

Long-Acting Insulin Preparations

a. Neutral Protamine Hagedorn (NPH), or isophane, insulin is an intermediate-acting insulin in which the onset of action is delayed by combining two parts of soluble crystalline zinc insulin with one part protamine zinc insulin. The mixture has equivalent concentrations of protamine and insulin, so that neither is in excess (isophane). Its onset of action is delayed by 2 to 4 hours, and its peak response is generally reached in about 8 to 10 hours. Because its duration of action is often less than 24 hours (with a range of 10-20 hours), most patients require at least two injections daily to maintain a sustained insulin effect.

Flocculation of suspended particles may occasionally frost the sides of a bottle of NPH insulin or clump within bottles from which multiple small doses are withdrawn over a prolonged period. This instability is a rare phenomenon and might occur less frequently if NPH human insulin were refrigerated when not in use and if bottles were discarded after 1 month of use. Patients should be vigilant for early signs of frosting or clumping of the NPH insulin, because it indicates a pronounced loss of potency. Several cases of diabetic ketoacidosis have been reported in patients with type 1 diabetes who had been inadvertently injecting this denatured insulin.

b. Insulin glargine is an insulin analog in which the asparagine at position 21 of the A chain of the human insulin molecule is replaced by glycine and two arginines are added to the carboxyl terminal of the B chain. The arginines raise the isoelectric point of the molecule close to neutral, making it more soluble in an acidic environment. In contrast, human insulin has an isoelectric point of pH 5.4. Insulin glargine is a clear insulin that, when injected into the neutral pH environment of the subcutaneous tissue, forms microprecipitates that slowly release the insulin into the circulation. It lasts for about 24 hours without any pronounced peaks and is given once a day to provide basal coverage. This insulin cannot be mixed with the other insulins because of its acidic pH. When this insulin was given as a single injection at bedtime to type 1 diabetes patients, fasting hyperglycemia was better controlled when compared with bedtime NPH insulin. The clinical trials also suggest that there may be less nocturnal hypoglycemia with this insulin when compared with NPH insulin.

In one clinical trial involving patients with type 2 diabetes, insulin glargine was associated with a slightly more rapid progression of retinopathy when compared with NPH insulin. The frequency was 7.5% with the analog and 2.7% with the NPH. This observation, however, was not confirmed in a 5-year open label prospective study of 1024 subjects randomized to NPH or insulin glargine. In *in vitro* studies, insulin glargine has a sixfold greater affinity for the IGF-1 receptor compared with the human insulin. There has also been a report that insulin glargine has increased mitogenicity compared with human insulin in a human osteosarcoma cell line. Circulating levels of insulin glargine, however, are low, and the clinical significance of these observations is not yet clear. An observational study from Germany of 127,031 patients who had exposure to regular insulin, short-acting insulin analogs, and insulin glargine reported a strong correlation between increased insulin dose and cancer risk. Moreover insulin glargine, dose for dose, appeared to carry a higher risk than regular insulin. Subsequent epidemiologic studies, however, failed to confirm this observation. A more concentrated form of insulin glargine (U300) is available as an insulin pen. In pharmacodynamic studies in type 1 patients, the U300 compared to the U100 preparation had approximately 5 hours longer duration of action. In clinical trials in type 1 patients, U300 use did not result in better control or reduce the rates of hypoglycemia. Although limited clinical data suggest that insulin glargine is safe in pregnancy, it is not approved for this use.

c. Insulin detemir is an insulin analog in which the threonine at position 30 of the B chain has been removed and a 14-C fatty acid chain (tetradecanoic acid) is attached to the lysine at position 29 by acylation. The fatty acid chain makes the molecule more lipophilic than native insulin, and the addition of zinc stabilizes the molecule and leads to formation of hexamers. After injection, self-association at the injection site and albumin binding in the circulation via the fatty acid side chain lead to slower distribution to peripheral target

tissues and prolonged duration of action. The affinity of insulin detemir is four- to fivefold lower than that of human soluble insulin and, therefore, the U100 formulation of insulin detemir has a concentration of 2400 nmol/mL compared to 600 nmol/mL for NPH. The duration of action for insulin detemir is about 17 hours at therapeutically relevant doses. It is recommended that the insulin is injected once or twice a day to achieve a stable basal coverage. Apparently this insulin has been reported to have lower within-subject pharmacodynamic variability compared to NPH insulin and insulin glargine. *In vitro* studies do not suggest any clinically relevant albumin binding interactions between insulin detemir and fatty acids or protein-bound drugs. Because there is a vast excess (~400,000) of albumin-binding sites available in plasma per insulin detemir molecule, it is unlikely that hypoalbuminemic disease states will affect the ratio of bound to free insulin detemir.

d. Insulin degludec In this insulin analog, the threonine at position B30 has been removed and the lysine at position B29 is conjugated to hexadecanoic acid via a gamma-L-glutamyl spacer. In the vial, in the presence of phenol and zinc, the insulin is in the form of dihexamers but when injected subcutaneously, it self-associates into large multi-hexameric chains consisting of thousands of dihexamers. The chains slowly dissolve in the subcutaneous tissue and insulin monomers are steadily released into the systemic circulation. The half-life of the insulin is 25 hours. Its onset of action is in 30 to 90 minutes and its duration of action is more than 42 hours. It is recommended that the insulin be injected once or twice a day to achieve a stable basal coverage. Insulin degludec is available in two concentrations, U100 and U200 and dispensed in prefilled disposable pens.

Insulin Mixtures

Patients with type 2 diabetes can sometimes achieve reasonable glucose control with just prebreakfast and presupper injections of mixtures of short acting and NPH insulins. The regular insulin or rapidly acting insulin analog is withdrawn first, then the NPH insulin and then injected immediately. Stable premixed insulins (70% NPH and 30% regular) are available as a convenience to patients who have difficulty mixing insulin because of visual problems or insufficient manual dexterity.

With increasing use of rapid-acting insulin analogs as a preprandial insulin, it has become evident that combination with an intermediate-acting or long-acting insulin is essential to maintain postabsorptive glycemic control. It has been demonstrated that insulin lispro can be acutely mixed with NPH insulin without affecting its rapid absorption. Premixed preparations of insulin lispro and NPH insulin however are unstable because of exchange of insulin lispro with the human insulin in the protamine complex. Consequently, over time, the soluble component becomes a mixture of regular and insulin lispro at varying ratios. In an attempt to remedy this, intermediate insulin composed of isophane complexes of protamine with insulin lispro was developed and given the name NPL (neutral protamine lispro). Premixed combinations of NPL and insulin lispro are now available for clinical use (Humalog Mix 75/25 and Humalog Mix 50/50). These mixtures have a more rapid onset of glucose-lowering activity compared with 70% NPH/30% regular human

insulin mixture and can be given within 15 minutes before or after starting a meal. Similarly, a 70% insulin aspart protamine/30% insulin aspart (NovoLogMix 70/30) is now available. The main advantages of these new mixtures are that (1) they can be given within 15 minutes of starting a meal and (2) they are superior in controlling the postprandial glucose rise after a carbohydrate-rich meal. These benefits have not translated into improvements in HbA$_{1c}$ levels when compared with the usual 70% NPH/30% regular mixture.

The longer-acting insulin analogs, insulin glargine or insulin detemir, cannot be acutely mixed with either regular insulin or the rapid-acting insulin analogs. Insulin degludec, however, can be mixed and is available as 70% insulin degludec/30% insulin aspart and is injected once or twice a day.

Methods of Insulin Administration

a. Insulin syringes and needles—Disposable plastic syringes with needles attached are available in 1-mL (100 units), 0.5-mL (50 units), and 0.3-mL (30 units) sizes. The "low-dose" 0.3 mL syringes are popular because many patients with diabetes do not take more than 30 units of insulin in a single injection except in rare instances of extreme insulin resistance. Three lengths of needles are available: 6 mm, 8 mm, and 12.7 mm. Long needles are preferable in obese patients to reduce variability of insulin absorption. The needles are of 28, 30, and 31 gauges. The 31 gauge needles are almost painless. Many patients reuse the syringes up to 3 to 5 times, maintaining adequate sterility by recapping between uses.

Any part of the body covered by loose skin can be used as an injection site, including the abdomen, thighs, upper arms, flanks, and upper-outer quadrants of the buttocks. Cleaning with alcohol is not necessary as long as the skin is clean. Rotation of sites is recommended to avoid delayed absorption when lipohypertrophy occurs from repeated use of a single site. In general, regular insulin is absorbed more rapidly from upper regions of the body such as the deltoid area or the abdomen rather than from the thighs or buttocks. Exercise appears to facilitate insulin absorption when the injection site is adjacent to the exercising muscle. For most patients, the abdomen is the recommended region for injection because it provides a considerable area in which to rotate sites, and there may be less variability of absorption with exercise than when the thigh or deltoid areas are used. The effect of anatomic regions appears to be much less pronounced with the analogs.

b. Insulin pen injector devices—Insulin pens eliminate the need for carrying insulin vials and syringes. Cartridges of insulin lispro, insulin aspart, and insulin glargine are available for reusable pens (Lilly, Novo Nordisk, and Owen Mumford). Disposable prefilled pens are also available for regular insulin (U100 and U500), insulin lispro, insulin aspart, insulin glulisine, insulin detemir, insulin glargine, insulin degludec, NPH, 70% NPH/30% regular, 75% NPL/25% insulin lispro, 50% NPL/50% insulin lispro, 70% insulin aspart protamine/30% insulin aspart, and 70% insulin degludec/30% insulin aspart. Pen needles are available in 29, 31, and 32 gauges and 4, 5, 6, 8, and 12.7 mm lengths.

c. Insulin pumps—In the United States, Medtronic MiniMed, Insulet, Animas, Roche, and Tandem make battery

operated subcutaneous insulin infusion pumps. These pumps are small (about the size of a pager) and easy to program. They have many features, including the ability to record a number of different basal rates throughout a 24-hour period and adjust the time over which bolus doses are given. They are able also to detect pressure build-up if the catheter is kinked. The catheter connecting the insulin reservoir to the subcutaneous cannula can be disconnected so the patient can remove the pump temporarily (eg, for bathing). Ominpod (Insulet Corporation) is an insulin infusion system in which the insulin reservoir and infusion set are integrated into one unit (pod), so there is no catheter (electronic patch pump). The pod, placed on the skin, delivers subcutaneous basal and bolus insulin based on wirelessly transmitted instructions from a personal digital assistant.

The great advantage of **continuous subcutaneous insulin infusion (CSII)** is that it allows for establishment of a basal profile tailored to the patient allowing for better overnight and between meals glucose control. The ability to adjust the basals makes it easier for the patient to manage glycemic excursions that occur with exercise. The pumps have software that can assist the patient to calculate boluses based on glucose reading and carbohydrates to be consumed. They also keep track of the time elapsed since last insulin bolus and the patient is reminded of this when he or she attempts to give additional correction bolus before the effect of the previous bolus has worn off (*insulin on board* feature). This feature reduces the risk of overcorrecting and subsequent hypoglycemia.

CSII therapy is appropriate for patients who are motivated, mechanically adept, educated about diabetes (diet, insulin action, treatment of hypo- and hyperglycemia), and willing to monitor their blood glucose four to six times a day. Known complications of CSII include ketoacidosis, which can occur when insulin delivery is interrupted, and skin infections. Another major disadvantage is the cost and the time demanded of physicians and staff in initiating therapy. Almost all patients use the rapid-acting insulin analogs in their pumps. Clinical trials have shown that when compared with regular insulin, subjects using rapid-acting insulin analogs in pumps had lower HbA$_{1c}$ values and improved postprandial glucose control with the same frequency of hypoglycemia.

V-go (Valeritas) is a mechanical patch pump designed specifically for people with type 2 diabetes who employ a basal/bolus insulin regimen. The device is preset to deliver one of three fixed and flat basal rates (20, 30, or 40 units) for 24 hours (at which point it must be replaced) and there is a button that delivers two units per press to help cover meals.

d. **Inhaled insulin**—Technosphere insulin (Afrezza) is a dry-powder formulation of regular insulin that can be inhaled. It consists of 2 to 2.5 μm crystals of the excipient, fumaryl diketopiperazine, that provide large surface area for adsorption of proteins like insulin. Pharmacokinetic studies show that technosphere insulin is rapidly absorbed with peak insulin levels reached in 12 to 15 minutes and declining to baseline in 3 hours. Pharmacodynamic studies show that median time to maximum effect with inhaled insulin is approximately 1 hour and declines to baseline by about 3 hours. In contrast, the median time to maximum effect with subcutaneous insulin lispro is about 2 hours and declines to baseline by 4 hours. In clinical trials, technosphere insulin

combined with basal insulin was as effective in glucose lowering as rapid-acting insulin analogs combined with basal insulin. It is formulated as a single use color coded cartridge delivering 4, 8, or 12 units immediately before the meal. The manufacturer provides a dose conversion table; patients injecting up to 4 units of rapid-acting insulin analog should use the 4 unit cartridge. Those injecting 5 to 8 units should use the 8-unit cartridge. If the dose is 9 to 12 units of rapid-acting insulin premeal then one 4-unit cartridge and one 8-unit cartridge or one 12-unit cartridge should be used. The inhaler is about the size of a referee's whistle.

The most common adverse reaction of the inhaled insulin was a cough affecting about 27% of patients. A small decrease in pulmonary function (forced expiratory volume in 1 second [FEV1]) was seen in the first 3 months of use, which persisted over 2 years of follow-up. Inhaled insulin is contraindicated in smokers and patients with chronic lung disease, such as asthma and chronic obstructive pulmonary disease. Spirometry should be performed to identify potential lung disease prior to initiating therapy. During the clinical trials, there were two cases of lung cancer in patients who were taking inhaled insulin and none in the comparator-treated patients. All the patients in whom lung cancer developed had a history of prior cigarette smoking. There were also two cases of squamous cell carcinoma of the lung in nonsmokers exposed to inhaled insulin; these cases occurred after completion of the clinical trials. Cases of lung cancer were also reported in cigarette smokers using a previously available inhaled insulin preparation (Exubera). The incidence rate in the Exubera treated group was 0.13 per 1000 patient years and 0.03 per 1000 patient years in the comparator-treated group.

e. **Pancreas transplantation**—Type 1 patients who are candidates for a kidney transplant should be evaluated for a pancreas transplant. Contraindications include age greater than 55 years old, uncorrectable coronary artery disease; extensive peripheral vacular disease, and significant obesity (weight >100 kg). The pancreas transplant may occur simultaneously (simultaneous pancreas/kidney) or after kidney transplant (pancreas after kidney).

Patients undergoing simultaneous pancreas and kidney transplantation have an 85% chance of pancreatic graft survival at 1 year and 69% at 5 years. Solitary pancreatic transplantation in the absence of a need for renal transplantation should be considered only in those rare patients who fail all other insulin therapeutic approaches and who have frequent severe hypoglycemia or who have life-threatening complications related to their lack of metabolic control. Pancreas transplant alone graft survival is 78% at 1 year and 54% at 5 years.

f. **Islet cell transplantation**—Total pancreatectomy is curative for severe pain syndrome associated with chronic pancreatitis. The pancreatectomy, however, results in surgical diabetes. Harvesting islets from the removed pancreas and autotransplanting them into the liver (via portal vein) can prevent the development of diabetes or result in "mild" diabetes (partial islet function) that is easier to manage. Since the islets are autologous, no immunosuppression is required. The number of islets transplanted is the main predictor of insulin independence.

People with type 1 diabetes can become insulin independent after receiving an islet cell transplant. The islets are isolated from a donor pancreas (alloislet transplant). The

islets are infused into the portal vein using a percutaneous transhepatic approach, and they lodge in the liver releasing insulin in response to physiologic stimuli. Long-term immunosuppression is necessary to prevent allograft rejection and to suppress the autoimmune process that led to the disease in the first place. Insulin independence for more than 5 years has been demonstrated in patients who got anti-CD3 antibody or anti-thymocyte globulin for induction of immunosuppression and calcineurin inhibitors, mTor inhibitors, and mycophenolate mofetil as maintenance immunosuppression. One major limitation is the need for more than one islet infusion to achieve insulin independence. This is because of significant loss of islets during isolation and the period prior to engraftment. Alloislet transplantation is currently an experimental procedure and widespread application will depend on improving insulin independence rates with one infusion and also demonstrating that the long-term outcomes are as good as those of pancreas transplant alone.

STEPS IN THE MANAGEMENT OF THE DIABETIC PATIENT

History and Examination

A complete history is taken and physical examination is performed for diagnostic purposes and to rule out the presence of coexisting or complicating disease. Nutritional status should be noted, particularly if catabolic features such as progressive weight loss are present despite a normal or increased food intake. The family history should include not only the incidence but also the age at onset of diabetes in other members of the family, and it should be noted whether affected family members were obese, whether they required insulin, and whether they developed complications from their diabetes. Other factors that increase cardiovascular risk, such as a smoking history, presence of hypertension or hyperlipidemia, or oral contraceptive pill use should be documented.

A careful physical examination should include baseline height and weight, pulse rate, and blood pressure. If obesity is present, it should be characterized as to its distribution, and a waist-to-hip ratio should be recorded. All peripheral arterial pulses should be examined, noting whether bruits or other signs of atherosclerotic disease are present. Neurologic and ophthalmologic examinations should be performed, with emphasis on investigation of abnormalities that may be related to diabetes, such as neovascularization of the retina or stocking/glove sensory loss in the extremities.

Laboratory Diagnosis

Laboratory diagnosis should include documentation of the presence of fasting hyperglycemia (plasma glucose ≥126 mg/dL [7 mmol/L]), postprandial (post-glucose tolerance test) values consistently greater than or equal to 200 mg/dL (11.1 mmol/L) or HbA_{1c} greater than or equal to 6.5%. An attempt should be made to characterize the diabetes as type 1 or type 2, based on the clinical features present and on whether ketonuria accompanies the glycosuria. For the occasional patient, measurement of ICA 512, GAD, insulin and zinc transporter 8 antibodies can help in distinguishing between type 1 and type 2 diabetes. Many newly diagnosed patients with type 1 diabetes still have significant endogenous insulin production, and C-peptide levels may not reliably distinguish between type 1 and type 2 diabetes. Other baseline laboratory measurements that should be made part of the record include hemoglobin A_{1c}, lipid profile, serum creatinine and electrolytes, complete blood count, electrocardiogram, and urine albumin measurement (type 2 patient).

Patient Education and Self-Management Training

Since diabetes is a lifelong disorder, education of the patient and the family is probably the most important obligation of the clinician who provides initial care. The best persons to manage a disease that is affected so markedly by daily fluctuations in environmental stress, exercise, diet, and infections are the patients themselves and their families. It must be remembered that education is necessary not only for patients with newly diagnosed diabetes and their families, but also for patients with diabetes of any duration who may never have been properly educated about their disorder or who may not be aware of advances in diabetes management. The *teaching curriculum* should include explanations by the physician or nurse of the nature of diabetes and its potential acute and chronic hazards and how they can be recognized early and prevented or treated. Self-monitoring of blood glucose should be emphasized, especially in insulin-requiring diabetic patients, and instructions must be given on proper testing and recording of data. Patients must also be helped to accept the fact that they have diabetes; until this difficult adjustment is made, efforts to cope with the disorder are likely to be futile. Counseling should be directed at avoidance of extremes such as compulsive rigidity or self-destructive neglect.

Patients on insulin should have an understanding of the actions of basal and bolus insulins. They should be taught how to determine whether the basal dose is appropriate and how to adjust the rapidly acting insulin dose for the carbohydrate content of a meal. Patients and their families or friends should also be taught to recognize signs and symptoms of hypoglycemia and how to institute appropriate therapy for hypoglycemic reactions. Strenuous exercise can precipitate hypoglycemia, and patients should know how much to reduce their insulin dosage in anticipation of strenuous activity or to take supplemental carbohydrate. Injection of insulin into a site farthest away from the muscles most involved in exercise may help ameliorate exercise-induced hypoglycemia, since insulin injected in the proximity of exercising muscle may be more rapidly mobilized. Exercise training also increases the effectiveness of insulin and insulin doses should be adjusted accordingly. Because infections, particularly pyogenic ones with fever and toxemia, provoke a marked increase in insulin requirements, patients must be taught how to appropriately administer supplemental rapid-acting insulin as needed to correct hyperglycemia during infections.

Type 2 diabetes on noninsulin medications should be informed about the time of onset, peak action, duration of action, and any

adverse effects of pharmacologic agents being used. They should also learn to inquire about possible drug interactions whenever any new medications are added to their regimens.

The targets for blood glucose control should be elevated appropriately in elderly patients since they have the greatest risk if subjected to hypoglycemia and the least long-term benefit from more rigid glycemic control. Patients should be provided advice on personal hygiene, including detailed instructions on foot and dental care. All infections (especially pyogenic ones) provoke the release of high levels of insulin antagonists such as catecholamines or glucagon and thus bring about a marked increase in insulin requirements. Patients who use oral agents may decompensate and temporarily require insulin. All patients receiving therapy that can cause hypoglycemia should wear a MedicAlert bracelet or necklace that clearly states that insulin or an oral sulfonylurea drug is being taken. Patients should be told about community agencies, such as American Diabetes Association chapters, that can serve as a continuing source of instruction.

Finally, vigorous efforts should be made to persuade new diabetics who smoke to give up the habit, since large vessel peripheral vascular disease and debilitating retinopathy are less common in nonsmoking diabetic patients.

Specific Therapy

A reasonable aim of therapy is to approach normal glycemic excursions without provoking severe or frequent hypoglycemia. Criteria for "acceptable" control includes the following: (1) blood glucose levels of 90 to 130 mg/dL (5-7.2 mmol/L) before meals and after an overnight fast, (2) levels no higher than 180 mg/dL (10 mmol/L) 1 hour after meals and 150 mg/dL (8.3 mmol/L) 2 hours after meals, and (3) HbA$_{1c}$ levels less than 7% for nonpregnant adults. Less stringent HbA$_{1c}$ goals may be appropriate in children, those with a history of severe hypoglycemia, limited life expectancy, and advanced microvascular and macrovascular disease. In the elderly frail patient, an HbA$_{1c}$ target of approximately 8% (preprandial blood glucose levels in the range of the 150-159 mg/dL) may be reasonable although formal evidence is lacking.

A. Type 1 diabetes   At the onset of type 1 diabetes, many patients recover some pancreatic β cell function and may temporarily need only low doses of exogenous insulin to supplement their own endogenous insulin secretion. This is known as the *honeymoon period*. Within 8 weeks to 2 years, however, most of these patients show either absent or negligible pancreatic β cell function. At this point, these patients should be switched to a more flexible insulin regimen with a combination of rapid-acting insulin analogs or regular insulin together with intermediate-acting or long-acting insulin. At a minimum, the patient should be on a three-injection regimen and frequently may need four or more injections. Twice-daily split-dose insulin mixtures cannot maintain near-normalization of blood glucose without hypoglycemia (particularly at night) and are not recommended. Self-monitoring of blood glucose levels is required for determining the optimal adjustment of insulin dosage and the modulation of food intake and exercise in type 1 diabetes.

TABLE 17–15 Examples of intensive insulin regimens using rapid-acting insulin analogs (insulin lispro, aspart, or glulisine) and NPH, or insulin detemir, glargine or degludec in a 70-kg man with type 1 diabetes.[a-c]

	Prebreakfast	Prelunch	Predinner	Bedtime
Rapid-acting insulin analog	5 U	4 U	6 U	—
NPH insulin	3 U	3 U	2 U	8-9 U
OR				
Rapid-acting insulin analog	5 U	4 U	6 U	—
Insulin glargine or degludec	—	—	—	15-16 U
Insulin detemir	6-7 U	—	—	8-9 U

[a]Assumes that patient is consuming approximately 75 g carbohydrate at breakfast, 60 g at lunch, and 90 g at dinner.

[b]The dose of rapid-acting insulin analogs can be raised by 1 or 2 U if extra carbohydrate (15-30 g) is ingested or if premeal blood glucose is >170 mg/dL. The rapid-acting insulin analogs can be mixed in the same syringe with NPH insulin.

[c]Insulin glargine or insulin detemir must be given as a separate injection.

A combination of rapid-acting insulin analogs and long-acting insulins (insulin glargine or insulin detemir or insulin degludec) allows for more physiologic insulin replacement. In clinical studies, combinations of rapid-acting insulin analogs (insulin lispro or insulin aspart) with meals together with intermediate-acting (NPH) or longer-acting insulin (insulin glargine) for basal coverage have now been shown to have improved HbA$_{1c}$ values with less hypoglycemia when compared with a regimen of regular insulin with meals and NPH at night. Table 17–15 illustrates some regimens that might be appropriate for a 70-kg person with type 1 diabetes eating meals of standard carbohydrate intake and moderate to low fat content.

Multiple injections of NPH insulin can be mixed in the same syringe as the insulin lispro, insulin aspart, and insulin glulisine. Insulin glargine or degludec are usually given once in the evening to provide 24-hour coverage. There are occasional patients in whom insulin glargine does not seem to last for 24 hours, and in such cases it needs to be given twice a day. Insulin detemir does not last for 24 hours and usually has to be given twice a day. The long acting insulin analogs cannot be *mixed* with any of the other insulins and must be given as a separate injection.

Continuous subcutaneous insulin infusion by portable battery-operated *open loop* insulin pumps currently provides the most flexible approach, allowing the setting of different basal rates throughout the 24 hours and permitting bolus dose adjustment by as little as 0.05 unit increments. The 24-hour basal dosage is

usually based on age and body weight. An adolescent might need as much as 0.4 U/kg/d; young adult (<25 years) 0.35 U/kg/d; and older adults 0.25 U/kg/d. For example, a 70-kg 30-year-old man may require a basal rate of 0.7 U/h throughout the 24 hours with the exception of 3 AM to 8 AM, when 0.8 U/h might be appropriate (to accomodate the *dawn phenomenon*). The dawn phenomenon is more pronounced in the adolescent and young adult. The meal bolus also varies based on the time of day and the person's age. Adolesecents and young adults usually require 1 unit for about 10 g carbohydrate. Older adults usually require about 1 unit for 15 g carbohydrate. The correction factor—how much insulin is needed to lower glucose levels by 50 mg/dL can be calculated from the insulin-to-carbohydrate ratios. For example, if 1 unit is required for 15 g carbohydrate, then 1 unit will lower glucose levels by 50 mg/dL. If on the other 1.5 units of insulin is required for 15 g of carbohydrate (ie, 1 unit for 10 g carbohydrate), then 1.5 units of insulin will lower glucose levels by 50 mg/dL (ie, 1 unit will lower glucose level by 33 mg/dL). For a 70-kg 30-year-old man, 1 unit per 15 g of carbohydrate plus 1 U for 50 mg/dL of blood glucose above a target value (eg, 120 mg/dL) is a common starting point. Further adjustments to basal and bolus dosages would depend on the results of blood glucose monitoring. Most patients use the rapid-acting insulin analogs in the pumps.

One of the more difficult therapeutic problems in managing patients with type 1 diabetes is determining the proper adjustment of insulin dose when the early morning blood glucose level is high before breakfast (Table 17–16). Prebreakfast hyperglycemia is sometimes due to the *Somogyi effect*, in which nocturnal hypoglycemia evokes a surge of counterregulatory hormones to produce high blood glucose levels by 7 AM. However, a more common cause of prebreakfast hyperglycemia is the waning of the evening or bedtime insulin and/or the dawn phenomenon. That is, reduced tissue sensitivity to insulin between 5 AM and 8 AM (dawn), due to spikes of growth hormone released hours before, at onset of sleep. Table 17–16 shows that diagnosis of the cause of prebreakfast hyperglycemia can be facilitated by self-monitoring of blood glucose at 3 AM in addition to the usual bedtime and 7 AM measurements. This is required for only a few nights, and when a particular pattern emerges from monitoring blood glucose levels overnight, appropriate therapeutic measures can be taken.

Prebreakfast hyperglycemia due to the Somogyi effect can be treated by reducing the dose of either intermediate- or long-acting insulin analog at bedtime. For hyperglycemia due to waning of overnight basal insulin and/or dawn phenomenon, an increase in the evening dose of the basal insulin or shifting it from dinnertime to bedtime (or both) can be effective. A bedtime dose either of insulin glargine or insulin detemir provides more sustained overnight insulin levels than human NPH and may be effective in managing refractory prebreakfast hyperglycemia. If this fails, insulin pump therapy may be required with a higher basal insulin infusion rate (eg, from 0.8 U/h to 0.9 U/h from 6 AM until breakfast).

Metformin use in type 1 diabetes patients has been shown to reduce the total daily insulin doses and promote weight loss but does not improve glucose control. GLP-1 receptor agonists similarly have been demonstrated to promote weight loss and reduce insulin doses in type 1 patients but not improve glucose control.

B. Type 2 diabetes   Therapeutic recommendations are based on the relative contributions of β cell insufficiency and insulin insensitivity in individual patients. The possibility that the individual patient has a specific etiological cause for their diabetes should always be considered, especially when the patient does not have a family history of type 2 diabetes or does not have any evidence of central obesity or insulin resistance. Such patients should be evaluated for other types of diabetes such as LADA or MODY. Patients with LADA should be prescribed insulin when their disease is diagnosed and treated like patients with type 1 diabetes. It is also important to note that many type 2 patients have a progressive loss of β cell function and will require additional therapeutic interventions with time.

Weight reduction—One of the primary modes of therapy in the obese patient with type 2 diabetes is weight reduction. Normalization of glycemia can be achieved by reducing adipose stores, with consequent restoration of tissue sensitivity to insulin. A combination of caloric restriction, increased exercise, modification of behavior, and consistent reinforcement of good eating habits is required if a weight reduction program is to be successful. Understanding the risks and complications of diabetes may motivate the patient to lose weight.

TABLE 17–16 Typical patterns of overnight blood glucose levels and serum-free immunoreactive insulin levels in prebreakfast hyperglycemia due to various causes in patients with type 1 diabetes.

	Blood Glucose Levels (mg/dL)			Serum-Free Immunoreactive Insulin Levels (µU/mL)		
	10 PM	3 AM	7 AM	10 PM	3 AM	7 AM
Somogyi effect	90	40	200	High	Slightly high	Normal
Dawn phenomenon	110	110	150	Normal	Normal	Normal
Waning of circulating insulin levels plus dawn phenomenon	110	190	220	Normal	Low	Low
Waning of circulating insulin levels plus dawn phenomenon plus Somogyi effect	110	40	380	High	Normal	Low

For selected patients, medical or surgical options for weight loss should be considered (also see Chapter 20). Orlistat, phentermine/topiramate, naltrexone/extended-release bupropion, and high-dose liraglutide (3 mg daily) are weight loss medications approved for use in combination with diet and exercise.

Orlistat is a reversible inhibitor of gastric and pancreatic lipases and prevents the hydrolysis of dietary triglycerides. These triglycerides are then excreted in the feces. In a 1-year study in obese patients with type 2 diabetes, those taking orlistat had lost more weight, had lower HbA$_{1c}$ values, and had improved lipid profiles. The main adverse reactions were gastrointestinal, with oily spotting, oily stool, flatus, and fecal urgency and frequency. Malabsorption of fat-soluble vitamins also occurs. Patients should take a multivitamin tablet containing fat-soluble vitamins at least 2 hours before or 2 hours after the administration of orlistat. Cases of severe liver injury have been reported with this drug although a cause and effect relationship has not been established.

Phentermine is a sympathomimetic amine that stimulates release of norepinephrine in the hypothalamus. Topiramate is primarily used as an anticonvulsant, but it also appears to reduce appetite. In a 56-week phase 3 study, an extended-release preparation of phentermine/topiramate (Qsymia), together with diet and lifestyle intervention, resulted in 10 kg weight loss (9.8%) compared to 1.4 kg (1.2%) with placebo. As might be expected, the diabetes subgroup on active therapy had greater reductions in HbA$_{1c}$ levels and fewer patients with prediabetes on active therapy progressed to diabetes. The adverse events are consistent with those of the constituent drugs. The most common adverse reactions were paresthesia, dizziness, dysgeusia, insomnia, constipation, and dry mouth. Topiramate can worsen depression and increase risk of suicidal thoughts. It is also teratogenic and the FDA has required the manufacturer to conduct a risk evaluation and mitigation strategy (REMS). The medication is only available through specialty mail-order pharmacies.

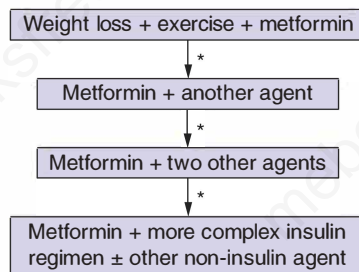
Lorcaserin (Belviq) is a 5-hydroxytryptamine receptor subtype 2C (5-HT2C) agonist. This receptor subclass regulates mood and appetite. In a 52-week study, patients taking lorcaserin had a 8.1-kg weight loss (8.2%) compared to 3.2 kg in the placebo group (3.3%). The main adverse reactions were headache and nausea. Fenfluramine, an agonist for the 5-HT2B receptor, was associated with serotonin-related cardiac valvulopathy. Activation of the 5-HT2C receptor, however, does not appear to be associated with valvulopathy. Sibutramine, a combined serotonin-norepinephrine reuptake inhibitor, was moderately effective in promoting weight loss, but it was withdrawn from the U.S. market because of its association with increased cardiovascular risk.

Naltrexone is an antagonist at mu- and kappa-opioid receptors and is used in the treatment of alcohol and opioid dependence. Bupropion is a partial agonist at the mu-opioid receptor, an antagonist at the kappa-opioid receptor and a partial agonist at the nociception receptor; it is used to treat depression, seasonal affective disorder, and as an aid to stop smoking. Naltrexone/extended-release bupropion (Contrave), together with diet and exercise in patients with diabetes, resulted in 2% more weight loss than placebo at 1 year of study. The weight loss with the medication was greater in the study of obese people without diabetes (4.1%). Serious neuropsychiatric events and seizures have been reported in patients taking bupropion. Naltrexone should not be given to patients receiving long-term opioid therapy. Naltrexone/extended bupropion should be discontinued if the patient needs intermittent opiate therapy. Patients should be warned that they may be more sensitive to opiates after the naltrexone/extended bupropion preparation has been discontinued.

Liraglutide 3 mg (Saxenda) is a GLP-1 receptor agonist. The 0.6 to 1.8 mg dose has been approved for the treatment of type 2 diabetes and is associated with modest weight loss. The 3-mg dose has been approved for weight loss in combination with diet and exercise. In nondiabetic obese persons, liraglutide together with diet and exercise resulted in 4.5% more weight loss than placebo at 1 year of treatment. In a study of people with diabetes, the average weight loss with the medication was 3.7% compared to placebo at 1 year. Common adverse reactions include nausea, vomiting, and diarrhea. Serious side effects include pancreatitis. The medication should not be used in patients with MEN 2 or personal or family history of medullary thyroid cancer.

Bariatric surgery (Roux-en-Y, gastric sleeve, biliopancreatic diversion/duodenal switch, or gastric banding) typically result in substantial weight loss, and improvement in glucose levels. A meta-analysis examining the impact of bariatric surgery on patients with diabetes and BMI of 40 kg/m^2 or greater noted that 82% of patients had resolution of clinical and laboratory manifestations of diabetes in the first 2 years after surgery and 62% remained free of diabetes more than 2 years after surgery. The improvement was most marked in the procedure that caused the greatest weight loss (biliopancreatic diversion/duodenal switch). There was, however, a high attrition of patients available for follow-up, and there was little information about different ethnic types. Weight regain does occur after bariatric surgery, and it can be expected that 20% to 25% of the lost weight will be regained over 10 years. The impact of this weight gain on diabetes recurrence depends principally on the degree of beta cell dysfunction. Also anatomic changes imposed by malabsorptive surgery can result in protein malnutrition, vitamin, and mineral deficiencies. Clinically significant deficiencies in calcium, folic acid, iron, and vitamins D, B$_{12}$, A, and K are common. Thus, patients undergoing malabsorptive procedures require lifelong supplementation and monitoring by a team familiar with possible deficiencies. Both early and late dumping symptoms can also occur.

Nonobese patients with type 2 diabetes frequently have increased visceral adiposity—the so-called metabolically obese normal-weight patient. There is less emphasis on weight loss but exercise remains an important aspect of treatment.

Antihyperglycemic agents—Figure 17–13 outlines the treatment approach based on the consensus algorithm proposed by the American Diabetes Association and the European Association for the Study of Diabetes. The current recommendation is to start metformin therapy at diagnosis and not wait to see if the patient can achieve target glycemic control with weight management and exercise. **Metformin** is advantageous because, apart from lowering glucose without the risk of hypoglycemia, it also lowers triglycerides and promotes some modest weight loss. The drug, however,


*If needed to reach individualized HbA_{1c} target after ~3 months

Seven main classes of agents: metformin, sulfonylureas (includes nateglinide, repaglinide), thiazolidinediones, GLP-1 receptor agonists, DPP-4 inhibitors, SGLT2 inhibitors, insulins (alpha-glucosidase inhibitors, colesevelam, pramlintide, bromocriptine not included because of limited efficacy and significant adverse reactions).

In making a therapeutic decision (single agent or in combination) take into account efficacy; hypoglycemia risk; effect on weight; major side effects; cost. The DPP-4 inhibitors are of moderate efficacy whereas all the other agents are of high efficacy. Sulfonylureas and insulins have increased risk of hypoglycemia. Metformin and DPP-4 inhibitors are weight neutral; GLP-1 receptor agonists, SGLT2 inhibitors promote weight loss; and sulfonylureas, insulins and thiazolidinediones are associated with weight gain. Metformin can cause lactic acidosis. Thiazolidinediones are associated with fluid retention, fracture risk and possibly bladder cancer. GLP-1 receptor agonists are associated with nausea and vomiting and possibly pancreatitis. DPP-4 inhibitors may increase pancreatitis risk. SGLT inhibitors are associated with genital mycotic infections, urinary tract infections, and hypotension. All the agents with the exception of metformin and sulfonylureas are expensive. Insulins are expensive if you take into consideration the additional costs of monitoring.

FIGURE 17–13 Suggested algorithm for the treatment of type 2 diabetes based partly on the recommendations of the consensus panel of the American Diabetes Association/European Association for the Study of Diabetes. (Data from Inzucchi SE, Bergenstal RM, Buse JB, et al. Management of hyperglycaemia in type 2 diabetes, 2015: a patient-centred approach. Update to a position statement of the American Diabetes Association and the European Association for the Study of Diabetes. *Diabetologia*. 2015 Mar;58(3):429-442.)

cannot be used in patients with renal or liver failure, and some patients have gastrointestinal side effects at even the lowest doses. Under these circumstances the choice of the initial agent depends on a number of factors, including comorbid conditions, adverse reactions to the medications, ability of the patient to monitor for hypoglycemia, drug cost, and patient and physician preferences.

Sulfonylureas have been available for many years, and their use in combination with metformin is well established. They do, however, have the propensity to cause hypoglycemia and weight gain. **Thiazolidinediones** improve peripheral insulin resistance and lower glucose without causing hypoglycemia. They also have been reported to improve nonalcoholic fatty liver disease. In addition, they have beneficial effects on the lipid profile and some other cardiovascular risk factors. They decrease microalbuminuria, and reduce neointimal tissue hyperplasia after coronary artery stent placement. Thiazolidinediones, however, can cause fluid retention and are contraindicated in patients with heart failure. They also very commonly increase weight, which patients find distressing, affecting adherence. The drugs are associated with increased fracture risk in women and this adverse effect significantly limits their use. Both drugs are contraindicated in patients with active liver disease and in patients with liver enzyme levels more than or equal to 2.5 times the upper limit of normal. The

α-glucosidase inhibitors have modest glucose-lowering effects and have gastrointestinal side effects. They have a lower risk of hypoglycemia than the sulfonylureas and promote weight loss. The GLP-1 receptor agonists have a lower risk of hypoglycemia than the sulfonylureas, and they promote weight loss. However, they need to be given by injection, cause nausea, may cause pancreatitis, and are contraindicated in patients with gastroparesis. The DPP-4 inhibitors also have a low risk of hypoglycemia, and they do not cause nausea or vomiting. They can also be used in patients with kidney impairment. There are, however, reports of serious allergic reactions, including anaphylaxis, angioedema, and Stevens-Johnson syndrome. There is concern that they, like the GLP-1 receptor agonists, may cause pancreatitis. The SGLT2 inhibitors lower fasting and postprandial glucose levels. They also have a low risk of hypoglycemia, promote weight loss, and lower blood pressure levels. They increase the risk for mycotic genital infections, urosepsis and possibly fractures. They can also cause volume depletion and are less effective in patients with kidney disease.

When patients are not well controlled on their initial therapy (usually metformin) then a second agent should be added. In those patients where the problem is hyperglycemia after a carbohydrate-rich meal (such as dinner), a short-acting secretagogue

before meals may suffice to put the glucose levels into the target range. Patients with severe insulin resistance or nonalcoholic fatty liver disease or microalbuminuria may be candidates for a thiazolidinedione. Subjects who are very concerned about weight gain may benefit from a trial of a GLP-1-receptor agonist, DPP-4 inhibitor, or SGLT2 inhibitor. If two agents are inadequate, then a third agent is added, although data on efficacy with such combined therapy are limited. When the combination of oral agents (and injectable GLP-1 receptor agonists) fail to achieve target glycemic control in patients with type 2 diabetes or if there are contraindications to their use, then insulin treatment should be instituted. Various insulin regimens may be effective. One proposed regimen is to continue the oral combination therapy and then simply add a bedtime dose of NPH or long-acting insulin analog to reduce excessive nocturnal hepatic glucose output and improve fasting glucose levels. If the patient does not achieve target glucose levels during the day, then daytime insulin treatment can be initiated. A convenient insulin regimen under these circumstances is a split dose of 70/30 NPH/regular mixture (or Humalog Mix 75/25 or NovoLogMix 70/30) before breakfast and before dinner. If this regimen fails to achieve satisfactory glycemic goals or is associated with unacceptable frequency of hypoglycemic episodes, then a more intensive regimen of multiple insulin injections can be instituted as in patients with type 1 diabetes. Metformin principally reduces hepatic glucose output, and it is reasonable to continue with this drug when insulin therapy is instituted. The thiazolidinediones, which improve peripheral insulin sensitivity, can be used together with insulin, but this combination is associated with more weight gain and peripheral edema. The sulfonylureas, the GLP-1-receptor agonists, and the DPP-4 inibitors also have been shown to be of continued benefit. Weight-reducing interventions should continue even after initiation of insulin therapy and may allow for simplification of the therapeutic regimen in the future.

IMMUNOPATHOLOGY OF INSULIN THERAPY

At least five molecular classes of insulin antibodies are produced during the course of insulin therapy: IgA, IgD, IgE, IgG, and IgM. Human insulin is much less antigenic than the older formulations of animal (especially beef) insulins, but because of its hexameric presentation at therapeutic injection doses, it is also treated as a foreign substance by the immune system and results in detectable—albeit low—titers of insulin antibodies in most patients.

A. Insulin allergy   Insulin allergy, a hypersensitivity reaction of the immediate type, is a rare condition in which local or systemic urticaria occurs immediately after insulin injection. This reaction is due to histamine release from tissue mast cells sensitized by adherence of IgE antibodies to their surface. In severe cases, anaphylaxis can occur. The appearance of a subcutaneous nodule at the site of insulin injection, occurring several hours after the injection and lasting for up to 24 hours, has been attributed to an IgG-mediated complement-binding Arthus reaction. The

sensitivity can be to the insulin or to the additives–protamine or cresol. Because sensitivity was often due to noninsulin protein contaminants, the highly purified insulins have markedly reduced the incidence of insulin allergy, especially of the local variety. Antihistamines, corticosteroids, and even desensitization may be required, especially for systemic hypersensitivity in an insulin-dependent patient. Rituximab followed by Omalizumab was reported to be successful in one patient with severe refractory insulin allergy. A trial of insulin analogs should also be considered. There is a case report of successful use of insulin lispro in the face of generalized allergy to human insulin.

B. Immune insulin resistance   All patients who receive insulin (including insulin analogs) develop a low titer of circulating IgG antibodies, and this neutralizes the rapid action of insulin to a small extent. With the animal insulins, a high titer of circulating antibodies is sometimes developed, resulting in extremely high insulin requirements, often to more than 200 U/d. This is now very rarely seen with the switch to the highly purified human insulins and has not been reported with use of the analogs.

C. Lipodystrophy at injection sites   Rarely, a disfiguring atrophy of subcutaneous fatty tissue occurs at the site of insulin injection. Although the cause of this complication is obscure, it seems to represent a form of immune reaction, particularly because it occurs predominantly in females and is associated with lymphocyte infiltration in the lipoatrophic area. This complication has become even less common because of the development of highly purified insulin preparations of neutral pH. Injection of highly purified preparations of insulin directly into the atrophic area often results in restoration of normal contours.

Lipohypertrophy, on the other hand, is not a consequence of immune responses; rather, it seems to be due to the pharmacologic effects of depositing insulin in the same location repeatedly (Figure 17–14). It is prevented by rotation of injection sites. There is a

FIGURE 17–14 Lipohypertrophy due to overuse of insulin infusion sites.

case report of a male patient who had intractable lipohypertrophy (fatty infiltration of injection site) with human insulin but no longer had the problem when he switched to insulin lispro.

ACUTE COMPLICATIONS OF DIABETES MELLITUS

Hypoglycemia

Hypoglycemic reactions (see Chapter 18) are the most common complications that occur in patients with diabetes who are treated with insulin. It can also occur in any patient taking oral agents that stimulate pancreatic β cells (eg, sulfonylureas, meglitinide, D-phenylalanine analogs), particularly if the patient is elderly and has renal or liver disease. It occurs more frequently with the use of long-acting sulfonylureas.

The signs and symptoms of hypoglycemia may be divided into those resulting from stimulation of the autonomic nervous system and those arising from neuroglycopenia (insufficient glucose for normal central nervous system function). When the blood glucose falls to around 54 mg/dL (3 mmol/L), the patient starts to experience both sympathetic (tachycardia, palpitations, sweating, tremulousness) and parasympathetic (nausea, hunger) nervous system symptoms. If these autonomic symptoms are ignored and the glucose levels fall further (to around 50 mg/dL [2.8 mmol/L]), then neuroglycopenic symptoms appear, including irritability, confusion, blurred vision, tiredness, headache, and difficulty speaking. A further decline in glucose (below 30 mg/dL [1.7 mmol/L]) can then lead to loss of consciousness or even a seizure.

With repeated episodes of hypoglycemia, there is adaptation and autonomic symptoms do not occur until the blood glucose levels are much lower and so the first symptoms are often due to neuroglycopenia. This condition, which is referred to as **hypoglycemic unawareness**, results from failure of the sympathetic nervous system to respond to hypoglycemia (Table 17–17). This adaptation of the central nervous system to recurrent hypoglycemic episodes is due to changes in glucose transportation or metabolism. It has been shown that hypoglycemic unawareness can be reversed by keeping glucose levels high for a period of several weeks. Except for sweating, most of the sympathetic symptoms of hypoglycemia are blunted in patients receiving β-blocking agents for angina pectoris or hypertension. Though not absolutely contraindicated, these drugs must be used with caution in insulin-requiring diabetics, and β₁-selective blocking agents are preferred.

Hypoglycemia in insulin-treated patients with diabetes occurs as a consequence of three factors: behavioral issues, impaired counterregulatory systems, and complications of diabetes.

Behavioral issues include injecting too much insulin for the amount of carbohydrates ingested. Drinking alcohol in excess, especially on an empty stomach, can also cause hypoglycemia. In patients with type 1 diabetes, hypoglycemia can occur during or even several hours after exercise, and so glucose levels need to be monitored and food and insulin adjusted. Some patients do not like their glucose levels to be high, and they treat every high glucose level aggressively. These individuals who *stack* their insulin, that is, give another dose of insulin before the first injection has had its full action, can develop hypoglycemia.

Counterregulatory issues resulting in hypoglycemia include impaired glucagon response and impaired sympathoadrenal responses (Table 17–18). Patients with diabetes of greater than 5 years duration lose their glucagon response to hypoglycemia. As a result, they are at a significant disadvantage in protecting themselves against falling glucose levels. Once the glucagon response is lost, their sympathoadrenal responses take on added importance. Unfortunately, aging, autonomic neuropathy, or hypoglycemic unawareness due to repeated low glucose levels further blunts the sympathoadrenal responses. Occasionally, Addison disease develops in persons with type 1 diabetes mellitus; when this happens, insulin requirements fall significantly, and unless insulin dose is reduced, recurrent hypoglycemia will develop.

TABLE 17–17 Hypoglycemic "unawareness" in type 1 diabetes mellitus.

I. Sleeping patient (nocturnal hypoglycemia)
II. Hypoglycemia with unawareness while awake
   A. Manifestations
     a. Neuroglycopenic symptoms first (weakness, lethargy, confusion, incoordination, blurred vision)
     b. Autonomic symptoms are delayed and blunted (tremor, anxiety, palpitations, sweating, hunger)
   B. Mechanisms
     1. Defective autonomic response:
       a. Adaptation to chronic hypoglycemia (increased brain glucose transporter I)
       b. Due to diabetic autonomic neuropathy
   C. Management
     1. Identify patients at risk and reevaluate glycemic goals
     2. Advise frequent self-monitoring of blood glucose; use of continuous glucose monitoring systems
     3. Learn to detect subtle symptoms of neuroglycopenia
     4. Avoid recurrent hypoglycemia
     5. Injectable glucagon made available to family

TABLE 17–18 Counterregulatory responses to hypoglycemia.

Normal Counterregulation	Defective Counterregulation in Type 1 Diabetes[a]
Glucagon rises rapidly to three to five times baseline after insulin-induced hypoglycemia, provoking hepatic glycogenolysis	Glucagon response to insulin-induced hypoglycemia is lost after onset of type 1 diabetes
Adrenergic discharge (1) raises hepatic glucose output by glycogenolysis and (2) provides warning to subject of impending hypoglycemic crisis	Blunted or absent adrenergic response may occur as a result of: (1) Neural damage associated with advanced age or autonomic neuropathy (2) Neural dysfunction (iatrogenic) from frequent hypoglycemia

[a]Type 2 diabetics are less well characterized as to their defective counterregulation of glucagon loss, but appear to have the same frequency and causes of adrenergic loss as do type 1 diabetics.

Complications of diabetes that increase the risk for hypoglycemia include autonomic neuropathy, gastroparesis, and renal failure. The sympathetic nervous system is an important system alerting the individual that the glucose level is falling by causing symptoms of tachycardia, palpitations, sweating, and tremulousness. Failure of the sympathoadrenal responses increases the risk of hypoglycemia. In patients with gastroparesis, insulin given before a meal promotes maximal glucose uptake into cells before the food is absorbed, causing the glucose levels to fall. Finally, in renal failure, hypoglycemia can occur presumably because of decreased insulin clearance as well as loss of the renal contribution to gluconeogenesis in the postabsorptive state.

To treat insulin-induced hypoglycemia, the diabetic patient should carry glucose tablets or juice at all times. For most episodes, ingestion of 15 g of carbohydrate is sufficient to reverse the hypoglycemia. The patient should be instructed to check the blood glucose in 15 minutes and treat again if the glucose level is still low.

A parenteral glucagon emergency kit (1 mg) should be provided to every patient with diabetes who is on insulin therapy. Family or friends should be instructed how to inject it subcutaneously or intramuscularly into the buttock, arm, or thigh in the event that the patient is unconscious or refuses food. The drug can occasionally cause vomiting and the unconscious patient should be turned on his or her side to protect the airway. Glucagon mobilizes glycogen from the liver raising the blood glucose by about 36 mg/dL (2 mmol/L) in about 15 minutes. After the patient recovers consciousness additional oral carbohydrate should be given. Glucagon is contraindicated in sulfonylurea-induced hypoglycemia where it paradoxically causes insulin release. People with diabetes on hypoglycemic drug therapy should also wear a MedicAlert bracelet or necklace or carry a card in his or her wallet.

Medical personnel treating severe hypoglycemia can give 50 mL of 50% glucose solution by rapid intravenous infusion. If intravenous therapy is not available, 1 mg of glucagon can be injected intramuscularly. If the patient is stuporous and glucagon is not available, small amounts of honey or maple syrup or glucose gel (15 g) can be inserted within the buccal pouch, although, in general, oral feeding is contraindicated in unconscious patients. Rectal administration of maple syrup or honey (30 mL per 500 mL of warm water) has been effective.

Most patients who arrive at emergency departments in hypoglycemic coma appear to recover fully; however, profound hypoglycemia or delays in therapy can result in permanent neurologic deficit or even death. Furthermore, repeated episodes of hypoglycemia may have a cumulative adverse effect on intellectual functioning. The physician should carefully review with the patient the events leading up to the hypoglycemic episode. Associated use of other medications, as well as alcohol or narcotics, should be noted. Careful attention should be paid to diet, exercise pattern, insulin or sulfonylurea dosage, and general compliance with the prescribed diabetes treatment regimen. Any factors thought to have contributed to the development of the episode should be identified and recommendations made in order to prevent recurrences of this potentially disastrous complication of diabetes therapy.

If the patient is hypoglycemic from use of a long-acting oral hypoglycemic agent (eg, chlorpropamide or glyburide) or from high doses of a long-acting insulin, admission to hospital for treatment with continuous intravenous glucose and careful monitoring of blood glucose is indicated.

Coma

Coma is a *medical emergency* calling for immediate evaluation to determine its cause so that proper therapy can be started. Patients with diabetes may be comatose because of hypoglycemia, diabetic ketoacidosis, hyperglycemic hyperosmolar coma, or lactic acidosis. When evaluating a comatose diabetic patient, these must be considered *in addition* to the myriad causes included in the differential diagnosis of coma (eg, cerebrovascular accidents, head trauma, intoxication with alcohol, or other drugs).

After emergency measures have been instituted (airway protection; laboratory tests; intravenous dextrose unless fingerstix blood glucose shows hyperglycemia), a careful history (from family, friends, or paramedics), physical examination, and laboratory evaluation are required to resolve the differential diagnosis. Patients in deep coma from a hyperosmolar nonketotic state or from hypoglycemia are generally flaccid and have quiet breathing—in contrast to patients with acidosis, whose respirations are rapid and deep if the pH of arterial blood has dropped to 7.1 or below. When hypoglycemia is a cause of the coma, the state of hydration is usually normal. Although the clinical laboratory remains the final arbiter in confirming the diagnosis, a rapid *estimate* of blood glucose and ketones can be obtained by the use of bedside glucose and ketone meters (see Laboratory Findings in diabetes mellitus, discussed earlier). Table 17–19 is a summary of some laboratory abnormalities found in diabetic patients with coma attributable to diabetes or its treatment.

1. DIABETIC KETOACIDOSIS

This acute complication of diabetes mellitus may be the first manifestation of previously undiagnosed type 1 diabetes or may result from increased insulin requirements in type 1 diabetes patients during the course of infection, trauma, myocardial infarction, or surgery. The National Data Group reports an annual incidence of five to eight episodes of diabetic ketoacidosis per 1000 diabetic patients. In all cases, precipitating factors such as infection should be searched for and treated appropriately. Poor compliance, either for psychological reasons or because of inadequate patient education, is probably the most common cause of recurrent diabetic ketoacidosis.

Diabetic ketoacidosis has been found to be one of the more common serious complications of insulin pump therapy, occurring in approximately 1 per 80 patient-months of treatment.

Patients with type 2 diabetes may also develop ketoacidosis under severe stress such as sepsis, trauma, or major surgery.

Pathogenesis

Acute insulin deficiency results in rapid mobilization of energy from stores in muscle and fat depots, leading to an increased flux

TABLE 17–19 Summary of some laboratory abnormalities in patients with coma directly attributable to diabetes or its treatment.

	Urine		Plasma			
	Glucose	**Ketones**	**Glucose**	**Bicarbonate**	**Ketones**	**Osmolality**
Diabetic ketoacidosis	++ to ++++	++++	High	Low	++++	+++
Hyperglycemic nonketotic coma	++ to ++++	0 or +[a]	High	Normal or slightly low[b]	0	++++
Hypoglycemia	0[c]	0 or +	Low	Normal	0	Normal
Lactic acidosis	0 to +	0 or +	Normal, low, or high	Low	0 or +	Normal

[a]A small degree of ketonuria may be present if the patient is severely stressed or has not been eating because of illness.

[b]A patient may be acidotic if there is severe volume depletion with cardiovascular collapse or if sepsis is present.

[c]Leftover urine in bladder might still contain sugar from earlier hyperglycemia.

of amino acids to the liver for conversion to glucose and of fatty acids for conversion to ketones (acetoacetate, β-hydroxybutyrate, and acetone). In addition to this increased availability of precursor, there is a direct effect of the low insulin-glucagon ratio on the liver that promotes increased production of ketones as well as of glucose. In response to both the acute insulin deficiency and the metabolic stress of ketosis, the levels of insulin-antagonistic hormones (corticosteroids, catecholamines, glucagon, and GH) are consistently elevated. Furthermore, in the absence of insulin, peripheral utilization of glucose and ketones is reduced. The combination of increased production and decreased utilization leads to an accumulation of these substances in blood, with plasma glucose levels reaching 500 mg/dL (27.8 mmol/L) or more and plasma ketones reaching levels of 8 to 15 mmol/L or more. β-Hydroxybutyrate is the predominant ketone and its ratio to acetoacetate increases from 1:1 to as much as 5:1.

The hyperglycemia causes osmotic diuresis leading to depletion of intravascular volume. As this progresses, impaired renal blood flow reduces the kidney's ability to excrete glucose, and hyperosmolality worsens. Severe hyperosmolality (>330 mOsm/kg) correlates closely with central nervous system depression and coma.

In a similar manner, impaired renal excretion of hydrogen ions aggravates the metabolic acidosis that occurs as a result of the accumulation of the ketoacids, β-hydroxybutyrate, and acetoacetate. The accumulation of ketones may cause vomiting, which exacerbates the intravascular volume depletion. In addition, prolonged acidosis can compromise cardiac output and reduce vascular tone. The result may be severe cardiovascular collapse with generation of lactic acid, which then adds to the already existent metabolic acidosis.

Clinical Features

A. Symptoms and signs

The appearance of diabetic ketoacidosis is usually preceded by a day or more of polyuria and polydipsia associated with marked fatigue, nausea, and vomiting. Eventually, mental stupor ensues and can progress to frank coma. On physical examination, evidence of dehydration in a stuporous

patient with rapid and deep respirations and the *fruity* breath odor of acetone strongly suggest the diagnosis. Postural hypotension with tachycardia indicates profound dehydration and salt depletion. Abdominal pain and even tenderness may be present in the absence of abdominal disease, and mild hypothermia is usually present.

B. Laboratory findings

Typically, the patient with moderately severe diabetic ketoacidosis has a plasma glucose of 350 to 900 mg/dL (19.4-50 mmol/L), serum ketones are positive at a dilution of 1:8 or greater and β-hydroxybutyrate levels are 4 mmol/L or higher, hyperkalemia of 5 to 8 mEq/L, slight hyponatremia of approximately 130 mEq/L, hyperphosphatemia of 6 to 7 mg/dL, and an elevated blood urea nitrogen and creatinine. Acidosis may be severe (pH ranging from 6.9-7.2 with a bicarbonate concentration ranging from 5 to 15 mEq/L); pCO_2 is low (15-20 mm Hg) secondary to hyperventilation. The difference between venous and arterial pH is 0.02 to 0.15 pH units and the difference in venous and arterial bicarbonate is 1.88 mEq/L. These small differences will not affect either the diagnosis or the management of diabetic ketoacidosis, and there is no need to collect arterial blood for measuring the acid-base status. The fluid depletion is typically about 100 mL/kg.

The hyperkalemia occurs despite total body potassium depletion, because of the shift of potassium from the intracellular to extracellular spaces in systemic acidosis. The average total body potassium deficit resulting from osmotic diuresis, acidosis, and gastrointestinal losses is about 3 to 5 mEq/kg body weight. Similarly, despite the elevated serum phosphate, total body phosphate is generally depleted. Serum sodium is generally reduced, due to loss of sodium ions by polyuria and vomiting (7-10 mEq/kg), and because severe hyperglycemia shifts intracellular water into the extracellular compartment (for every 100 mg/dL of plasma glucose above normal, serum sodium decreases by 1.6 mEq/L [5.56 mmol/L]). Hypertriglyceridemia should be considered if the corrected sodium is very low. Serum osmolality can be directly measured by standard tests of freezing point depression or can be

estimated by calculating the molarity of sodium, chloride, and glucose in the serum. A convenient formula for estimating *effective* serum osmolality is:

$$mOsm/kg = 2[measured\ Na^+] + \frac{Glucose\ (mg/dL)}{18}$$

The effective serum osmolality in humans is generally between 280 and 300 mOsm/kg. These calculated estimates are usually 10 to 20 mOsm/kg lower than values recorded by standard cryoscopic techniques. Central nervous depression or coma occurs when the effective serum osmolality exceeds 320 to 330 mOsm/L.

Blood urea nitrogen and serum creatinine are invariably elevated because of dehydration. Urea exerts an effect on freezing point depression as measured in the laboratory, but it is freely permeable across cell membranes and therefore not included in calculations of effective serum osmolality. Serum creatinine may also be falsely elevated due to interference from acetoacetate with some automated creatinine assays. However, most laboratories can correct for these interfering chromogens by using a more specific method, if asked to do so.

The nitroprusside reagents (Acetest and Ketostix) used for the bedside assessment of ketoacidemia and ketoaciduria measure only acetoacetate and its by-product, acetone. The sensitivity of these reagents for acetone, however, is quite poor, requiring over 10 mmol/L. This level is seldom reached in the plasma of ketoacidotic subjects—although this detectable concentration is readily achieved in urine. Thus, in the plasma of ketotic patients, only acetoacetate is measured by these reagents. The more prevalent β-hydroxybutyrate has no ketone group and is therefore not detected by the conventional nitroprusside tests. This takes on special importance in the presence of circulatory collapse during diabetic ketoacidosis, wherein an increase in lactic acid can shift the redox state to increase β-hydroxybutyrate at the expense of the readily detectable acetoacetate. Bedside diagnostic reagents would then be unreliable, suggesting no ketonemia in cases where β-hydroxybutyrate is a major factor in producing the acidosis. Combined bedside glucose and ketone meters (Precision Xtra, Nova Max Plus) that measure blood β-hydroxybutyrate concentration on capillary blood are now available. Many clinical laboratories also offer direct blood β-hydroxybutyrate measurement.

Nonspecific elevations of serum amylase and lipase occur in about 16% to 25% of cases of diabetic ketoacidosis, and an imaging study may be necessary if the diagnosis of acute pancreatitis is being seriously considered. Leukocytosis as high as 25,000/mL with a left shift may occur with or without associated infection. The presence of an elevated or even a normal temperature would suggest the presence of an infection, since patients with diabetic ketoacidosis are generally hypothermic if uninfected.

Treatment

Patients with mild DKA are alert and have pH between 7.25 and 7.30 and β-hydroxybutyrate levels of 3 to 4 mmol/L; those with moderate DKA are alert or slightly drowsy and have pH between 7.0 and 7.24 and β-hydroxybutyrate levels of 4 to 8 mmol/L; and those with severe DKA are stuporous, have pH less than 7.0 and β-hydroxybutyrate levels of greater than 8 mmol/L. Those with mild DKA can be treated in the emergency room, but those with moderate or severe DKA require admission to the intensive care unit or step-down unit.

The therapeutic goals are to restore plasma volume and tissue perfusion; reduce blood glucose and osmolality toward normal; correct acidosis; replenish electrolyte losses; and identify and treat precipitating factors. Gastric intubation is recommended in the comatose patient to prevent vomiting and aspiration that may occur as a result of gastric atony, a common complication of diabetic ketoacidosis. In patients with preexisting cardiac or renal failure or those in severe cardiovascular collapse, a central venous pressure catheter or a Swan-Ganz catheter should be inserted to evaluate the degree of hypovolemia and to monitor subsequent fluid administration.

A comprehensive flow sheet that includes vital signs, serial laboratory data, and therapeutic interventions (eg, fluids, insulin) should be meticulously maintained by the clinician responsible for the patient's care. Plasma glucose should be recorded hourly and electrolytes and pH at least every 2 to 3 hours during the initial treatment period. A bedside glucose meter should be used to titrate the insulin therapy. The patient should not receive sedatives or opioids in order to avoid masking signs and symptoms of impending cerebral edema.

1. **Fluid replacement.** In most adult patients, the fluid deficit is 4 to 5 L. Once the diagnosis of diabetic ketoacidosis is established in the emergency department, administration of at least 2 L of isotonic saline (0.9% saline solution) in an adult patient in the first 2 to 3 hours is necessary to help restore plasma volume and stabilize blood pressure while acutely reducing the hyperosmolar state. In addition, by improving renal plasma flow, fluid replacement also restores the renal capacity to excrete hydrogen ions, thereby ameliorating the acidosis as well. After the first 2 L of fluid have been given, the intravenous infusion should be at a rate of 300 to 400 mL/h. Use 0.9% saline unless the serum sodium is greater than 150 mEq/L when 0.45% ("half normal") saline should be used. Failure to give sufficient volume replacement (at least 3-4 L in 8 hours) to restore normal perfusion is one of the most serious therapeutic shortcomings affecting satisfactory recovery. In the same way, excessive fluid replacement (>5 L in 8 hours) may contribute to acute respiratory distress syndrome or cerebral edema. When blood glucose falls to approximately 250 mg/dL (13.9 mmol/L), the fluids should be changed to a 5% glucose containing solution to maintain plasma glucose in the range of 250 to 300 mg/dL (13.9-16.7 mmol/L). This prevents the development of hypoglycemia and also reduces the likelihood of cerebral edema, which may result from a too rapid decline of blood glucose.

2. **Insulin treatment.** Immediately after the initiation of fluid replacement and determination that the patient's serum potassium is more than 3.5 mEq/L, a bolus of 0.1 U/kg can be given intravenously to prime the tissue insulin receptors. This inhibits both gluconeogenesis and ketogenesis while promoting utilization of glucose and keto acids. Following the initial bolus, an intravenous insulin infusion is initiated at a rate of 0.1 U/kg/h. A prospective randomized study showed that a bolus dose is not required if patients are given insulin infusion

at a rate of 0.14 U/kg/h. When a continuous infusion of insulin is used, 25 U of regular human insulin should be placed in 250 mL of isotonic saline and the first 50 mL of solution flushed through to saturate the tubing before connecting it to the intravenous line. The insulin infusion should be piggy-backed into the fluid line so that the rate of fluid replacement can be changed without altering the insulin delivery rate. If the plasma glucose level fails to fall at least 10% in the first hour, a repeat loading dose (0.1 or 0.14 U/kg) is recommended. Rarely, a patient with insulin resistance is encountered; this requires doubling the insulin dose every 2 to 4 hours if severe hyperglycemia does not improve after the first two doses of insulin and fluid replacement. The insulin dose should be adjusted with the goal of lowering the glucose concentration by about 50 to 70 mg/dL/h (2.8-3.9 mmol/L). If clinical circumstances prevent use of insulin infusion, then the insulin can be given intramuscularly. An initial 0.1 U/kg of regular insulin is given intravenously, and at the same time, the same size dose is given intramuscularly. Subsequently, regular insulin is given intramuscularly hourly at a dose of 0.1 U/kg until the blood glucose falls to around 250 mg/dL, when the insulin can be given subcutaneously. Insulin therapy, either as a continuous infusion or as injections given every 1 to 2 hours, should be continued until arterial pH has normalized. Patients who normally take long acting basal insulins (insulin glargine or insulin detemir or insulin degludec) can be given their usual maintenance doses during initial treatment of their diabetic ketoacidosis. The continuation of their subcutaneous basal insulins means that lower doses of intravenous insulin will be needed, and there will be a smoother transition from intravenous insulin infusion to the subcutaneous regimen.

3. **Potassium replacement.** Total body potassium loss from polyuria and vomiting may be as high as 200 mEq. However, because of shifts of potassium from cells into the extracellular space as a consequence of acidosis, serum potassium is usually normal to slightly elevated prior to institution of treatment. As the acidosis is corrected, potassium flows back into the cells, and hypokalemia can develop if potassium replacement is not instituted. If the patient is not uremic and has an adequate urine output, potassium chloride in doses of 10 to 30 mEq/h should be infused during the second and third hours after beginning therapy. Replacement should be started sooner, if the initial serum potassium is inappropriately normal or low, and should be delayed, if serum potassium fails to respond to initial therapy and remains above 5 mEq/L, as in cases of renal insufficiency. Occasionally, a patient may present with a serum potassium level less than 3.5 mEq/L, in which case insulin therapy should be delayed until the potassium level is corrected to greater than 3.5 mEq/L. An electrocardiogram can be help in monitoring the patient's potassium status: high peaked T waves are a sign of hyperkalemia, and flattened T waves with U waves are a sign of hypokalemia. Foods high in potassium content should be prescribed when the patient has recovered sufficiently to take food orally. Tomato juice has 14 mEq of potassium per 240 mL, and a medium-sized banana has about 10 mEq. Cooperative patients with only mild ketoacidosis may receive part or all of their potassium replacement orally.

4. **Sodium bicarbonate treatment.** The use of sodium bicarbonate in management of diabetic ketoacidosis has been questioned because clinical benefit was not demonstrated in one prospective randomized trial and because of the following potentially harmful consequences: (1) development of hypokalemia from rapid shift of potassium into cells if the acidosis is overcorrected, (2) tissue anoxia from reduced dissociation of oxygen from hemoglobin when acidosis is rapidly reversed (leftward shift of the oxygen dissociation curve), and (3) cerebral acidosis resulting from lowering of cerebrospinal fluid pH. It must be emphasized, however, that these considerations are less important when severe acidosis exists. It is therefore recommended that bicarbonate be administered to diabetic patients in ketoacidosis if the arterial blood pH is 7.0 or less with careful monitoring to prevent overcorrection.

One to two ampules of sodium bicarbonate (one ampule contains 44 mEq/50 mL) should be added to 1 L of 0.45% saline with 20 mEq KCl or to 400 mL of sterile water with 20 mEq KCl and infused over 1 to 2 hours. (**Note:** Addition of sodium bicarbonate to 0.9% saline would produce a markedly hypertonic solution that could aggravate the hyperosmolar state already present.) It can be repeated until the arterial pH reaches 7.1, but *it should not be given if the pH is 7.1 or greater*, because additional bicarbonate increases the risk of rebound metabolic alkalosis as ketones are metabolized. Alkalosis shifts potassium from serum into cells, which can precipitate a fatal cardiac arrhythmia. As noted earlier, serious consideration should be given to placement of a central venous catheter when administering fluids to severely ill patients with cardiovascular compromise.

5. **Phosphate.** Phosphate replacement is seldom required in treating diabetic ketoacidosis. However, if severe hypophosphatemia of less than 1 mg/dL (<0.35 mmol/L) develops during insulin therapy, a small amount of phosphate can be replaced per hour as the potassium salt. Correction of hypophosphatemia helps restore the buffering capacity of the plasma, thereby facilitating renal excretion of hydrogen. It also corrects the impaired oxygen dissociation from hemoglobin by regenerating 2,3-diphosphoglycerate. However, three randomized studies in which phosphate was replaced in only half of a group of patients with diabetic ketoacidosis did not show any apparent clinical benefit from phosphate administration. Moreover, attempts to use potassium phosphate as the sole means of replacing potassium have led to a number of reported cases of severe hypocalcemia with tetany. To minimize the risk of inducing tetany from too rapid replacement of phosphate, the average deficit of 40 to 50 mmol of phosphate should be replaced intravenously at a rate *no greater than 3 to 4 mmol/h* in a 60- to 70-kg person. A stock solution (Abbott) provides a mixture of 1.12 g KH_2PO_4 and 1.18 g K_2HPO_4 in a 5-mL single-dose vial (this equals 22 mmol of potassium and 15 mmol of phosphate). One-half of this vial (2.5 mL) should be added to 1 L of either 0.45% saline or 5% dextrose in water. Two liters of this solution, infused at a rate of 400 mL/h, corrects the phosphate deficit at the optimal rate of 3 mmol/h and provides 4.4 mEq of potassium per hour. Additional potassium should be administered as potassium chloride to provide a total of 10 to 30 mEq of potassium per hour, as noted earlier. If the serum phosphate remains below 2.5 mg/dL after this infusion, a repeat 5-hour infusion can be given.

6. **Hyperchloremic acidosis during therapy.** Because of the considerable loss of keto acids in the urine during the initial phase of therapy, substrate for subsequent regeneration of bicarbonate is lost, and correction of the total bicarbonate deficit is hampered. A portion of the bicarbonate deficit is replaced with chloride ions infused in large amounts as saline to correct the dehydration. In most patients, as the ketoacidosis clears during insulin replacement, a hyperchloremic, low-bicarbonate pattern emerges with a normal anion gap. This is a relatively

benign condition that reverses itself over the subsequent 12 to 24 hours once intravenous saline is no longer being administered. Using a balanced electrolyte solution with a pH of 7.4 and 98 mEq/L chloride instead of normal saline (pH ~5.5; chloride 154 mEq/L) has been reported to prevent the hyperchloremic acidosis.

TRANSITION TO SUBCUTANEOUS INSULIN REGIMEN

Once the diabetic ketoacidosis is controlled and the patient is awake and able to eat, subcutaneous insulin therapy can be initiated. Initially, the patient may still have significant tissue insulin resistance and may require a total daily insulin dose of ~0.6 U/kg. Half of the total daily dose can be given as long-acting basal insulin and the other half as short-acting insulin premeals. The patient should get injection of the basal insulin and a dose of the rapid-acting insulin analog with the first meal and the insulin infusion discontinued an hour later. The overlap of the subcutaneous insulin action and insulin infusion is necessary to prevent relapse of diabetic ketoacidiosis. In patients with preexisting diabetes, giving their basal insulin by subcutaneous injection at initiation of treatment of diabetic ketoacidosis simplifies the transition from intravenous to subcutaneous regimen. The increased tissue insulin resistance is only present for a few days at most and as the patient improves the doses of both basal and bolus insulins should be reduced to avoid hypoglycemia. In fact, a patient with new diagnosis of type 1 diabetes who still has significant β cell function may not require any basal insulin and only very low doses of rapid-acting insulin analogs before meals after full recovery from the ketoacidosis. Patients with type 2 diabetes and diabetes ketoacidosis due to severe illness may initially require insulin therapy but can often transition back to oral agents during outpatient follow-up.

Complications and Prognosis

Low-dose insulin infusion and fluid and electrolyte replacement combined with careful monitoring of patients' clinical and laboratory responses to therapy have dramatically reduced the mortality rates of diabetic ketoacidosis to less than 5%. However, this complication remains a significant risk in the aged who have mortality rates over 20% and in patients in profound coma in whom treatment has been delayed. Acute myocardial infarction and infarction of the bowel following prolonged hypotension worsen the outlook. Prior kidney dysfunction worsens prognosis because the kidney plays a key role in compensating for pH and electrolyte abnormalities. Symptomatic cerebral edema occurs primarily in the pediatric population. Risk factors for development include severe baseline acidosis, rapid correction of hyperglycemia, and excess volume administration in the first 4 hours. Onset of headache or deterioration in mental status during treatment should lead to consideration of this complication. Intravenous mannitol at a dosage of 1 to 2 g/kg given over 15 minutes is the mainstay of therapy. Excess crystalloid infusion can precipitate pulmonary edema. Acute respiratory distress syndrome is a rare complication of treatment for DKA.

Disposition

After recovery and stabilization, patients should receive intensive detailed instructions about how to avoid this potentially disastrous complication of diabetes mellitus. They should be taught to recognize the early symptoms and signs of ketoacidosis.

Urine ketones or capillary blood β-hydroxybutyrate should be measured in patients with signs of infection or in those using an insulin pump when capillary blood glucose is unexpectedly and persistently high. When heavy ketonuria and glycosuria persist on several successive examinations, supplemental regular insulin should be administered, and liquid foods such as lightly salted tomato juice and broth should be ingested to replenish fluids and electrolytes. Patients should be instructed to contact the physician if ketonuria persists and, especially, if vomiting develops, or if appropriate adjustment of the infusion rate on an insulin pump does not correct the hyperglycemia and ketonuria. Table 17–20 summarizes the guidelines for patients regarding ketone testing and what to do with the results. Recurrent episodes of severe diabetic ketoacidosis often indicate poor compliance with the insulin regimen, and these patients should receive intensive counseling.

2. HYPERGLYCEMIC, HYPEROSMOLAR STATE

This form of hyperglycemic coma is characterized by severe hyperglycemia, hyperosmolality, and dehydration in the absence of significant ketosis. It occurs in patients with mild or occult diabetes and patients are typically middle-aged or elderly. Lethargy and confusion develop as serum osmolality exceeds 300 mOsm/kg, and coma can occur if osmolality exceeds 330 mOsm/kg. Underlying renal insufficiency or congestive heart failure is common, and the presence of either worsens the prognosis. A precipitating event such as pneumonia, cerebrovascular accident, myocardial infarction, burns, or recent operation can often be identified. Certain drugs, such as phenytoin, diazoxide, glucocorticoids, and thiazide diuretics, have been implicated in its development, as have procedures associated with glucose loading such as peritoneal dialysis.

TABLE 17–20   Guidelines for treatment of ketones in patients with type 1 diabetes.

Check Ketones if Blood Glucose Persistently over 250 mg/dL or if Nauseated or Vomiting	
Blood ketones <1.5 mmol/L or urine ketones absent or small	Blood ketones >1.5 or urine ketones moderate or large
Drink plenty of fluids Give fast-acting insulin by syringe Monitor glucose levels	Call medical team for advise or go to urgent care or emergency room Drink plenty of fluids Give fast-acting insulin by syringe Monitor ketone levels

Note: Blood ketones <0.6 mmol/L are normal.

Pathogenesis

A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization by muscle, fat, and liver, while promoting hyperglucagonemia and increasing hepatic glucose output. The result is hyperglycemia that leads to glycosuria and osmotic diuresis with obligatory water loss. The presence of even small amounts of insulin is believed to prevent the development of ketosis by inhibiting lipolysis in the adipose stores. Therefore, even though a low insulin-glucagon ratio promotes ketogenesis in the liver, the limited availability of precursor free fatty acids from the periphery restricts the rate at which ketones are formed. If a patient is unable to maintain adequate fluid intake because of an associated acute or chronic illness or has suffered excessive fluid loss (eg, from burns or therapy with diuretics), marked dehydration results. As plasma volume contracts, renal insufficiency develops; this, then, limits renal glucose excretion and contributes markedly to the rise in serum glucose and osmolality. As serum osmolality exceeds 320 to 330 mOsm/kg, water is drawn out of cerebral neurons, resulting in mental obtundation and coma.

Clinical Features

A. Symptoms and signs   The onset of the hyperglycemic, hyperosmolar, nonketotic state may be insidious, preceded for days or weeks by symptoms of weakness, polyuria, and polydipsia. A history of reduced fluid intake is common, whether due to inappropriate absence of thirst, gastrointestinal upset, or, in the case of elderly or bedridden patients, lack of access to water. A history of ingestion of large quantities of sugar-containing fluids, such as soft drinks or orange juice, can occasionally be obtained; these patients are usually less hyperosmolar than those in whom fluid intake was restricted. The absence of toxic features of ketoacidosis may retard recognition of the syndrome and thus delay institution of therapy until dehydration is profound. Because of this delay in diagnosis, the hyperglycemia, hyperosmolality, and dehydration in hyperglycemic, hyperosmolar, nonketotic coma is often more severe than in diabetic ketoacidosis.

Physical examination reveals the presence of profound dehydration (orthostatic fall in blood pressure and rise in pulse, supine tachycardia, or even frank shock, dry mucous membranes, decreased skin turgor). The patient may be lethargic, confused, or comatose. Kussmaul respirations are absent unless the precipitating event for the hyperosmolar state has also led to the development of metabolic acidosis (eg, sepsis or myocardial infarction with shock).

B. Laboratory findings   Severe hyperglycemia is present, with blood glucose values ranging from 800 to as high as 2400 mg/dL (44.4-133.2 mmol/L). In mild cases, where dehydration is less severe, dilutional hyponatremia as well as urinary sodium losses may reduce serum sodium to about 120 to 125 mEq/L—this protects, to some extent, against extreme hyperosmolality. Once dehydration progresses further, however, serum sodium can exceed 140 mEq/L, producing serum osmolalities of 330 to 440 mOsm/kg (normal, 280-295 mOsm/kg; see the section Diabetic Ketoacidosis for a convenient method for estimating serum

osmolality). Ketosis is usually absent or mild; however, a small degree of ketonuria may be present if the patient has not been eating because of illness. Acidosis is not a part of the hyperglycemic, hyperosmolar state, but it may be present (often lactic acidosis) because of other acute underlying conditions (eg, sepsis, acute renal failure, myocardial infarction). Prerenal azotemia is the rule with blood urea nitrogen frequently over 100 mg/dL.

The physician must initiate a careful search for the event that precipitated the episode of hyperglycemic, hyperosmolar state if it is not obvious after the initial history and physical examination. Chest x-rays and cultures of blood, urine, and other body fluids should be obtained to look for occult sources of sepsis. Cardiac enzymes and serial electrocardiograms can be ordered to look for evidence of silent myocardial infarction.

Treatment

There are some differences in fluid, insulin, and electrolyte replacement in this disorder, as compared with diabetic ketoacidosis. However, in common with the treatment of ketoacidotic patients, careful monitoring of the patient's clinical and laboratory response to therapy is essential.

1. **Fluid replacement.** The fluid deficit may be as much as 100 to 200 mL/kg or about 9 L. If circulatory collapse is present, fluid therapy should be initiated with isotonic saline. In all other cases, initial replacement with hypotonic (usually 0.45%) saline is preferable, because these patients are hyperosmolar with considerable loss of body water and excess solute in the vascular compartment. As much as 4 to 6 L of fluid may be required in the first 8 to 10 hours. Careful monitoring of fluid quantity and type, urine output, blood pressure, and pulse is essential. Placement of a central venous pressure catheter should be strongly considered to guide replacement of fluid, especially if the patient is elderly or has underlying renal or cardiac disease. Because insulin therapy decreases plasma glucose and therefore serum osmolality, a change to isotonic saline may be necessary at some time during treatment. Once blood glucose reaches 250 mg/dL, 5% dextrose in 0.45% or 0.9% saline solution should be substituted for the sugar-free fluids. The rate of dextrose infusion should be adjusted to maintain glycemic levels of 250 to 300 mg/dL (13.9-16.7 mmol/L) in order to reduce the risk of cerebral edema. An important endpoint of fluid therapy is to restore urinary output to 50 mL/h or more. When consciousness returns, oral fluids should be encouraged.

2. **Electrolyte replacement.** Hyperkalemia is less marked, and much less potassium is lost in the urine during the osmotic diuresis of hyperglycemic, hyperosmolar, nonketotic coma than in diabetic ketoacidosis. There is, therefore, less severe total potassium depletion, and less potassium replacement is needed to restore potassium stores to normal. However, because the initial serum potassium usually is not elevated and because it declines rapidly as insulin therapy allows glucose and potassium to enter cells, it is recommended that potassium replacement be initiated earlier than in ketotic patients: 10 mEq of potassium chloride can be added to the *initial* liter of fluid administered if the initial serum potassium is not elevated and if the patient is making urine. When serum phosphate falls below 1 mg/dL during insulin therapy, phosphate replacement can be given intravenously with the same precautions as those

outlined for ketoacidotic patients (see earlier). If the patient is awake and cooperative, part or all of the potassium and phosphate replacement can be given orally.

3. **Insulin therapy.** In general, less insulin is required to reduce the hyperglycemia of nonketotic patients than is the case for patients in diabetic ketoacidosis. In fact, fluid replacement alone can decrease glucose levels considerably. Insulin treatment should therefore be delayed unless the patient has significant ketonemia (β-hydroxybutyrate >1 mmol/L). Start the insulin infusion rate at 0.05 U/kg/h (no need to give bolus) and titrate to lower blood glucose by 50 to 70 mg/dL/h. Once the patient has stabilized and the blood glucose falls to around 250 mg/dL, insulin can be given subcutaneously.

Complications and Prognosis

The severe dehydration and low output state may predispose the patient to complications such as myocardial infarction, stroke, pulmonary embolism, mesenteric vein thrombosis, and disseminated intravascular coagulation. Fluid resuscitation remains the primary approach to the prevention of these complications. Low-dose heparin prophylaxis is reasonable but benefits of routine anticoagulation remain doubtful. Rhabdomyolysis is a recognized complication of the hyperosmolar state, and it should be looked for and treated.

The overall mortality rate of hyperglycemic, hyperosmolar, nonketotic coma is over 10 times that of diabetic ketoacidosis, chiefly because of its higher incidence in older patients, who may have compromised cardiovascular systems or associated major illnesses. When patients are matched for age, the prognoses of these two forms of hyperosmolar coma are reasonably comparable. When prompt therapy is instituted, the mortality rate can be reduced from nearly 50% to that related to the severity of coexistent disorders. After the patient is stabilized, the appropriate form of long-term management of the diabetes must be determined. Insulin treatment should be continued for a few weeks, but the patients usually recover sufficient endogenous insulin secretion to make a trial of diet or diet plus oral agents worthwhile. When the episode occurs in a patient who has known diabetes, then education of the patient and caregivers should be instituted. They should be taught how to recognize situations (gastrointestinal upset, infection) that predispose to recurrence of hyperglycemic, hyperosmolar state as well as detailed information on how to prevent the escalating dehydration (small sips of sugar-free liquids, increase in usual hypoglycemic therapy, or early contact with the physician) that culminates in hyperosmolar coma.

3. LACTIC ACIDOSIS

When severely ill diabetic patients present with profound acidosis and an anion gap over 15 mEq/L but relatively low or undetectable levels of keto acids in plasma, the presence of excessive plasma lactate (>5 mmol/L) should be considered, especially if other causes of acidosis such as uremia are not present.

Pathogenesis

Lactic acid is the end product of the anaerobic metabolism of glucose. Normally, the principal sources of this acid are the erythrocytes (which lack the enzymes for aerobic oxidation), skeletal muscle, skin, and brain. The chief pathway for removal of lactic acid is by hepatic (and to some degree renal) uptake for conversion first to pyruvate and eventually back to glucose, a process that requires oxygen. Lactic acidosis occurs when excess lactic acid accumulates in the blood. This can be the result of overproduction (tissue hypoxia), deficient removal (hepatic failure), or both (circulatory collapse). Lactic acidosis is not uncommon in any severely ill patient suffering from cardiac decompensation, respiratory or hepatic failure, septicemia, or infarction of the bowel or extremities. Type A lactic acidosis is associated with tissue hypoxia from hypovolemia or endotoxic shock and need not be associated with hyperglycemia. Type B lactic acidosis is defined as that which occurs in the absence of clinical evidence for tissue hypoxia and is associated with diabetes per se or with biguanide therapy.

With the discontinuance of phenformin therapy in the United States, lactic acidosis in patients with diabetes mellitus has become uncommon, but it still must be considered in the acidotic diabetic patient if the patient is seriously ill, and especially if the patient is receiving metformin therapy as well. Most cases of metformin-associated lactic acidosis occur in patients in whom there were contraindications to the use of metformin, in particular renal failure.

Clinical Features

A. Symptoms and signs The main clinical features of lactic acidosis are marked hyperventilation and mental confusion, which may progress to stupor or coma. When lactic acidosis is secondary to tissue hypoxia or vascular collapse, the clinical presentation is variable, reflecting that of the prevailing catastrophic illness. In the rare instance of idiopathic or spontaneous lactic acidosis, the onset is rapid (usually over a few hours), the cardiopulmonary status is stable, and mentation may be relatively normal.

B. Laboratory findings Plasma glucose can be low, normal, or high in diabetic patients with lactic acidosis, but usually it is moderately elevated. Plasma bicarbonate and arterial pH are quite low. An anion gap is present (calculated by subtracting the sum of the plasma bicarbonate and chloride from the plasma sodium; normal is 12-15 mEq/L). Ketones are usually absent from plasma, but small amounts may be present in urine if the patient has not been eating recently. Other causes of anion gap metabolic acidosis should be excluded—for example, uremia, diabetic or alcoholic ketoacidosis, and salicylate, methanol, ethylene glycol, or paraldehyde intoxication. In the absence of azotemia, hyperphosphatemia may be a clue to the presence of lactic acidosis.

The diagnosis is confirmed by demonstrating, in a sample of blood that is promptly chilled and separated, a plasma lactate concentration of 6 mmol/L or higher (normal is ~1 mmol/L). Failure to rapidly chill the sample and separate the plasma can lead to falsely high plasma lactate values as a result of continued glycolysis by the red blood cells. Frozen plasma remains stable for subsequent assay.

Treatment

The cornerstone of therapy is aggressive treatment of the precipitating cause. An adequate airway and good oxygenation should

be ensured. If hypotension is present, fluids and, if appropriate, pressor agents must be given to restore tissue perfusion. Appropriate cultures and empiric antibiotic coverage should be instituted in any seriously ill patient with lactic acidosis in whom the cause is not immediately apparent. Alkalinization with intravenous sodium bicarbonate to keep the pH above 7.2 has been recommended in the emergency treatment of severe lactic acidosis. However, there is no evidence that the mortality rate is favorably affected by administering bicarbonate, and the matter is at present controversial, particularly because of the hazards associated with bicarbonate therapy. Hemodialysis may be useful in those cases associated with metformin toxicity. Dichloroacetate, an anion that facilitates pyruvate removal by activating pyruvate dehydrogenase, reverses certain types of lactic acidosis in animals, but in a prospective controlled clinical trial involving 252 patients with lactic acidosis, dichloroacetate failed to alter either hemodynamics or survival.

CHRONIC COMPLICATIONS OF DIABETES MELLITUS (TABLE 17–21)

In most patients with diabetes, a number of pathologic changes occur at variable intervals during the course of the disease. These changes involve the vascular system for the most part; however, they also occur in the nerves, the skin, and the lens. In addition to these complications, patients with diabetes have an increased incidence of certain types of infections and may handle their infections less well than the general population.

Classifications of Diabetic Vascular Disease

Diabetic vascular disease is conveniently divided into two main categories: microvascular disease and macrovascular disease.

A. Microvascular disease   Disease of the smallest blood vessels, the capillary and the precapillary arterioles, is manifested mainly by thickening of the capillary basement membrane. Microvascular disease involving the retina leads to diabetic retinopathy, and disease involving the kidney causes diabetic nephropathy. Small vessel disease may also involve the heart, and cardiomegaly with heart failure has been described in diabetic patients with patent coronary arteries.

B. Macrovascular disease   Large vessel disease in diabetes is essentially an accelerated form of atherosclerosis. It accounts for the increased incidence of myocardial infarction, stroke, and peripheral gangrene in diabetic patients. Just as in the case of atherosclerosis in the general population, the exact cause of accelerated atherosclerosis in the diabetic population remains unclear. Abnormalities in vessel walls, platelets and other components of the clotting system, red blood cells, and lipid metabolism have all been postulated to play a role. In addition, there is evidence that coexistent risk factors, such as cigarette smoking and hypertension, may be important in determining the course of the disease.

TABLE 17–21   Chronic complications of diabetes mellitus.

Eyes
    Diabetic retinopathy
        Nonproliferative (background)
        Proliferative
    Cataracts
        Subcapsular (snowflake)
        Nuclear (senile)
Kidneys
    Intercapillary glomerulosclerosis
        Diffuse
        Nodular
    Infection
        Pyelonephritis
        Perinephric abscess
        Renal papillary necrosis
    Renal tubular necrosis
        Following dye studies (urograms, arteriograms)
Nervous System
    Peripheral neuropathy
        Distal, symmetric sensory loss
    Motor neuropathy
        Foot drop, wrist drop
        Cranial nerves III, IV, VI, VII
        Diabetic amyotrophy
    Autonomic neuropathy
        Postural hypotension
        Resting tachycardia
        Loss of sweating
        Gastroparesis
        Diabetic diarrhea
        Urinary bladder atony
        Impotence (may also be secondary to pelvic vascular disease)
Skin
    Diabetic dermopathy (shin spots)
    Necrobiosis lipoidica diabeticorum
    Candidiasis
    Foot and leg ulcers
        Neurotropic
        Ischemic
Cardiovascular System
    Heart disease
        Myocardial infarction
        Cardiomyopathy
    Peripheral vascular disease
        Ischemic ulcers: gangrene
    Cerebrovascular disease
Bones and Joints
        Diabetic cheiroarthropathy
        Dupuytren contracture
        Charcot joint
        Osteomyelitis
Unusual Infections
        Necrotizing fasciitis
        Necrotizing myositis
        Mucor meningitis
        Emphysematous cholecystitis
        Malignant otitis externa

Prevalence of Chronic Complications by Type of Diabetes

Although all of the known complications of diabetes can be found in both types of the disease, some are more common in one type than in the other. In type 1 diabetes, end-stage renal disease

develops in up to 40% of patients, compared with less than 20% of patients with type 2 diabetes. Although blindness occurs in both types, it occurs more commonly as a result of severe proliferative retinopathy, vitreous hemorrhages, and retinal detachment in type 1 disease, whereas macular edema and ischemia are the usual cause in type 2 disease. Similarly, although diabetic neuropathy is common in both type 1 and type 2 diabetes, severe autonomic neuropathy with gastroparesis, diabetic diarrhea, resting tachycardia, and postural hypotension is much more common in type 1.

In patients with type 1 diabetes, complications from end-stage renal disease are a major cause of death, whereas patients with type 2 diabetes are more likely to have macrovascular diseases leading to myocardial infarction and stroke as the main causes of death. Cigarette use adds significantly to the risk of both microvascular and macrovascular complications in diabetic patients.

Molecular Mechanisms by Which Hyperglycemia Causes Microvascular and Macrovascular Damage

Epidemiological data and prospective intervention studies such as the DCCT have confirmed the central role of glucose in the development of chronic diabetic complications.

Four molecular mechanisms of glucose-induced damage have been proposed: (1) increased polyol pathway flux; (2) increased intracellular advanced glycation end product (AGE) formation; (3) activation of protein kinase C; and (4) increased hexosamine pathway flux.

Increase flux through the polyol pathway consumes NADPH. Because this cofactor is needed to regenerate reduced glutathione, NADPH depletion is predicted to exacerbate intracellular oxidative stress and cause cellular injury. Inhibitors of aldose reductase, the first enzyme in the polyol pathway have been shown to improve diabetic neuropathy.

Intracellular autoxidation of glucose results in production of intracellular dicarbonyls (glyoxal, 3-deoxyglucosone, methylglyoxal), also referred to as AGE precursors. These precursors damage target tissues by modifying intracellular and extracellular proteins and matrix components. Intracellular protein modifications may alter cellular functions. Modifications of extracellular matrix proteins result in abnormal interactions with other matrix proteins and integrins. The modified plasma proteins bind to receptors on endothelial cells, mesangial cells, and macrophages causing expression of cytokines and growth factors including interleukin 1, IGF-1, TNF-α, transforming growth factor-β (TGF-β), macrophage colony stimulating factor, granulocyte-macrophage stimulating factor, platelet-derived growth factor, thrombomodulin, tissue factor, vascular cell adhesion molecule 1 (VCAM 1), and vascular endothelial growth factor (VEGF). Induction of VEGF has been implicated in the vascular hyperpermeability associated with diabetes.

Protein kinase C isoforms β and δ are activated by diacylglycerol whose levels are increased by elevated intracellular glucose. Activation of these isoforms leads to alterations in expression of endothelial nitric oxide synthase, endothelin 1, VEGF, TGF-β, PAI-1, and activation of nuclear factor κB and NADPH oxidases.

Inhibitors of the protein kinase β isoform improve retinopathy and nephropathy in experimental models.

Hyperglycemia increases hexosamine pathway flux by providing more fructose-6-phosphate for the rate-limiting enzyme of the pathway glutamine: fructose-6-phosphate amidotransferase. Activity of this pathway leads to increased donation of N-acetylglucosamine moieties to serine and threonine moieties of complication-promoting factors such as PAI-1 or TGF-β.

It has been proposed that all four of these pathways are associated with overproduction of superoxide by mitochondria. High ambient glucose leads to increased substrate flux through glycolysis and the tricarboxylic acid cycle. This leads to increased potential difference across the inner mitochondrial membrane and generation of superoxide by the electron transport chain. The increased production of superoxide reduces glyceraldehyde-3-phosphate dehydrogenase (GAPDH) activity, which in turn leads to upstream increase in intracellular glucose and accumulation of glycolytic intermediates such as glyceraldehyde-3-phosphate and fructose-6-phosphate. The increased intracellular glucose leads to increased flux through the polyol pathway and also is the primary initiating event in the formation of both intracellular and extracellular AGEs. The glycolytic intermediates are important initiators of the hexosamine pathway (fructose-6-phosphate) or the protein kinase C pathway (glyceraldehyde-3-phosphate).

Genetic Factors in Susceptibility to Development of Chronic Complications of Diabetes

Although no genetic susceptibility genes have been identified as yet, two unrelated observations indicate that approximately 40% of people with diabetes may be unusually susceptible to the ravages of hyperglycemia or other metabolic sequelae of an inadequate insulin effect.

(1) In one retrospective study of 164 juvenile-onset diabetic patients with a median age at onset of 9 years, 40% were incapacitated or dead from end-stage renal disease with proliferative retinopathy after a 25-year follow-up, whereas the remaining subjects were either mildly affected (40%) or had no clinically detected microvascular disease (20%). This study was completed long before the availability of glycemic self-monitoring methodology, so it is unlikely that any of these patients were near optimal glycemic control.

(2) Data from renal transplantation indicate that only about 40% of normal kidneys developed evidence of moderate to severe diabetic nephropathy within 6 to 14 years of being transplanted into diabetic subjects with end-stage renal failure, whereas as many as 60% were only minimally affected. These observations support the hypothesis that although approximately 60% of people suffer only minimal consequences from hyperglycemia and other metabolic hazards of insulin insufficiency, 40% or so suffer severe, potentially catastrophic microvascular complications if the disease is poorly controlled. The genetic mechanisms for this increased susceptibility are as yet

unknown but could be related to one or more of the molecular mechanisms outlined earlier. Identification of the genetic mechanism(s) would be very helpful in justifying more intensive insulin therapy in the group susceptible to complications in an effort to achieve near-normalization of blood glucose. The remaining 60% of less susceptible individuals might then be spared the inconveniences of strict glycemic control as well as the risks of hypoglycemia inherent in present methods of intensive insulin therapy.

SPECIFIC CHRONIC COMPLICATIONS OF DIABETES MELLITUS (TABLE 17–21)

1. OPHTHALMOLOGIC COMPLICATIONS

Diabetic Retinopathy

For early detection of diabetic retinopathy, adolescent or adult patients who have had type 1 diabetes for more than 5 years and *all* patients with type 2 diabetes should be referred to an ophthalmologist for examination and follow-up. In patients with type 1 diabetes, after 10 to 15 years, 25% to 50% of patients show some signs of retinopathy. This prevalence increases to 75% to 95% after 15 years and approaches 100% after 30 years of diabetes. In patients with type 2 diabetes, 60% have nonproliferative retinopathy after 16 years. When hypertension is present in a patient with diabetes, it should be treated vigorously because hypertension is associated with an increased incidence and accelerated progression of diabetic retinopathy.

A. Pathogenesis and clinical features   It is now recognized that diabetic retinopathy is not only a microvascular complication of endothelial dysfunction but also a neurodegenerative disease. There is thinning of the inner nuclear layer; reduction in synapse numbers and synaptic proteins and changes in dendritic morphology.

Two main categories of diabetic retinopathy exist: nonproliferative and proliferative. Diabetic macular edema can occur at any stage but more prevalent in the later phases.

Nonproliferative (background) retinopathy (Figure 17–15) represents the earliest stage of retinal involvement by diabetes and is characterized by such changes as microaneurysms, dot hemorrhages, exudates, and retinal edema. During this stage, the retinal capillaries leak proteins, lipids, or red cells into the retina. When this process occurs in the macula (clinically significant macular edema), the area of greatest concentration of visual cells, there is interference with visual acuity; this is the most common cause of visual impairment in type 2 diabetes.

Proliferative retinopathy (Figure 17–16) involves the growth of new capillaries and fibrous tissue within the retina and into the vitreous chamber. It is a consequence of small vessel occlusion, which causes retinal hypoxia; this in turn stimulates new vessel growth. New vessel formation may occur at the optic disc or elsewhere on the retina. Proliferative retinopathy can occur in both types of diabetes but is more common in type 1, developing about 7 to 10 years after onset of symptoms, with a prevalence of 25% after 15 years' duration. Prior to proliferation of new capillaries, a preproliferative phase often occurs in which arteriolar ischemia is manifested as cotton-wool spots (small infarcted areas of retina).
FIGURE 17–15 Nonproliferative diabetic retinopathy with intraretinal hemorrhages and microaneurysms along inferotemporal arcade; and hard exudates temporal to macula. (Used with permission from Dr. Jacque Duncan, University of California, San Francisco.)
FIGURE 17–16 Proliferative diabetic retinopathy with neovascularization of the disc, venous beading, hemorrhages, and cotton wool spots nasal to the optic nerve. Early frame of fluorescein angiogram shows extensive macular capillary nonperfusion and early leakage from neovascularization along the superotemporal arcade. (Used with permission from Dr. Jacque Duncan, University of California, San Francisco.)

Vision is usually normal until vitreous hemorrhage or retinal detachment occurs. Proliferative retinopathy is a leading cause of blindness in the United States, particularly because it increases the risk of retinal detachment.

B. Treatment Extensive scatter xenon or argon photocoagulation and focal treatment of new vessels reduce severe visual loss in those cases in which proliferative retinopathy is associated with recent vitreous hemorrhages or in which extensive new vessels are located on or near the optic disk. Vitreoretinal surgery is used for sight threatening complications of proliferative diabetic retinopathy such as vitreous hemorrhage, tractional retinal detachment, and epimacular proliferation.

Macular edema, which is more common than proliferative retinopathy in patients with type 2 diabetes (up to 20% prevalence), has a guarded prognosis, but it has also responded to scatter therapy with improvement in visual acuity if detected early. Intravitreal anti-vascular endothelial growth factor (anti-VEGF) agents (ranibizumab, bevacizumab, pegaptanib, and aflibercept) have emerged as new treatments for diabetic macular edema and in clinical trials are better than laser therapy in preserving and improving vision. A significant proportion of patients, however, may still require focal or grid laser treatment. Intravitreal corticosteroids are effective and are used in patients affected by persistent or refractory diabetic macular edema, especially in pseudophakic eyes. Avoiding tobacco use and correction of associated hypertension are important therapeutic measures in the management of diabetic retinopathy. There is no contraindication to using aspirin in patients with proliferative retinopathy.

Cataracts

Two types of cataracts occur in diabetic patients: subcapsular and senile. **Subcapsular cataract** occurs predominantly in patients with type 1 diabetes, may come on fairly rapidly, and has a significant correlation with the hyperglycemia of uncontrolled diabetes. This type of cataract has a flocculent or *snowflake* appearance and develops just below the lens capsule.

Senile cataract represents a sclerotic change of the lens nucleus. It is by far the most common type of cataract found in either diabetic or nondiabetic adults and tends to occur at a younger age in diabetic patients, particularly when glycemic control is poor.

Two separate abnormalities found in diabetic patients, both of which are related to elevated blood glucose levels, may contribute to the formation of cataracts: (1) glycosylation of the lens protein, and (2) an excess of sorbitol, which is formed from the increased quantities of glucose found in the insulin-independent lens. Accumulation of sorbitol leads to osmotic changes in the lens that ultimately result in fibrosis and cataract formation.

Glaucoma

Glaucoma occurs in approximately 6% of persons with diabetes. It is generally responsive to the usual therapy for open-angle disease. Closed-angle glaucoma can result from neovascularization of the iris in diabetic patients, but this is relatively uncommon except after cataract extraction when accelerated new vessel growth involving the angle of the iris obstructs outflow.

2. RENAL COMPLICATIONS

Diabetic Nephropathy

A. Pathogenesis and clinical findings About 4000 cases of end-stage renal disease due to diabetic nephropathy occur annually among diabetic patients in the United States. This represents about one-third of all patients being treated for renal failure.

The cumulative incidence of nephropathy differs between the two major types of diabetes. Patients with type 1 diabetes, who have not received intensive insulin therapy and have had only fair to poor glycemic control, have a 30% to 40% chance of having nephropathy after 20 years—in contrast to the much lower frequency in patients with type 2 diabetes, who are not receiving intensive therapy, in whom only about 15% to 20% develop clinical renal disease. However, because so many more individuals are affected with type 2 diabetes, end-stage renal disease is much more prevalent in people with type 2 diabetes in the United States and especially throughout the rest of the world. There is no question that improved glycemic control and more effective therapeutic measures to correct hypertension can reduce the incidence of end-stage renal disease in both types of diabetes in the future.

Diabetic nephropathy is initially manifested by proteinuria; subsequently, as kidney function declines, urea and creatinine accumulate in the blood. Thickening of capillary basement membranes and of the mesangium of renal glomeruli produces varying degrees of glomerulosclerosis and renal insufficiency. Diffuse glomerulosclerosis is more common than nodular intercapillary glomerulosclerosis (Kimmelstiel-Wilson lesions); both produce heavy proteinuria.

Sensitive radioimmunoassay methods have permitted detection of microgram concentrations of urinary albumin. Conventional 24-hour urine collections, in addition to being inconvenient for patients, also show wide variability of albumin excretion, since several factors such as sustained erect posture, dietary protein, and exercise tend to increase albumin excretion rates. For these reasons, an albumin-creatinine ratio in an early morning spot urine collected upon awakening is preferable. In the early morning spot urine, a ratio of albumin (μg/L) to creatinine (mg/L) of less than 30 μg/mg creatinine is normal, and a ratio of 30 to 300 μg/mg creatinine suggests abnormal microalbuminuria. At least two early morning spot urine collections over a 3- to 6-month period should be abnormal before a diagnosis of microalbuminuria is made.

Subsequent renal failure can be predicted by persistent urinary albumin excretion rates exceeding 30 μg/mg creatinine. Glycemic control as well as a protein diet of 0.8 g protein/kg body weight/d may reduce both the hyperfiltration and the elevated microalbuminuria in patients in the early stages of diabetes and those with incipient diabetic nephropathy. Antihypertensive therapy also decreases microalbuminuria. Evidence from some studies—but not the UKPDS—supports a specific role for ACE inhibitors in reducing intraglomerular pressure in addition to lowering systemic blood pressure. An ACE inhibitor (captopril, 50 mg twice daily) in normotensive diabetics impedes progression to proteinuria and prevents the increase in albumin excretion rate. Since microalbuminuria has been shown to correlate with elevated nocturnal systolic blood pressure, it is possible that normotensive diabetic patients with microalbuminuria have slightly elevated systolic blood pressure during sleep, which is lowered during antihypertensive therapy. This action may contribute to the reported efficacy of ACE inhibitors in reducing microalbuminuria in normotensive patients.

If treatment is inadequate, then the disease progresses with proteinuria of varying severity, occasionally leading to nephrotic syndrome with hypoalbuminemia, edema, and an increase in circulating LDL cholesterol as well as progressive azotemia. In contrast to all other renal disorders, the proteinuria associated with diabetic nephropathy does not diminish with progressive renal failure (patients continue to excrete 10-11 g daily as creatinine clearance diminishes). As renal failure progresses, there is an elevation in the renal threshold at which glycosuria appears.

Patients with diabetic nephropathy should be evaluated and followed by a nephrologist. There has been gradual improvement in quality of life of diabetic patients receiving dialysis but mortality remains higher than in nondiabetic patients. During 5 years of follow-up in a European registry study, the mortality rate in people with diabetes receiving dialysis was 226.9 deaths/1000 patient years whereas the rate was 151.4 deaths/1000 patient years in people receiving dialysis who did not have diabetes.

Renal transplantation, especially from related donors, is often successful. For patients with compatible donors and no contraindications (such as severe cardiovascular disease), it is the treatment of choice. Diabetic nephropathy accounts for about 20% of kidney transplantations performed annually in the United States.

Necrotizing Papillitis

This unusual complication of pyelonephritis occurs primarily in diabetic patients. It is characterized by fever, flank pain, pyuria, and sloughing of renal papillae in the urine. It is treated by intravenous administration of appropriate antibiotics.

Renal Decompensation After Administration of Radiographic Dyes

The use of radiographic contrast agents in diabetic patients with reduced creatinine clearance has been associated with the development of acute renal failure. Contrast-induced nephropathy is defined as an increase in serum creatinine of at least 0.5 mg/dL or 25% compared with baseline after exposure to intravenous contrast. The increase in serum creatinine occurs shortly after the procedure and peaks 3 to 5 days later before improving over the next 1 to 3 weeks. Although frequently transient, it can cause permanent impairment of renal function. Diabetic patients with normal renal function do not appear to be at increased risk for contrast nephropathy. If a contrast study is considered essential, patients with a serum creatinine of 1.5 to 2.5 mg/dL should be adequately hydrated before the procedure. Hydration with saline has been the cornerstone of contrast nephropathy prevention: intravenous saline 1 mL/kg/h is started 12 hours before the procedure and continued for 12 hours afterward. Some studies suggest that sodium bicarbonate infusions are more effective, and an alternate option is to infuse sodium bicarbonate: 150 mL of sodium bicarbonate (1 mEq/mL) is added to 1 L of 5% dextrose and infused at 3.5 mL/kg/h for 1 hour before the procedure; 1.2 mg/kg/h during the procedure and for 6 hours afterward. *N*-acetylcysteine has also been shown in some trials to decrease the incidence of contrast nephropathy. One regimen consists of using oral *N*-acetylcysteine 600 mg twice a day starting the day before the procedure for a total of four doses. A combination of *N*-acetylcysteine and intravenous saline or intravenous sodium

bicarbonate may be more beneficial. Radiographic contrast material should not be given to a patient with a serum creatinine greater than 3 mg/dL unless the potential benefit outweighs the high risk of acute renal failure.

3. NEUROLOGIC COMPLICATIONS (DIABETIC NEUROPATHY)

Peripheral and autonomic neuropathies are the two most common complications of both types of diabetes. Up to 50% of patients with type 2 diabetes are affected. The pathogenesis of both types of neuropathy is poorly understood. Some lesions, such as the acute cranial nerve palsies and diabetic amyotrophy, have been attributed to ischemic infarction of the involved peripheral nerve. The much more common symmetric sensory and motor peripheral neuropathies and autonomic neuropathy are felt to be due to metabolic complications.

Unfortunately, there is no consistently effective treatment for any of the neuropathies. However, several long-term clinical trials have definitively shown that normalization of blood glucose levels can prevent development and progression of this devastating complication.

Peripheral Neuropathy

A. Distal symmetric polyneuropathy This is the most common form of diabetic peripheral neuropathy in which loss of function appears in a stocking-glove pattern and is due to an axonal neuropathic process. Longer nerves are especially vulnerable—hence the impact on the foot. Both motor and sensory nerve conduction is delayed in the peripheral nerves, and ankle jerks may be absent.

Sensory involvement usually occurs first and is generally bilateral, symmetric, and associated with dulled perception of vibration, and temperature. Pain, when present, can range from mild discomfort to severe incapacitating symptoms (discussed later). The sensory deficit may eventually be of sufficient degree to prevent patients from feeling pain. Patients with symptoms of sensory neuropathy should be examined with a 5.07 Semmes-Weinstein filament. Those who cannot feel the filament must be considered at risk for unperceived neuropathic injury.

The denervation of the small muscles of the foot results in clawing of the toes and displacement of the submetatarsal fat pads anteriorly. These changes, together with the joint and connective tissue changes, alter the biomechanics of the foot, increasing plantar pressures. This combination of decreased pain threshold, abnormally high foot pressures, and repetitive stress (eg, walking) can lead to calluses and ulcerations in the high-pressure areas such as over the metatarsal heads (Figure 17-17). Peripheral neuropathy also predisposes to the development of Charcot arthropathy. Other predisposing factors for this condition include autonomic neuropathy and trauma. The acute Charcot foot presents with pain and swelling, and if the condition is untreated, it leads to a rocker bottom deformity and ulceration. The early radiologic changes are of joint subluxation and periarticular fractures. As the

FIGURE 17–17 Neuropathic ulceration over first metatarsal head.

process progresses, there is frank osteoclastic destruction leading to deranged and unstable joints particularly in the midfoot.

Not surprisingly, the key issue for healing of neuropathic ulcers in a foot with good vascular status is mechanical unloading. Additionally, any infection should be treated with debridement and appropriate antibiotics. Healing times of 8 to 10 weeks are typical. In the occasional patient, where healing appears refractory, platelet-derived growth factor (becaplermin) should be considered for local application. A postmarket epidemiologic study showed increased cancer deaths in patients who had used three or more tubes of becaplermin on their leg or feet ulcers, and there is now a boxed warning in the drug label. Once ulcers are healed, therapeutic footwear is key to preventing recurrences. Custom-molded shoes are reserved for patients with significant foot deformities. Other patients with neuropathy may require accommodative insoles that distribute the load over as wide an area as possible. Patients with foot deformities and loss of protective threshold should seek regular care from a podiatrist. They should be educated about appropriate footwear, and those patients with loss of protective threshold should be instructed to inspect their feet daily for reddened areas, blisters, abrasions, or lacerations.

In some patients, hypersensitivity to light touch and occasionally severe burning pain, particularly at night, can become physically and emotionally disabling. Nortriptyline or desipramine in doses of 25 to 150 mg/d orally may provide dramatic relief for pain from diabetic neuropathy, often within 48 to 72 hours. This rapid response is in contrast to the 2 or 3 weeks required for an antidepressive effect. Patients often attribute the benefit to having a full night's sleep. Mild to moderate morning drowsiness is a side effect that generally improves with time or can be lessened by giving the medication several hours before bedtime. This medication should not be continued if improvement has not occurred after 5 days of therapy. Amitriptyline, 25 to 75 mg orally at bedtime can also be used but has more anticholinergic effects. Tricyclic antidepressants, in combination with the phenothiazine,

fluphenazine, have been shown in two studies to be efficacious in painful neuropathy, with benefits unrelated to relief of depression.

Gabapentin (900-1800 mg/d in three divided doses) has also been shown to be effective in the treatment of painful neuropathy and should be tried if the tricyclic drugs prove ineffective. Pregabalin, a congener of gabapentin, has been shown in an 8-week study to be more effective than placebo in treating painful diabetic peripheral neuropathy. However, this drug was not compared with an active control. Also, because of its abuse potential, it has been categorized as a Schedule V controlled substance. Duloxetine (60-120 mg), a serotonin and norepinephrine reuptake inhibitor, has been approved for the treatment of painful diabetic neuropathy. In clinical trials, this drug reduced the pain sensitivity score by 40% to 50%. Capsaicin, a topical irritant, has been found to be effective in reducing local nerve pain; it is dispensed as a cream (Zostrix 0.025% and Zostrix-HP 0.075%) to be rubbed into the skin over the painful region two to four times daily. Gloves should be used for application, because hand contamination could result in discomfort if the cream comes in contact with eyes or sensitive areas such as the genitalia. Five percent lidocaine patch applied over an area of maximal pain has been reported to be of benefit.

Rapid normalization of glucose levels in a patient with long standing poor control can precipitate an acute painful neuropathy (also called "insulin neuritis" or "treatment induced neuropathy"). Autonomic dysfunction may also be present. The symptoms improve with time. The initial report of this condition noted that stopping the insulin treatment resolved the symptoms. There is, however, no conclusive evidence that deliberately raising glucose levels will ameliorate the symptoms. Treatment induced neuropathy can probably be avoided by lowering glucose levels gradually.

Diabetic neuropathic cachexia is a syndrome characterized by a symmetric peripheral neuropathy associated with profound weight loss (up to 60% of total body weight) and painful dysesthesias affecting the proximal lower limbs, the hands, or the lower trunk. Treatment is usually with insulin and analgesics. The prognosis is usually good, and patients typically recover their baseline weight with resolution of the painful sensory symptoms within 1 year.

B. Isolated peripheral neuropathy   Involvement of the distribution of only one nerve (mononeuropathy) or of several nerves (mononeuropathy multiplex) is characterized by sudden onset with subsequent recovery of all or most of the function. This neuropathology has been attributed to vascular ischemia or traumatic damage. Cranial and femoral nerves are commonly involved, and motor abnormalities predominate. The patient with cranial nerve involvement usually presents with diplopia. Clinical examination reveals signs of single third, fourth, or sixth nerve weakness, and the pupil is spared. A full recovery of function occurs in 6 to 12 weeks. Diabetic amyotrophy presents with onset of severe pain in the front of the thigh. Within a few days or weeks of the onset of pain, the patient develops weakness and wasting of the quadriceps. Usually as the weakness appears, the pain tends to improve. Management includes analgesia and improved diabetic control. The symptoms improve over 6 to 18 months.

Autonomic Neuropathy

Neuropathy of the autonomic nervous system is common in patients with diabetes of long duration and can be a very disconcerting clinical problem. It can affect many diverse visceral functions including blood pressure and pulse, gastrointestinal activity, bladder function, and erectile function. Treatment is directed specifically at each abnormality.

Involvement of the gastrointestinal system may be manifested by nausea, vomiting, and postprandial fullness (from gastric atony); symptoms of reflux or dysphagia (from esophageal involvement); constipation and recurrent diarrhea, especially at night (from involvement of the small bowel and colon); and fecal incontinence (from anal sphincter dysfunction). Gall bladder function is altered, and this enhances stone formation.

Gastroparesis should be considered in type 1 diabetic patients in whom unexpected fluctuations and variability in their blood glucose levels develops after meals. Radiographic studies of the stomach and radioisotopic examination of gastric emptying after liquid and solid meals are of diagnostic value in these patients. Metoclopramide has been of some help in treating diabetic gastroparesis. It is a dopamine antagonist that has central antiemetic effects as well as a cholinergic action to facilitate gastric emptying. It is given in a dose of 10 mg orally three or four times a day, 30 minutes before meals and at bedtime. Drowsiness, restlessness, fatigue, and lassitude are common adverse effects. Tardive dyskinesia and extrapyramidal effects can occur especially when the drug is used for longer than 3 months and the FDA has cautioned against its chronic use. Domperidone is also a dopamine antagonist and as effective as metoclopramide but with less central side effects. The dose is 10 to 20 mg three or four times a day. It can cause prolongation of the QT interval and a baseline ECG and follow-up ECG should be performed. The drug is not licensed for sale in the United States but the FDA will allow its use through the "expanded access to investigational drugs program." Erythromycin appears to bind to motilin receptors in the stomach and has been found to improve gastric emptying in doses of 250 mg three times daily over the short term, but its effectiveness seems to diminish over time. Gastric electrical stimulation has been reported to improve symptoms and quality of life indices in patients with gastroparesis refractory to pharmacologic therapy.

Diarrhea associated with autonomic neuropathy has occasionally responded to broad-spectrum antibiotic therapy (such as rifaximin, metronidazole, amoxicillin/clavulanate, ciprofloxacin, or doxycycline), although it often undergoes spontaneous remission. Refractory diabetic diarrhea is often associated with impaired sphincter control and fecal incontinence. Therapy with loperamide, 4 to 8 mg daily, or diphenoxylate with atropine, two tablets up to four times a day, may provide relief. In more severe cases, tincture of paregoric or codeine (60-mg tablets) may be required to reduce the frequency of diarrhea and improve the consistency of the stools. Clonidine has been reported to lessen diabetic diarrhea; however, its usefulness is limited by its tendency to cause orthostatic hypotension in these patients who already have autonomic neuropathy. Constipation usually responds to stimulant laxatives such as senna. Metamucil and other bulk-providing

agents may relieve either the diarrhea or the constipation phases, which often alternate.

Inability to completely empty the bladder can sometimes occur. Bethanechol in doses of 10 to 50 mg three times a day has occasionally improved emptying of the atonic urinary bladder. Catheter decompression of the distended bladder has been reported to improve its function, and considerable benefit has been reported after surgical severing of the internal vesicle sphincter.

Use of Jobst fitted stockings, tilting the head of the bed, and arising slowly from the supine position are useful in minimizing symptoms of orthostatic hypotension. Some patients may require the addition of a mineralocorticoid such as fludrocortisone acetate (0.1-0.2 mg twice daily). Fludrocortisone therapy, however, can result in supine hypertension and hypokalemia. Midodrine (10 mg three times a day), an alpha adrenergic agonist, can be tried if Jobst stockings and sleeping upright prove ineffective in providing symptomatic relief.

Erectile dysfunction due to neuropathy differs from the psychogenic variety in that the latter may be intermittent (erections occur under special circumstances), whereas diabetic erectile dysfunction is usually persistent. To distinguish neuropathic or psychogenic erectile dysfunction from the erectile dysfunction caused by aortoiliac occlusive disease or vasculopathy, papaverine is injected into the corpus cavernosum of the penis. If the blood supply is competent, a penile erection occurs (see Chapter 12). Urinary incontinence, with large volumes of residual urine, and retrograde ejaculation can also result from pelvic neuropathy.

There are medical, mechanical, and surgical approaches available for treatment of erectile dysfunction. Penile erection depends on relaxation of the smooth muscle in the arteries of the corpus cavernosum, and this is mediated by nitric oxide-induced cyclic $3',5'$-guanosine monophosphate (cGMP) formation. cGMP-specific phosphodiesterase type 5 (PDE5) inhibitors impair the breakdown of cGMP and improve the ability to attain and maintain an erection. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) have been shown in placebo-controlled clinical trials to improve erections in response to sexual stimulation. The recommended dose of sildenafil for most patients is one 50-mg tablet taken approximately 1 hour before sexual activity. The peak effect is at 1.5 to 2 hours, with some effect persisting for 4 hours. Patients with diabetes mellitus using sildenafil reported 50% to 60% improvement in erectile function. The maximum recommended dose is 100 mg. The recommended dose of both vardenafil and tadalafil is 10 mg. The doses may be increased to 20 mg or decreased to 5 mg based on efficacy and side effects. Tadalafil has been shown to improve erectile function for up to 36 hours after dosing. In clinical trials, only a few adverse effects have been reported—transient mild headache, flushing, dyspepsia, and, in some, altered color vision. Priapism can occur with these drugs and patients should be advised to seek immediate medical attention if an erection persists for longer than 4 hours. The PDE5 inhibitors potentiate the hypotensive effects of nitrates, and their use is contraindicated in patients who are concurrently using organic nitrates in any form. Caution is advised for men who have suffered a heart attack, stroke, or life-threatening arrhythmia within the previous 6 months; men who have resting hypotension or hypertension, and men who have a history of cardiac failure or have unstable angina. Rarely, a decrease in vision or permanent visual loss has been reported after PDE5 inhibitor use.

Intracorporeal injection of vasoactive drugs causes penile engorgement and erection. Drugs most commonly used include papaverine alone, papaverine with phentolamine, and alprostadil (prostaglandin E_1). Alprostadil injections are relatively painless, but careful instruction is essential to prevent local trauma, priapism, and fibrosis. Intraurethral pellets of alprostadil avoid the problem of injection of the drug.

External vacuum therapy (Erec-Aid System) is a nonsurgical treatment consisting of a suction chamber operated by a hand pump that creates a vacuum around the penis. This draws blood into the penis to produce an erection that is maintained by a specially designed tension ring inserted around the base of the penis and which can be kept in place for up to 20 to 30 minutes. Although this method is generally effective, its cumbersome nature limits its appeal.

Surgical implants of penile prostheses remain an option for those patients in whom the nonsurgical approaches are ineffective.

4. CARDIOVASCULAR COMPLICATIONS
Heart Disease

Microangiopathy occurs in the heart and may explain the existence of congestive cardiomyopathies found in diabetic patients without demonstrable coronary artery disease. Much more commonly, however, heart failure in patients with diabetes is a consequence of coronary atherosclerosis. Myocardial infarction is three to five times more common in diabetic patients than in age-matched controls and is the leading cause of death in patients with type 2 diabetes. Cardiovascular disease risk is increased in patients with type 1 diabetes as well, although the absolute risk is lower than in patients with type 2 diabetes. Women with diabetes lose the protection against myocardial infarction that is usually present during the childbearing years. The increased risk of atherosclerosis in people with diabetes may reflect the combination of hyperlipidemia, abnormalities of platelet adhesiveness, coagulation factors, hypertension, and oxidative stress and inflammation.

Large intervention studies of risk factor reduction in diabetes are lacking, but it is reasonable to assume that reducing these risk factors would have beneficial effects. Lowering LDL cholesterol reduces first events in patients without known coronary disease and secondary events in patients with known coronary disease. These intervention studies included some patients with diabetes, and the benefits of lowering LDL cholesterol were apparent in this group. The National Cholesterol Education Program clinical practice guidelines have designated diabetes as a coronary risk equivalent and have recommended that patients with diabetes should have an LDL cholesterol goal of less than 100 mg/dL. Lowering LDL cholesterol to 70 mg/dL may have additional benefit and is a reasonable target for most patients with type 2 diabetes who have multiple risk factors for cardiovascular disease. In people with diabetes, the association of blood pressure with microvascular and macrovascular events is a continuum. The UKPDS reported that a 10 mm Hg decrease in mean systolic pressure was associated with a risk reduction of 11% for myocardial infarction; 13% for

microvascular complication; and 15% for deaths related to diabetes. There was no threshold of risk for any endpoint and the lowest risk was in those patients whose systolic pressure was less than 120 mm Hg. Meta-analyses of clinical trials that included patients with diabetes report that if baseline systolic pressure is greater than 140, treatment to decrease blood pressure toward the normal range reduces risk of mortality and macrovascular and microvascular events. The data on treatment when baseline systolic pressure is less than 140 is conflicting. One meta-analysis found that treating patients with baseline systolic pressure less than 140 was associated with a reduced risk of stroke and albuminuria. Another meta-analysis, however, found that if baseline systolic blood pressure was less than 140, further treatment increased the risk of cardiovascular mortality. These meta-analyses included studies of diabetic patients with known cardiovascular disease, chronic renal failure, heart failure; and stroke and it is possible that including these very high-risk patients attenuated or even worsened outcomes from blood pressure treatment.

The antihypertensive regimen used does not seem to be that important. The key exception is heart failure where diuretics seem to beneficial. Dual renin-angiotensin blockade with a renin blocker, such as aliskiren, with ACE-inhibition or ARB blockade is not recommended because of increased risk of hyperkalema, hypotension and stroke. Similarly, combining an ARB and ACE inhibitor has also failed to show benefit and is associated with hypotension and renal dysfunction. Although evidence that ACE inhibitors or ARB are of particular benefit is sparse, these classes of drugs are well tolerated and are recommended as the first line antihypertensive treatment in patients with diabetes.

The ADA recommends lowering systolic blood pressure to less than 140 mm Hg and diastolic pressure to less than 90 mm Hg in people with diabetes. The systolic target of 130 mm Hg or less and diastolic of 80 mm Hg or less is recommended for the younger patient if it can be achieved without undue treatment burden. The Systolic Blood Pressure Intervention Trial (SPRINT) reported that treating to a systolic blood pressure of less than 120 mm Hg reduced cardiovascular events by 25% and death from cardiovascular causes by 43% during 3.26 years of follow-up. People with diabetes, however, were excluded from this study and it is unclear if the results are applicable to this population.

Aspirin (81-325 mg daily) inhibits thromboxane synthesis by platelets and is effective in reducing cardiovascular morbidity and mortality in patients who have a history of myocardial infarction or stroke (secondary prevention). It is unclear if aspirin prevents primary cardiovascular events in people with diabetes. The current recommendation is to give aspirin to those people with diabetes who are at increased risk for cardiovascular events (>10% 10-year risk of cardiovascular events). Typically this includes most 50-year-old men and 60-year-old women with one or more additional risk factors (smoking, hypertension, dyslipidemia, family history of premature cardiovascular disease, and albuminuria). Contraindications for aspirin therapy include age less than 21 years (because of risk of Reye syndrome), aspirin allergy, bleeding tendency (eg, anticoagulant therapy), recent gastrointestinal bleeding, or active hepatic disease. The Early Treatment Diabetic Retinopathy Study (ETDRS) showed that aspirin does not influence the course of proliferative retinopathy. There was no statistically significant difference in the severity of vitreous/preretinal hemorrhages or their rate of resolution between the aspirin and placebo groups. Thus, it appears that there is no contraindication to aspirin use to achieve cardiovascular benefit in diabetic patients who have proliferative retinopathy.

Peripheral Vascular Disease

Atherosclerosis is markedly accelerated in the larger arteries. It is often diffuse, with localized enhancement in certain areas of turbulent blood flow, such as at the bifurcation of the aorta or other large vessels. Clinical manifestations of peripheral vascular disease include ischemia of the lower extremities, impotence, and intestinal angina.

The incidence of **gangrene of the feet** in people with diabetes is 30 times that in age-matched controls. The factors responsible for the development of this condition, in addition to peripheral vascular disease, are small vessel disease, peripheral neuropathy with loss of both pain sensation and neurogenic inflammatory responses, and secondary infection. In two-thirds of patients with ischemic gangrene, pedal pulses are not palpable. In the remaining one-third who has palpable pulses, reduced blood flow through these vessels can be demonstrated by plethysmographic or Doppler ultrasound examination. Prevention of foot injury is imperative. Agents that reduce peripheral blood flow such as tobacco and propranolol should be avoided. Control of other risk factors such as hypertension is essential. Cholesterol-lowering agents are useful as adjunctive therapy when early ischemic signs are detected and when dyslipidemia is present. Patients should be advised to seek immediate medical care if a diabetic foot ulcer develops. Improvement in peripheral blood flow with endarterectomy and bypass operations is possible in certain patients.

5. SKIN AND MUCOUS MEMBRANE COMPLICATIONS

Chronic pyogenic infections of the skin may occur, especially in poorly controlled diabetic patients. Candidal infection can produce erythema and edema of intertriginous areas below the breasts, in the axillas, and between the fingers. It causes vulvovaginitis in most chronically uncontrolled diabetic women with persistent glucosuria and is a frequent cause of pruritus. While antifungal creams containing miconazole or clotrimazole offer immediate relief of vulvovaginitis, recurrence is frequent unless glucosuria is reduced.

In some patients with type 2 diabetes, poor glycemic control can cause a severe hypertriglycemia, which can present as eruptive cutaneous xanthomas and pancreatitis. The skin lesions appear as yellow morbilliform eruptions 2 to 5 mm in diameter with erythematous areolae. They occur on extensor surfaces (elbows, knees, buttocks) and disappear after triglyceride levels are reduced.

Necrobiosis lipoidica diabeticorum (Figure 17-18) are oval or irregularly shaped plaques with reddish demarcated borders and a glistening yellowish surface usually located over the anterior surfaces of the legs or the dorsal surfaces of the ankles. Rarely, lesions can occur on the hands, fingers, forearms, face, and scalp. The necrobiosis lesion usually starts out as an oval violaceous patch that slowly expands. The advancing border is red and the central

FIGURE 17–18 Necrobiosis lipoidica diabeticorum.

area turns yellow-brown. The thinning of the dermis in the center of the lesion leads to the shiny surface and prominent telangiectasia. It also allows the subcutaneous fat to become more visible hence the yellowish appearance. Pathologically, the lesions show degeneration of collagen, granulomatous inflammation of subcutaneous tissues and blood vessels, capillary basement membrane thickening, and obliteration of vessel lumina. The condition is associated with type 1 diabetes, although it can occur in patients with type 2 diabetes and also in people without diabetes. It occurs in about 0.3% of patients with diabetes, usually in patients in their 30s and 40s, and is about three times more common in women than in men. In some studies an association with microalbuminuria and retinopathy has been reported. Improving glycemic control may help the condition. The first-line treatment includes topical and subcutaneous corticosteroids. Second-line treatments include systemic steroids, cyclosporine, ticlodipine, nicotinamide, clofazimine, fumarate esters, intralesional etanercept, and topical psoralen with ultraviolet A radiation. Pulsed dye lasers can improve the appearance of telangiectasias. Flare-ups are frequent. No treatment is completely effective.

Shin spots are uncommon in adult diabetics. They are brownish, rounded, painless atrophic lesions of the skin in the pretibial area.

6. BONE AND JOINT COMPLICATIONS

Bone and joint complications are generally attributed to metabolic or vascular sequelae of long-standing diabetes.

Diabetic cheiroarthropathy is a syndrome of chronic progressive stiffness of the hand secondary to contracture and tightening of the skin over the joints. It is characterized by inability to flatten the palms against a flat surface (prayer sign). It is believed to be due to glycosylation of collagen and perhaps other proteins in connective tissue. It is associated with poor glycemic control and with longer duration of diabetes.

Dupuytren contractures consist of nodular thickening and contracture of the palmar fascia of the hand, producing flexure contractures of the fingers. It can occur in the absence of diabetes, but is more common in people with diabetes. The etiology is unclear but there may be an inflammatory component. Glucocorticoid injection into discrete nodules can sometimes help but the standard treatment is surgical fasciectomy.

Carpal tunnel syndrome occurs when the median nerve is compressed within the carpal tunnel. It is more common in people with diabetes, especially those who also have diabetic cheiroarthropathy. It is presumably due to glycosylation of collagen and other proteins in the connective tissue.

Patients with adhesive capsulitis of the shoulder (frozen shoulder) complain primarily of stiffness and loss of range of motion. They may also have shoulder pain. It occurs more frequently in people with long-standing diabetes—the incidence being two to four times higher than in the general population. The patients may also have diabetic cheiroarthropathy or Dupuytren contractures. In most cases it is a limited condition that responds to physical therapy. Patients should be warned that recovery may take 6 to 18 months. For a few patients surgery may be necessary. Adhesive capsulitis of the hip has also been described.

Data on bone mineral density and fracture risk in people with diabetes are contradictory. Bone mineral density has been reported to be low, normal, or high in type 2 diabetes patients. Type 2 diabetes patients do appear to be at increased risk for nonvertebral factures. Women with type 1 diabetes have an increased risk of fracture when compared to women without diabetes. It is likely that other factors such as duration of diabetes and diabetes complications such as neuropathy and renal disease affect both the bone mineral density and fracture risk.

Diffuse idiopathic skeletal hyperostosis (DISH) is a skeletal disease characterized by ossification of the anterior longitudinal ligament of the spine and various extraspinal ligaments. It causes stiffness and decreased range of spinal motion. The peripheral joints most commonly affected are the metacarpophalangeal joints, elbows, and shoulders. Diabetes, obesity, hypertension, and dyslipidemia are risk factors for this condition.

Hyperuricemia and gout are disorders associated with the metabolic syndrome. Thus, it is not surprising that type 2 diabetes patients are at increased risk for acute gout as well as chronic tophaceous gout.

Bursitis, particularly of the shoulders and hips, occurs more frequently than expected in patients with diabetes.

7. INFECTION

There are also several unusual infections that occur almost exclusively in diabetic patients (eg, emphysematous cholecystitis, mucormycosis, malignant otitis externa, and necrotizing

papillitis). As noted earlier, atherosclerosis with peripheral vascular disease is very common in the diabetic population, and the resultant ischemia undoubtedly plays a role in the frequent and severe lower extremity infections seen in these patients.

MANAGEMENT OF DIABETES IN THE HOSPITALIZED PATIENT

A number of studies have observed that hospitalized patients with diabetes and those with new-onset hyperglycemia (ie, those without a preadmission diagnosis of diabetes) have higher inpatient morbidity and mortality. The morbidity and mortality in diabetics is twice that of nondiabetics. Those with new-onset hyperglycemia have even a higher mortality—almost eightfold greater in one study. These observations have led to increased interest in improving glucose control in the hospitalized diabetic patient.

Most patients with diabetes are hospitalized for reasons other than their diabetes. Up to 10% to 15% of all hospitalized patients have diabetes. Audits suggest that as many as a 30% of hospitalized diabetic patients have inappropriate management of their diabetes such as being given metformin where contraindicated, failure to act on high blood glucose levels, omission of diabetes medication, no record of diabetes complications, inappropriate insulin management, or infrequent blood glucose monitoring. Use of outpatient oral therapies or insulin regimens in the hospital is challenging. Patients are not eating according to their normal schedule and are often fasting for procedures. It is, therefore, usual to use insulin, subcutaneous or intravenous, in the hospitalized patient. Insulin is safe to use in patients with cardiac, renal, and liver disease and its dosing can be adjusted to match changing inpatient needs.

Surgery represents a stressful situation during which most of the insulin antagonists (catecholamines, GH, corticosteroids) are mobilized. In the patient with diabetes, this can lead to a worsening of hyperglycemia and perhaps even ketoacidosis. The aim of medical management of people with diabetes during the perioperative period is to minimize these stress-induced changes. Recommendations for management depend both on the patient's usual diabetic regimen and on the type of surgery (major or minor) to be done.

For people with diabetes controlled with diet alone, no special precautions are necessary unless diabetic control is markedly disturbed by the procedure. If this occurs, small amounts of short-acting insulin, as needed, will correct the hyperglycemia. Patients on oral agents should not take them on the day of surgery. If there is significant hyperglycemia, short-acting insulin can be given as needed. If this approach does not provide adequate control, an insulin infusion should be started in the manner indicated later. The oral agents can be restarted once the patient is eating normally after the operation. It is important to order a postoperative serum creatinine level to ensure normal renal function prior to restarting metformin therapy.

Patients taking insulin represent the only serious challenge to management of diabetes when surgery is necessary. The insulin regimen used to control the glucose depends on the kind of diabetes (type 1 or type 2); whether it is minor surgery (<2 hours and patient eating afterward) or major surgery (longer than 2 hours, invasion of body cavity, not eating afterward); and the preoperative insulin regimen (eg, basal bolus or premixed insulin twice a day or premeal bolus only or regular before meals and NPH at bedtime). Type 1 patients have to be on some insulin to prevent the development of diabetic ketoacidosis. Many type 2 patients on insulin are fine without insulin for a few hours. Ideally patients with diabetes should undergo surgery early in the morning. Table 17–22 summarizes the approach for these various kinds of patients. One insulin infusion method adds 10 U of regular insulin to 1 L of 5% dextrose in half-normal saline, and this is infused intravenously at a rate of 100 to 180 mL/h. This gives the patient 1 to 1.8 U of insulin per hour, which, except in the most severe cases, generally keeps the blood glucose within the range of 100 to 250 mg/dL (5.5-13.9 mmol/L). The infusion may be continued for several days if necessary. Plasma glucose or blood glucose should be determined every 2 to 4 hours to be sure metabolic control is adequate. If it is not, adjustments in the ratio of insulin to dextrose in the intravenous solution can be made.

An alternative method, which is gaining increasing popularity, consists of separate infusions of insulin and glucose delivered by pumps to permit independent adjustments of each infusion rate, depending on hourly variation of blood glucose values. There are a number of different algorithms available for insulin infusions. Table 17–23 provides guidelines for management with an insulin infusion and an algorithm designed to achieve glycemic control in the range of 120 to 180 mg/dL blood glucose.

TABLE 17–22 Recommendations for management of insulin-treated diabetes during surgery.

	Minor Surgical Procedures (2 h; Eating Afterward)	Major Surgical Procedures (>2 h; Invasion of Body Cavity; Not Eating Immediately After Recovery)
Type 2 patients on basal bolus insulin regimen; twice daily premixed insulin	No insulin on the day of operation. Start 5% dextrose infusion; monitor fingerstix blood glucose and give subcutaneous short-acting insulin every 4 or 6 h	Same regimen as minor procedure. If control is not satisfactory, then intravenous insulin infusion
Type 1 patient on basal bolus insulin regimen or on insulin pump	Patients on pump should discontinue the pump the evening before procedure and should be given 24 h basal insulin. On day of procedure, start 5% dextrose; monitor blood glucose and give subcutaneous short-acting insulin every 4 or 6 h	Initiate insulin infusion on morning of procedure and transition back to usual regimen when eating

TABLE 17–23 Guideline for perioperative diabetes management with an intravenous insulin infusion.

1. **Maintenance of IV fluids (IV dextrose infusion must be maintained while the patient is on insulin infusion. Minimum rate of 10 mL/h)**
   ☐ D5 NS at 100 mL/h
   ☐ D5 1/2 NS at 100 mL/h
   ☐ D10 NS at _____ mL/h (for patients with fluid restrictions or renal failure)
   ☐ Additive: KCl 20 mEq/L (*generally 20 mEq/L*)
   ☐ Other_____ at _____ mL/h
2. **Regular insulin infusion 100 U regular insulin in 100 mL NS (1 U = 1 mL)**
   A. Flush first 20 mL of infusion through tubing before connecting to patient
   B. Before beginning infusion, check blood glucose (BG) with glucose meter
3. **Start insulin infusion rate as follows (when BG ≥100 mg/dL)**
   ☐ 0.3 U/h taking <30 U insulin daily (*recommended for type 1; Pancreatectomy*)
   ☐ 1 U/h for patients previously diet controlled, taking oral hypoglycemic agent, or <30 U insulin daily
   ☐ 1.5 U/h for patients taking >30 U insulin daily
   ☐ Other _____ U/h
4. **Adjust insulin infusion rate as follows:**

   ☐ **Standard adjustment**   ☐ **Sensitive Adjustment (for Type 1; Pancreatectomy)**
   BG <80 mg/dL; stop infusion and **call MD;**   BG <80 mg/dL; stop infusion and **call MD;**
   see instruction #5 below   **see instruction #5 below**
   Do not restart insulin infusion   Do not restart insulin infusion
   until BG >100 mg/dL[a]   until BG >100 mg/dL[a]
   BG 80-120; decrease drip by 0.5 U/h   BG 80-120; decrease drip by 0.2 U/h
   BG 121-180; no change in drip rate   BG 121-180; no change in drip rate
   BG 181-250; increase drip by 0.5 U/h   BG 181-250; increase drip by 0.2 U/h
   BG >250 bolus 5 U regular insulin IV and   BG >250 bolus 2 U regular insulin IV and
   increase drip by 0.5 U/h   increase drip by 0.2 U/h

5. **For a BG <80 mg/dL or >400 mg/dL on insulin infusion, call MD**
   ☒ BG <80 mg/dL but >60 mg/dL, stop insulin infusion; check BG every 15 min
   ☒ BG ≤60 mg/dL, stop insulin infusion; give **50-mL D50W IV push**; check BG every 15 min and repeat treatment until BG ≥100 mg/dL. When BG ≥100 mg/dL, call MD for new insulin infusion rate
   ☒ BG >400 mg/dL, call MD to reassess insulin infusion rate
   ☒ If TPN or tube feeds are interrupted for longer than 30 min, start D10W at 50 mL/h. Notify MD about change and future action
6. **When converting to subcutaneous (SQ) insulin, give prescribed SQ dose 30 min prior to discontinuing insulin infusion. Use Adult** SQ Insulin Order Sheet
7. **If patient eating meals give _____ U aspart SQ after patient eats carbohydrates and continue insulin infusion**
8. **Discontinue insulin infusion maintenance IV fluids when insulin infusion discontinued**

[a]Check BG every hour with glucose meter until stable (range 100-180 mg/dL) for two consecutive readings and then every 2 hours.

After surgery, when the patient has resumed an adequate oral intake, intravenous administration of insulin and dextrose can be stopped half an hour after the first subcutaneous insulin injection. Insulin needs may vary in the first several days after surgery because of continuing postoperative stresses and because of variable caloric intake. In this situation, multiple doses of regular insulin, guided by blood glucose determinations, can keep the patient in acceptable metabolic control.

In the intensive care units, glucose levels are controlled most frequently using insulin infusions. Patients on total parental nutrition (TPN) can have insulin added to the bag. Standard TPN contains 25% dextrose, so 50-mL/h infusion delivers 12.5 g of dextrose per hour.

On the general surgical and medical wards, most patients are managed on subcutaneous insulin regimens. Limited cross-sectional and prospective studies suggest that the best glucose control is achieved on a combination of basal and bolus regimen with 50% of daily insulin needs provided by intermediate or long-acting insulins. Standardized order sets prompt medical personnel to write more physiological insulin orders, reduce errors, and include algorithms for recognition and treatment of hypoglycemia (see http://ucsfinpatientdiabetes.pbworks.com for examples). Table 17–24 is an example of one such order set for a subcutaneous insulin regimen.

Targets for Glucose Control in the Hospitalized Patient

A number of studies have observed that hospitalized patients with diabetes and those with new-onset hyperglycemia (ie, those without a preadmission diagnosis of diabetes) have higher inpatient morbidity and mortality. Also, poor glucose control in diabetics at admission is associated with increased size of myocardial infarction and in some studies increased nosocomial infections after surgery. These observations have led to the question of whether lowering glucose levels close to normal in the hospital improves outcomes.

Initial studies of patients in surgical and medical ICUs suggested that aggressive treatment of hyperglycemia (blood glucose <110 mg/dL) reduced mortality and morbidity. A large multicenter, multinational study (NICE-SUGAR), however, failed to confirm these reports. This study recruited 6104 surgical and medical ICU patients with hyperglycemia (20% had diabetes) and randomized them to tight control (81-108 mg/dL) or less tight control (<180 mg/dL). The tight group achieved blood glucose levels of 115 ± 18 and the conventional group 144 ± 23. There were more deaths (829 vs 751) in the tight glucose control group compared to the less tight glucose control group ($p = 0.02$). The intensively treated group also had more cases of severe

TABLE 17–24 Example of a standardized subcutaneous insulin order set for inpatient use.

1. Check blood glucose and give insulin before meals, bedtime, and 2 AM.

2. Discontinue previous SQ insulin order.

3. If patient becomes NPO for procedure/stops eating:

• **HOLD** nutritional dose of rapid-acting analog

• Give correctional dose of rapid-acting analog if BG >130 mg/dL

• Give glargine dose. If BG has been <70 mg/dL in last 24 h, call MD to consider adjusting glargine dose

• Call MD for NPO orders if patient on 70/30, NPH insulin or has been NPO >12 h

A. Basal and nutritional insulin dose (in units):

Time	Breakfast	Lunch	Dinner	Bedtime
Rapid-acting analog				
NPH				
Insulin glargine				
Insulin mixture				

B. Meal time correctional insulin with rapid-acting analog. Check box to choose scale. Add or subtract from nutritional dose of rapid-acting analog.

Blood Glucose Range	☐ Sensitive BMI <25 and/or <50 U/d	☐ Average BMI 25-30 and/or 50-90 U/d	☐ Resistant BMI >30 and/or >90 U/d	☐ Custom
<70 mg/dL Once BG • 100, give	Treat for hypoglycemia per protocol (see order #6). Once BG •100 mg/dL give rapid-acting analog with following change when patient eats:			
	2 U less	3 U less	3 U less	- - - U less
70-100	1 U less	2 U less	3 U less	- - - U less
101-130	Give nutritional rapid-acting insulin as in #4A			
131-150	+ 0	+ 1	+ 2	+ - - -
151-200	+ 1	+ 2	+ 3	+ - - -
201-250	+ 2	+ 4	+ 6	+ - - -
251-300	+ 3	+ 6	+ 9	+ - - -
301-350	+ 4	+ 8	+ 12	+ - - -
351-400	+ 5	+ 10	+ 15	+ - - -
>400	+ 6	+ 12	+ 18	+ - - -

C. ☒ Bedtime and 2 AM correctional insulin with rapid-acting analog if BG ≥200 mg/dL.

BG Range (mg/dL)	Default Value (U)	Custom
200-250	1	- - - U
251-300	2	- - -
>300	3	- - -

4. Call MD for BG <70 mg/dL or >400 mg/dL.

5. For BG <70 mg/dL, use Hypoglycemia Protocol below. These hypoglycemia orders remain active for duration of SQ insulin administration. For patient taking PO, give 20 g of oral fast-acting carbohydrate per patient preference:

☒ Give 4 glucose tablets (5 g glucose/tablet). Repeat Q 15 min until BG ≥100 mg/dL.

or

☒ Give 6 oz fruit juice. Repeat Q 15 min until BG ≥100 mg/dL.

☒ Give 25-mL D50W IV push if patient cannot take PO. Repeat Q 15 min until BG ≥100 mg/dL.

☒ Check fingerstick glucose every 15 min and repeat treatment until BG is ≥100 mg/dL.

6. Discontinue above monitoring and intervention orders when SQ insulin is discontinued.

Note: Glargine (Lantus) *cannot* be mixed with any other insulin. Give glargine as a separate injection.

hypoglycemia (206 vs 15 cases), and the excess deaths in the intensive group were due to cardiovascular events.

A study on tight intraoperative glycemic control during cardiac surgery also failed to show any benefit; if anything, the intensively treated group had more events. The United Kingdom Glucose Insulin in Stroke Trial (GIST-UK) failed to show beneficial effect of tight glycemic control in stroke patients; however, the investigators acknowledged that, because of slow recruitment, the study was underpowered.

Thus, based on the evidence available so far, ICU patients with diabetes and new-onset hyperglycemica with blood glucose levels above 180 mg/dL should be treated aiming for target glucose levels between 140 mg/dL (7.8 mmol/L) and 180 mg/dL (10 mmol/L). Targeting blood glucose control in the intensive care unit close to 100 mg/dL (5.6 mmol/L) has not been proven to be beneficial and may even be harmful. When patients leave the ICU, target glucose values between 100 mg/dL and 180 mg/dL may be appropriate, although this view is based on clinical observations rather than conclusive evidence.

DIABETES MELLITUS AND PREGNANCY

Hormone and Fuel Balance During Pregnancy

During pregnancy, the rapidly growing fetus impacts metabolism in the mother and causes profound hormonal and metabolic changes. These changes significantly affect the management of preexisting diabetes, and can precipitate hyperglycemia and diabetes in previously nondiabetic mothers.

Early in pregnancy, the hormones of pregnancy initiate changes that prepare the mother for the increasing nutrient requirements of the fetus late in pregnancy. Fat deposition is accentuated in early pregnancy due to enhanced conversion of glucose to triglyceride after meals in pregnant compared with nonpregnant subjects. Elevated prolactin and placental lactogen drive the production of serotonin by the β cell, which leads to β cell expansion, a process that peaks in mid gestation. β cell mass approximately doubles during pregnancy, and both β cell glucose sensitivity and insulin secretory capacity increase. At the same time, α cell mass and glucagon secretion remain unchanged.

As the pregnancy progresses and nutrient utilization by the fetus increases, plasma concentrations of glucose in the fasting state tend to decline slightly. Since the flow of glucose and other nutrients to the fetus depends on the gradient across the placenta, maintenance of maternal glucose levels becomes increasingly important and is achieved through increasing insulin resistance in the liver, muscle, and adipose tissue. Several pregnancy hormones contribute to insulin resistance, but progesterone, which increases steadily through pregnancy and peaks shortly prior to parturition, provides the major drive. Glucose availability for the fetus increases as increased lipolysis in adipose tissue leads to a shift toward fatty acid utilization by maternal tissues. Ketogenesis is also accentuated in the postabsorptive state during pregnancy, secondary to hormonal effects on the maternal liver cells and

increased provision of substrate FFA. The increased FFAs contribute to the marked reduction in insulin-mediated glucose uptake by skeletal muscle characteristic of late pregnancy. As a net result, during the third trimester, pregnant women without diabetes run slightly higher blood glucose and ketone levels than nondiabetic subjects, and women with preexisting diabetes that do not adjust therapy appropriately can develop severe hyperglycemia.

The fetus also plays a role in the maintenance of the maternal to fetal glucose gradient—the fetal glucose levels being determined by fetal insulin levels and the fetal insulin sensitivity. Maternal hyperglycemia due to inadequate control of maternal diabetes early in pregnancy will lead to an increase in fetal glucose levels, fetal hyperinsulinemia, and large for gestational age fetus.

Pregnancy in Women with Preexisting Diabetes

A. Prevalence The prevalence of pregestational diabetes in pregnant women is increasing. In the United Kingdom, the prevalence of type 1 diabetes increased from 1.56 to 4.09 per 1000 pregnancies between 1995 and 2015. For type 2 diabetes, the prevalence increased from 2.34 to 5.09 per 1000 pregnancies between 1995 and 2008 with a more rapid increase to 10.62 per 1000 pregnancies by 2012.

B. Maternal, fetal, and neonatal consequences of presence of diabetes during pregnancy If diabetes is poorly controlled in the first weeks of pregnancy, the risks of spontaneous abortion and congenital malformation of the infant are increased. Poor glycemic control later in pregnancy is associated with still births, fetal macrosomia, polyhydramnios, and neonatal hypoglycemia. Preexisting diabetes-related complications, particularly gastroenteropathy, retinopathy, and nephropathy can impact both the pregnant woman and the fetus.

Congenital anomalies Poorly controlled diabetes in the first weeks of pregnancy raises the risks of spontaneous abortion and congenital anomalies of the infant. The commonest anomalies are cardiac, neural tube defects, and genitourinary abnormalities. Their incidence compared to the normal population and their presumed time of occurrence during embryonic development are listed in Table 17–25. The rate of anomalies is higher in diabetic women with poor preconception control. Observational studies demonstrate a linear relationship between glycated hemoglobin levels and malformation rates. From a systematic review of several observational studies, it was estimated that the relative risk reduction of congenital anomalies for each 1% decrease in HbA_{1c} ranged from 0.39 to 0.59. Attending preconception clinics with intensive diabetic management instituted prior to conception and continued through early pregnancy, results in significant reduction in the frequency of anomalies—to rates near the population norms.

Polyhdramnios Later in pregnancy, polyhydramnios, a common complication in women with poorly controlled diabetes, may lead to preterm delivery. Polyhydramnios also increases the risk for

TABLE 17–25 Congenital malformations in infants of diabetic mothers.[a]

	Ratio of Incidences Diabetic vs Control Group	Latest Gestational Age for Occurrence (Weeks after Menstruation)
Caudal regression syndrome (due to premature termination of the vertebral column—resulting in agenesis of the sacrum and coccyx and/or malformations of the pelvis and legs)	252	5

[a]Data from Kucera J. Rate and type of congenital anomalies among offspring of diabetic women. *J Reprod Med*. 1971;7:61; and Mills JL, Baker L, Goldman AS. Malformations in infants of diabetic mothers occur before the seventh gestational week: implications for treatment. *Diabetes*. 1979;28:292.

placenta abruptio and postpartum uterine atony. Polyhydramnios is an excess volume of amniotic fluid (>1000 mL, often >3000 mL). It is most often associated with fetal macrosomia. The excess volume of amniotic fluid is not related simply to the concentration of glucose or other solutes in amniotic fluid or to excess fetal urine output as measured by change in bladder size on ultrasonography. Other possible factors include decreased fetal swallowing, decidual and amniotic fluid prolactin, and as yet unknown determinants of the complicated multicompartmental intrauterine transfer of water. Polyhydramnios is rare in women with well-controlled diabetes.

Fetal macrosomia   Many fetuses of poorly controlled diabetic mothers are **macrosomic** (birth weight >90th percentile for gestational age), with increased fat stores, increased length, and increased abdomen-to-head or thorax-to-head ratios. The hypothesis that fetal macrosomia results from the causal chain of maternal hyperglycemia → fetal hyperglycemia → fetal hyperinsulinemia → fetal macrosomia has been confirmed by clinical and experimental studies. Macrosomic infants of diabetic mothers have significantly higher concentrations of C peptide (representing endogenous insulin secretion) in their cord sera or amniotic fluid than in those with birth weights appropriate for gestational age. Monkey fetuses with insulin-releasing pellets implanted in utero become macrosomic. Other metabolic substrates that cross the placenta, such as branched-chain amino acids may also play a role in fetal macrosomia, and transplacental lipids could contribute to fat deposition.

Prevention of maternal hyperglycemia throughout pregnancy can reduce the incidence of macrosomia. The glycemic threshold for fetal macrosomia seems to be *postprandial* peak values above 130 mg/dL (7.2 mmol/L). On the other hand, excessively tight glycemic control (average peak postprandial blood glucose levels <110 mg/dL [6.1 mmol/L]) can be associated with insufficient fetal growth and small-for-date infants.

Complications of macrosomia include fetopelvic disproportion leading to shoulder dystocia and its attendant risk for brachial plexus injury and humeral and clavicle fractures. The neonate with macrosomia is also at increased risk for hypoglycemia, hyperbilirubinemia, hypocalcemia, respiratory distress syndrome, and polycythemia.

Adverse maternal outcomes of difficult vaginal delivery include severe perineal lacerations and subsequent urinary and/or fecal incontinence.

Intrauterine growth retardation   The fetus of a woman with diabetes of long duration and vascular disease may suffer intrauterine fetal growth restriction related to inadequate uteroplacental perfusion. All body diameters may be below normal on ultrasonographic measurements, but the abdominal circumference is especially affected, and oligohydramnios and abnormal Doppler flow measurements of the umbilical cord are common. In these patients provision of adequate rest, meticulous control of hypertension (target <135/85 mm Hg), maintenance of normal blood glucose levels, and intensive fetal surveillance are all essential for success.

Intrauterine death   Prior to the 1970s, the incidence of apparently sudden intrauterine fetal demise in the third trimester of diabetic pregnancies was at least 5%. Except for congenital malformations, the cause of stillbirth is often not obvious. The risk is greater with poor diabetic control, and the incidence of fetal death exceeds 50%, if ketoacidosis develops in the mother. Some instances of fetal demise are associated with preeclampsia-eclampsia, which is more common in pregnancies complicated by diabetes. Fetal death has also been associated with pyelonephritis—this is now largely prevented by screening for and treating asymptomatic bacteriuria. Other than these known risk factors, one can presume (based on experimental studies) that the combination of fetal hyperglycemia and hypoxia leads to acidosis and myocardial dysfunction. Good glycemic control in diabetic women greatly reduces the risk of stillbirth.

Neonatal hypoglycemia   Hypoglycemia is common in the first 48 hours after delivery from previously hyperglycemic mothers and is defined as blood glucose below 36 mg/dL (2.0 mmol/L) regardless of gestational age. The risk is as high for infants of mothers with type 2 diabetes as type 1 diabetes. Neonatal

hypoglycemia is most closely linked to poor maternal glucose control and elevated fetal insulin levels during labor and delivery, although data from amniotic fluid insulin studies suggest that the more hyperinsulinemic the fetus in the late third trimester, the higher the risk of neonatal hypoglycemia. Infants of diabetic mothers may also have deficient catecholamine and glucagon secretion, and the hypoglycemia may be related to diminished hepatic glucose production and oxidation of free fatty acids. The symptomatic infant may be lethargic with associated apnea, tachypnea, cyanosis, or seizures. Early feeding with 10% dextrose in water by bottle or gavage by 1 hour of age should be instituted in the at-risk neonate. If this is not successful, treatment with intravenous dextrose solutions is indicated. There are usually no long-term sequelae of episodes of neonatal hypoglycemia. Keeping maternal blood glucose levels below 144 mg/dL and tight glycemic control during labor can reduce the frequency of neonatal hypoglycemia.

Diabetic gastroenteropathy   In early gestation, diabetic gastroparesis can severely exacerbate the nausea and vomiting of pregnancy (hyperemesis gravidarum), which sometimes continues into the third trimester. Drugs stimulating gastric motility such as erythromycin may be useful, but many patients with this complication require hyperalimentation to achieve nutritional intake adequate for fetal development.

Diabetic retinopathy   Background diabetic retinopathy may develop or progress during pregnancy, but it usually regresses postpartum. If background retinopathy is already present in early pregnancy, the rate of progression to neovascularization over the course of the pregnancy (proliferative diabetic retinopathy) is 6% if the background retinopathy is mild; 18% if it is moderate; and 38% if severe preproliferative changes are present. The risk factors for progression to proliferative retinopathy include poor glycemic control before and during early pregnancy, rapid improvement in glycemic control during pregnancy, hypertension, and perhaps the many growth factors derived from placental tissue. These risks are an important reason to institute intensified preconception management of diabetes. During pregnancy, sequential ophthalmologic examinations are essential in women with type 1 or type 2 diabetes, and laser photocoagulation treatment of the retina may be necessary.

Diabetic nephropathy   The risk of worsening of diabetic nephropathy during pregnancy depends on baseline renal function and the degree of hypertension. Total urinary albumin excretion does not increase substantially in normal pregnancy, but total urinary protein collections, which obstetricians have used to define preeclampsia, may show a twofold increase in uncomplicated gestation. Diabetic women with microalbuminuria (30-299 mg/24 h) may have worsening of the albuminuria during pregnancy and 15% to 45% develop the preeclamptic syndrome. Albuminuria usually regresses postpartum. Women with macroalbuminuria (24-hour urinary albumin >300 mg) and well-preserved renal function (serum creatinine <1.2 mg/dL [<106 µmol/L]; creatinine clearance >80 mL/min) at the beginning of pregnancy are likely to have moderate decline in renal function during gestation, and

approximately 6% may have renal failure at follow-up several years after pregnancy. The latter figure may not be different from the course of diabetic nephropathy in nonpregnant women with this level of renal dysfunction. If initial renal function in pregnancy is impaired (serum creatinine >1.2 mg/dL [>106 µmol/L]; creatinine clearance <80 mL/min), then 35% to 40% are expected to show further decline during pregnancy, and 45% to 50% have renal failure at follow-up several years later. Thus, careful preconception counseling is important for these patients and their family members.

Management

Pregnant women with preexisiting diabetes should ideally receive care in a multidisciplinary clinic staffed by obstetricians, endocrinologists, diabetes nurse specialists, dietitians, and specialist midwives. There is substantial evidence that this improves the outcomes in women with pregestational diabetes.

Preconception counseling   All diabetic women of reproductive age should be counseled to use adequate birth control and plan their pregnancies. Before any planned pregnancy, the couple should be referred for preconception assessment and counseling. There should be assessment and discussion regarding management of diabetic complications. Baseline measurements should include thyroid function tests including autoantibodies; early morning spot urine albumin/creatinine ratio; urinalysis to rule out asymptomatic bacteriuria; retinal examination; and cardiological assessment in high-risk patients such as those with evidence of microvascular disease. ACE inhibitors and ARBs cannot be used during pregnancy. If necessary, alternative antihypertensive agents that are safe for use in pregnancy (methyldopa, nifedipine, amlodipine, labetolol) should be prescribed. Lipid-lowering therapies are also contraindicated, and lipid abnormalities must be managed by dietary measures. There should be discussion of risks and expected management strategies in the pregnancy. The patient should be given glycemic goals with the aim of achieving control as close to normal as possible before conception.

Glucose and insulin management   Women are seen every 2 to 4 weeks in the first and second trimester and then every 1 to 2 weeks until 36 weeks and then weekly to term. The goal of glucose management during pregnancy is to prevent both preprandial and postprandial hyperglycemia. Patients with type 2 diabetes on oral agents are usually switched to insulin treatment during pregnancy. There are small nonrandomized studies suggesting that metformin use is safe in the first trimester. The drug does cross the placenta, but it has not been associated with teratogenesis. Glyburide was thought not to cross the placenta and has been considered safe for use in pregnancy. More recently it has been found that glyburide does cross the placenta and fetal glyburide levels are approximately 70% of maternal plasma levels. Until larger randomized control studies of metformin and glyburide use at conception and early pregnancy are available, caution should be exercised regarding their use early in pregnancy.

Perinatal outcome is optimal if patients aim for fasting plasma glucose levels below 100 mg/dL (5.6 mmol/L) and

postprandial levels below 130 mg/dL (7.2 mmol/L). For patients with a history of recurrent severe hypoglycemic reactions, somewhat higher blood glucose targets should be selected. Self-monitoring of capillary blood glucose should be performed eight or more times a day. Occasional monitoring in the middle of the night is recommended to monitor for nocturnal hypoglycemia. There is evidence that CGM systems may be helpful in reducing both hyperglycemia and hypoglycemic excursions. These systems do not replace self-monitoring of blood glucose but allow for fine-tuning of glycemic control and alert the patient to rapid changes in glucose levels. One randomized study showed that pregnancies using CGM had better glycemic control in the third trimester and lower risk of macrosomia. Clinical trials using continuous glucose monitors during pregnancy are currently underway. Confirmation of long-term control is provided by sequential measurement of glycosylated hemoglobin and fructosamine every 4 to 6 weeks.

Patients should see the nutritionist to assess caloric needs and get instructed on carbohydrate counting. The caloric intake is based on ideal body weight and it is approximately 30 to 35 kcal/kg for normal-weight women; about 24 kcal/kg current weight for overweight women; and 10 to 15 kcal/kg current weight for obese women. All patients should learn how to self-adjust their doses of short-acting insulin based on planned carbohydrate load or pre-meal blood glucose levels.

Type 1 patients are typically on a basal-bolus insulin regimen (see Table 17–15). Regular insulin, insulin aspart, and insulin lispro are the approved bolus insulins; and NPH and insulin detemir are used for basal coverage. Studies on insulin glargine use during pregnancy are limited. Retrospective case control studies have not shown any adverse effects of glargine use at the time of conception and during pregnancy. Many type 1 patients elect to use insulin pumps during pregnancy. Since the risk of diabetic ketoacidosis is increased with pump use, it is especially critical that patients have adequate instruction on the use of insulin pumps and can troubleshoot any problems that may arise.

Women with type 2 diabetes can be managed with regular insulin or short-acting insulin analogs before meals and NPH or insulin detemir at bedtime. Sometimes NPH or insulin detemir is also required in the morning.

Total insulin requirements vary during gestation. There is usually an increase in insulin dose between weeks 3 and 7, then a slight decrease between weeks 7 and 15 followed by a gradual increase until about week 35. The insulin requirements in type 1 diabetes at around 35 weeks (1.0 U/kg/24 h) are almost double the prepregnancy requirements. Women with type 2 diabetes usually start out with higher doses and may eventually require as much as 1.5 to 2 U/kg/24 h. Exercise can improve insulin sensitivity and should be encouraged in type 2 patients. The benefits of exercise are less obvious in women with type 1 diabetes, and there is always a concern about exercise-induced hypoglycemia.

Hypoglycemic reactions are more frequent and sometimes more severe in early gestation but are a risk at any time during pregnancy. Therefore, insulin-treated patients should take snacks between meals and at bedtime to prevent hypoglycemia. Family members should be instructed in the use of glucagon. The use of

TABLE 17–26 Schedule of obstetric tests and procedures.

Procedure	Risk Based on Glycemic Control, Presence of Vascular Disease	
	Low Risk	**High Risk**
Ultrasound to date gestation	8-12 wk	8-12 wk
Prenatal genetic diagnosis	As needed	As needed
Targeted perinatal ultrasound; fetal echocardiography	18-22 wk	18-22 wk
Fetal kick counts	28 wk	28 wk
Ultrasound for fetal growth	28 and 37 wk[a]	Every 3-8 wk
Antepartum FHR monitoring, backup with biophysical profile	36 wk, weekly	27 wk, 1-3 per wk
Amniocentesis for lung	…	35-38 wk
Induction of labor	41 wk[b]	35-38 wk

[a]Not needed in normoglycemic, diet-treated women with gestational diabetes mellitus.
[b]Earlier for obstetric reasons or for impending fetal macrosomia.

continuous glucose monitors is encouraged. Hypoglycemic reactions have not been associated with fetal death or congenital anomalies, but they pose a risk to maternal health.

Fetal monitoring (Table 17–26)   First-trimester ultrasound is often obtained to document viability, as the rate of miscarriage is higher in women with diabetes, and to estimate gestational age. A second-trimester, detailed ultrasound examination of fetal anatomy is performed at approximately 18 weeks for detection of congenital anomalies. Ultrasound examination in the third trimester (at 28-32 weeks and 38 weeks) is performed to assess fetal growth.

Antepartum fetal testing is recommended using fetal movement counting, biophysical profile, nonstress test (NST), and/or contraction stress test (CST) initiated at 32 to 34 weeks of gestation. Most simply, the infrequency of fetal movement as noted in regular fetal kick counts (fewer than four per hour) may indicate fetal jeopardy. The fetal biophysical profile is a rigorous analysis of fetal activity patterns using ultrasound to assess gross body movements, the tone of the limbs, and chest wall motions as well as reactivity of the fetal heart rate (FHR) and the volume of amniotic fluid. The presence of FHR accelerations and long-range variability on the NST and the absence of late decelerations (lower FHR persisting after the contraction subsides) on the CST indicate that the fetus is well oxygenated. Generally, the NST and CST are sensitive screening tests, and abnormal results of FHR monitoring in these tests overestimate the diagnosis of fetal distress. Therefore, it is wise to obtain additional evidence of fetal jeopardy (by biophysical ultrasonographic assessment) before cesarean delivery is recommended in preterm pregnancies. In term gestation with abnormal fetal testing, there is little to be gained by continuing the pregnancy. In complicated patients with IUGR, oligohydramnios, preeclampsia, or poor blood glucose control, testing may start as early as 26 weeks and is performed more frequently.

Timing of delivery   Unless maternal or fetal complications arise, the goal for delivery in diabetic women should be 38 to 41 weeks in order to reduce neonatal morbidity from preterm deliveries. On the other hand, the obstetrician may wish to induce labor before 39 weeks, if there is concern about increasing fetal weight. Before a preterm delivery decision (<37 weeks) is made or delivery is considered in women with poor glycemic control at 37 to 38 weeks of gestation, fetal pulmonary maturity should be determined. Tests for maturity using amniocentesis assess risk of neonatal respiratory distress syndrome and include the lecithin-sphingomyelin (L/S) ratio, phosphatidylglycerol, and other biochemical or physical assays of surfactant activity. In pregnancies complicated by hyperglycemia, fetal hyperinsulinemia can lead to low pulmonary surfactant apoprotein production. The lowest risk of respiratory distress syndrome is attained by delaying delivery (if possible) until 38 to 41 weeks and minimizing the need for cesarean sections.

Route of delivery   Once fetal lung maturity is likely, the route of delivery must be selected based on the usual obstetric indications. If the fetus seems large (>4200 g) on clinical and ultrasonographic examination of diabetic women, cesarean section probably should be performed because of the possibility of shoulder dystocia and birth trauma. Otherwise, induction of labor is reasonable, because maternal and peripartum risks are fewer following vaginal delivery. Once labor is underway, continuous FHR monitoring is essential. Maternal blood glucose levels greater than 150 mg/dL (8.3 mmol/L) can be associated with intrapartum fetal hypoxia.

Insulin and glucose management during labor and delivery   It is important to avoid maternal hyperglycemia during labor because it increases the risk for fetal acidemia and neonatal hypoglycemia. The goal is to maintain glucose levels between 70 and 110 mg/dL (3.9-6.1 mmol/L). Maternal glucose levels above 180 mg/dL (10 mmol/L) are consistently associated with neonatal hypoglycemia. During the latent phase of labor, maternal metabolic demands are fairly stable but there is significant energy expenditure during active labor and delivery and insulin needs are minimal. Glucose control is typically managed using intravenous dextrose (at 100-125 mL/h) and insulin infusions (Table 17–27).

After delivery of the placenta, the insulin-resistant state rapidly disappears, and insulin requirements are close to prepregnancy levels. Type 1 or type 2 patients who were previously on insulin can go back to their usual prepregnancy insulin regimens and doses once they start eating. Type 2 patients who were on oral agents prepregnancy frequently do not require any medication during the first 24 to 48 hours postpartum. They can stay on insulin while breastfeeding or go on metformin or glyburide which are safe while breastfeeding.

Neonatal management   Planning for the care of the infant should be started prior to delivery, with participation by the pediatrician or neonatologist in decisions about timing and management of delivery. In complicated cases, the pediatrician must be in attendance to learn about antenatal problems, to assess the need for resuscitation, to identify major congenital anomalies, and to

TABLE 17–27   Protocol for intrapartum insulin infusion.[a]

Intravenous Fluids
If blood glucose is >130 mg/dL (>7.2 mmol/L), infuse mainline Ringer lactate at a rate of 125 mL/h.
If blood glucose is <130 mg/dL (<7.2 mmol/L), infuse mainline Ringer lactate to keep vein open and begin Ringer lactate and 5% dextrose at a rate of 125 mL/h controlled by infusion pump.

Insulin Infusion
Mix 100 U of regular human insulin (U100) in 100 mL NaCl 0.9% and piggyback to mainline. The concentration is 1 U/mL. Adjust intravenous insulin hourly according to the following table when the blood glucose is >70 mg/dL (>3.9 mmol/L). Target blood glucose 70-110 mg/dL.

Blood Glucose in mg/dL (mmol/L)	Type 1	Type 2	Gestational Diabetes	Custom
<70 (<3.9)	No insulin	No insulin	No insulin	
71-90 (3.9-5)	0.5 U/h	No insulin	No insulin	
91-110 (5.1-6.1)	1	1 U/h	No insulin	
111-130 (6.2-7.2)	1.5	2	1 U/h	
131-150 (7.3-8.3)	2	3	2	
151-170 (8.4-9.4)	2.5	4	3	
171-190 (9.5-10.6)	3	5	4	
>190 (>10.6)	Call MD and check urine ketones			

[a]Protocol useful also for diabetic pregnant women who are "NPO" or being treated with beta-adrenergic tocolysis or corticosteroids. The scale dosages may need to be doubled for the latter. Boluses of short-acting insulin must be used to cover meals.

plan initial therapy for the sick infant if required. Infants of mothers with poorly controlled diabetes have an increased risk of respiratory distress syndrome. Possible reasons include abnormal production of pulmonary surfactant or connective tissue changes leading to decreased pulmonary compliance. However, in recent years, the incidence of respiratory distress syndrome in these pregnancies has declined from 24% to 5%, probably related to better maternal glycemic control, selected use of amniotic fluid tests, and delivery of most infants at term. Other possible problems in infants of diabetic mothers include hypocalcemia less than 7 mg/dL (1.75 mmol/L), hyperbilirubinemia greater than 15 mg/dL (256 μmol/L), polycythemia (central hematocrit >70%), and poor feeding. These complications are presumably related to fetal hyperglycemia and hyperinsulinemia and probably to intermittent low-level fetal hypoxia. Improved control of the maternal diabetic state has reduced their incidence.

Gestational Diabetes

Gestational diabetes (GDM) is defined as glucose intolerance that develops or is first recognized during pregnancy. As insulin resistance increases during pregnancy, euglycemia depends on a compensatory increase in insulin secretion. Failure to compensate with increased insulin secretion leads to gestational diabetes.

As the increase in insulin resistance is greatest in the third trimester, GDM usually develops going into this period. The prevalence of GDM in a population is reflective of the prevalence of type 2 diabetes in that population. In low-risk populations, such as those found in Sweden, the prevalence in population-based studies is lower than 2% even when universal testing is offered, while studies in high-risk populations, such as the Native American Cree, Northern Californian Hispanics, and Northern Californian Asians, reported prevalence rates ranging from 4.9% to 12.8%. Other risk factors include a history of macrosomia (birth weight >4000 g), polycystic ovarian syndrome, essential hypertension or pregnancy-related hypertension, history of spontaneous abortions and unexplained still births, family history of diabetes, obesity, age older than 25 years, and history of gestational diabetes (Table 17–28).

Women with GDM are at increased risk for urinary tract infections, pyelonephritis, asymptomatic bacteriuria, and preeclampsia. There is a 10% risk of polyhydramnios. Fetal risks of poor glucose control include stillbirths and macrosomia. There is no increase in risk for congenital anomalies since the glucose intolerance develops later in pregnancy.

Strategies for diagnosis are outlined in Table 17–29. Currently, international consensus is lacking regarding the diagnostic criteria for GDM. The 100 g 3-hour OGTT test is commonly used in the United States and the 75 g 2-hour WHO test is used in many other countries. The risk assessment for GDM (see Table 17–28) should be performed at the first prenatal visit. Those women at high risk should undergo OGTT testing as soon as feasible. If the test is negative, then they should be retested at 24 to 28 weeks of gestation. A fasting plasma glucose of more than or equal to 126 mg/dL or random glucose of more than or equal to 200 mg/dL confirmed on repeat testing is diagnostic of diabetes and negates the need to perform a glucose challenge test. Lower risk women are screened for GDM using a two-step protocol performed at 24 to 28 weeks. First, a glucose challenge test is performed using a 50 g glucose load. The patient does not have to be fasting. A 1-hour

Previous macrosomia/polyhydramnios
Previous unexplained stillbirth
Polycystic ovarian syndrome

TABLE 17–29   Screening and diagnosis of gestational diabetes.

Perform blood glucose testing at 24-28 wk

Two-step protocol:

A. **Glucose challenge test:** 1-h plasma glucose after 50 g glucose load. Patient is not fasting. ≥140 mg/dL (≥7.8 mmol/L) identifies ~80% of women with GDM; ≥130 mg/dL (≥7.2 mmol/L) increases sensitivity to ~90%.

B. **100 g OGTT:** If a woman meets or exceeds threshold on glucose challenge test then perform fasting diagnostic 100 g OGTT within a week. The test is performed after an at least 8-h overnight fast and after at least 3 d of unrestricted diet (≥150 g carbohydrate per day). Subject should be seated and should not smoke during test.

The test is positive if two of the following glucose levels are found.

	Carpenter/Coustan criteria	National Diabetes Data group criteria
Fasting:	≥95 mg/dL (≥5.3 mmol/L)	>105 mg/dL (5.8 mmol/L)
1 h:	≥180 mg/dL (≥10 mmol/L)	>190 mg/dL (10.6 mmol/L)
2 h:	≥155 mg/dL (≥8.6 mmol/L)	>165 mg/dL (9.2 mmol/L)
3 h:	≥140 mg/dL (≥7.8 mmol/L)	>145 mg/dl (8.0 mmol/L)

If one value is abnormal, repeat test in 4 wk

One step protocol proposed by International Association of the Diabetes and Pregnancy Study Groups:

Fasting glucose at first prenatal visit. Value >92 mg/dL (5.1 mmol/L) is diagnostic of GDM and no additional testing is indicated. If negative then perform diagnostic 75 g OGTT testing at 24 to 28 wk after overnight fast of 8 h. The test is positive if one of the following glucose levels is found.

Fasting:	>92 mg/dL (5.1 mmol/L)
1 h:	>180 mg/dL (10.0 mmol/L)
2 h:	>153 mg/dL (8.5 mmol/L)

plasma glucose value of 140 mg/dL (7.8 mmol/L) or greater identifies approximately 80% of women with GDM; decreasing the cutoff value to 130 mg/dL (7.2 mmol/L) increases the sensitivity to approximately 90%. Women with the positive glucose challenge test should undergo a 3-hour 100 g oral glucose tolerance test within the week.

Although there is continuing debate regarding universal screening, recent studies are supportive of this position. An observational study of Caucasian women, where all were tested with the oral glucose tolerance test, found that the prevalence of GDM among women with no risk factors was 2.8%. Excluding this low-risk group would still require 80% of women to be tested and would miss 10% of all cases of GDM. The Hyperglycemia and Pregnancy Outcome (HAPO) study reported a continuous relationship between glucose concentration with the 28-week oral glucose tolerance test and neonatal adiposity, cesarean sections, neonatal hypoglycemia, premature delivery, shoulder dystocia, need for intensive neonatal care, hyperbilirubinemia, and preeclampsia. A study by Landon and colleagues of women with mild GDM on a 100 g 3-hour glucose tolerance test found that treatment reduced the risk of fetal overgrowth, shoulder dystocia, cesarean delivery, and hypertensive disorders. The United States Preventive Services Task Force on Preventive Health Care has concluded that there is good evidence to support universal screening for GDM after 24 weeks but not for universal screening earlier in pregnancy. Women who have a history of GDM with previous pregnancy should undergo preconception counseling similar to those patients with pregestational diabetes. They should begin to monitor their glucose levels when they begin to try to conceive or as soon as their new pregnancy is confirmed. These women do not need retesting for GDM.

HbA$_{1c}$ values are helpful for assessment of pregestational diabetes but are not helpful for management of GDM where they are normal.

The goal of therapy is prevention of fasting and postprandial hyperglycemia. The Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS) trial found that intervention to lower glucose levels to less than 100 mg/dL before meals and less than 126 mg/dL 2 hours after meals reduced the rate of serious perinatal outcomes (defined as death, shoulder dystocia, bone fracture, and nerve palsy) from 4% to 1%. After diagnosis, the patient should be placed on a diabetic meal plan modified for pregnancy. The caloric intake is based on ideal body weight—25 to 35 kcal/kg ideal weight, 40% to 55% carbohydrate, 20% protein, and 25% to 40% fat. Calories are distributed over three meals and three snacks (see Table 17–24). Most patients can be taught to count their carbohydrates and to read food labels. This caloric distribution will help 75% to 80% of patients to become normoglycemic. Patients should also be encouraged to participate in moderate aerobic exercise such as walking or antenatal exercise classes, of at least 15- to 30-minutes duration, three or more times a week. In normal pregnancy, expected weight gain varies according to the prepregnancy weight. The Fifth International Workshop-Conference on GDM recommends a relatively small gain during pregnancy of 7 kg (15 lb) for obese women (BMI ≥30 kg/m^2) and a proportionally greater weight gain (up to 18 kg or 40 lb) for underweight women (BMI <18.5 kg/m^2) at the onset of pregnancy. However, there are no data on optimal weight gain for women with GDM.

If fasting capillary blood glucose levels exceed 90 to 100 mg/dL (5-5.6 mmol/L) or if 1-hour or 2-hour postprandial glucose values are consistently greater, respectively, than 130 or 105 mg/dL (7.2 or 5.8 mmol/L) therapy is begun with insulin. The total insulin dose varies from 0.7 to 2 U/kg. NPH or insulin detemir are the preferred long-acting insulins. Insulin glargine has not been well studied. Insulin aspart or lispro and regular insulin can be used. Hypoglycemia is a risk factor with aggressive management of glucose levels with insulin. Patients and family members should be instructed on monitoring for and treating hypoglycemia.

Metformin and glyburide have been considered as alternative options to insulin therapy. Metformin does cross the placenta but has not been associated with teratogenesis. The advantage of this drug is that it does not result in hypoglycemia. An open label study (the MiG trial) of 751 women with GDM at 20 to 33 weeks of gestation randomized to either metformin or insulin did not show a difference in primary composite outcome of neonatal complications. Forty-six percent of the subjects on metformin did, however, require supplemental insulin. Langer and colleagues randomized 404 women with GDM at 11 to 33 weeks of gestation to glyburide therapy or insulin treatment. There was no significant difference in fetal outcomes in the two groups—large for gestational infants, macrosomia, neonatal ICU admission, or fetal abnormalities. Target glycemic control was achieved in 88% of patients on insulin and 82% on glyburide. There was significant reduction in maternal hypoglycemic episodes in the glyburide group compared to the insulin group (2% vs 20%). A large retrospective observational study, however, has raised concerns about glyburide's safety in gestational diabetes. The study reviewed the fetal outcomes of approximately 9000 women with gestational diabetes treated with either glyburide or insulin. They found that infants of women treated with glyburide had higher risk of respiratory distress, neonatal hypoglycemia, birth injury, and large for gestational age.

Patients are usually scheduled for follow-up visits every 1 to 2 weeks. A 24-hour urine collection may be performed to establish baseline level of proteinuria and creatinine clearance due to the higher likelihood of preeclampsia. It is not necessary to routinely perform ophthalmic examinations in these patients unless there is a strong suspicion of preexisting type 2 diabetes mellitus. Fetal monitoring is warranted in those patients who are not well controlled, requiring insulin therapy, or who have other complications of pregnancy. The most commonly used test is a twice-weekly nonstress test.

If blood glucose levels are close to normal and there are no other complications, the delivery can go to term. It is generally recommended that the pregnancy does not go beyond term. Most patients do not require insulin during delivery. Blood glucose levels should be monitored the following day to ensure that the patient has reverted to normoglycemia. About 95% of patients return to normal glucose status.

Progression to type 2 diabetes later in life occurs in 5% to 50% of women with gestational diabetes. The wide range in incidence is influenced by body weight, family history, glucose levels, and

the need for insulin treatment during pregnancy—and the choice of contraception and lifestyle after pregnancy. All patients with gestational diabetes should undergo a 75 g 2-hour glucose tolerance test at 6 to 10 weeks after delivery to guide future medical management. Follow-up protocols after pregnancy and criteria for the diagnosis of diabetes mellitus in the nonpregnant state are presented in Table 17–11.

Hypoglycemic Disorders

Umesh Masharani, MB, BS, MRCP (UK),
Stephen E. Gitelman, MD, and Roger K. Long, MD

ACE	Angiotensin-converting enzyme		IGFBP3	IGF-binding protein-3
ACTH	Adrenocorticotrophic hormone		K_{ATP}	ATP-sensitive potassium channel
ADP	Adenosine diphosphate		Kir	Inward rectifier potassium channel
ALS	Acid-labile subunit		NADH	Nicotinamide adenine dinucleotide (reduced form)
ATP	Adenosine triphosphate			
GDH	Glutamate dehydrogenase		NICTH	Nonislet cell tumor hypoglycemia
GIP	Glucose-dependent insulinotropic polypeptide		NIPHS	Noninsulinoma pancreatogenous hypoglycemic syndrome
GLP-1	Glucagon-like peptide 1			
G-6-Pase	Glucose-6-phosphatase		PEPCK	Phosphoenolpyruvate carboxykinase
HbA_{1c}	Hemoglobin A_{1c}		RIA	Radioimmunoassay
ICMA	Immunochemiluminometric		SSTR	Somatostatin receptor
IGF-II	Insulin-like growth factor II		SUR	Sulfonylurea receptor

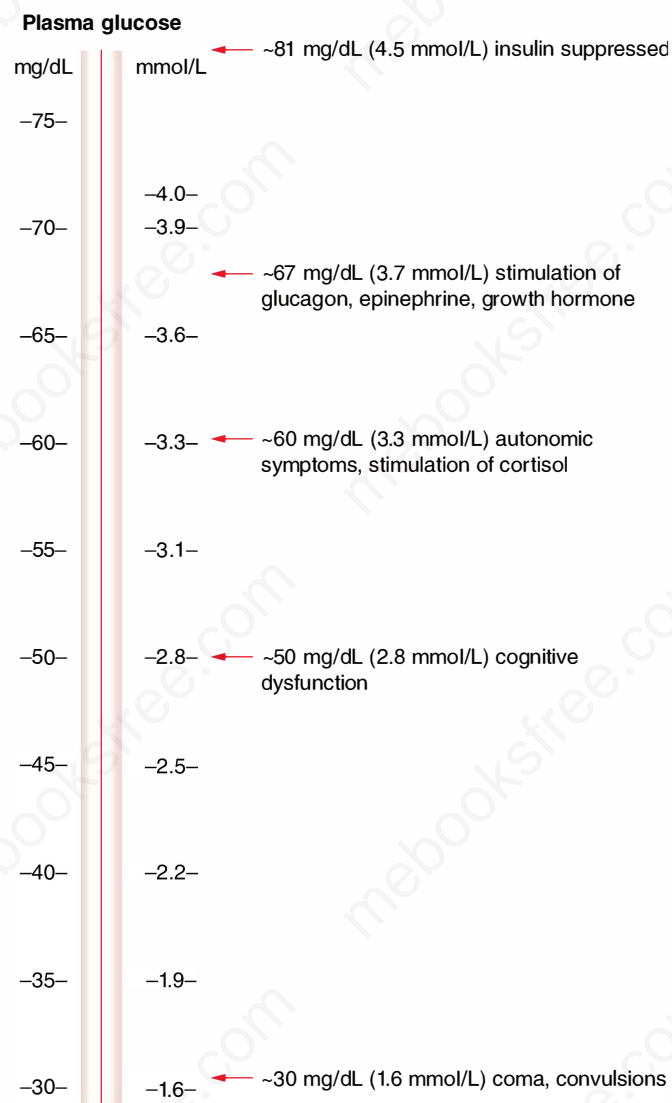
Circulating plasma glucose concentrations are kept within a relatively narrow range by a complex system of interrelated neural, humoral, and cellular controls. Under the usual metabolic conditions, the central nervous system is wholly dependent on plasma glucose and counteracts declining blood glucose concentrations with a carefully programmed response. This is often associated with a sensation of hunger and, as the brain receives insufficient glucose to meet its metabolic needs (neuroglycopenia), an autonomic response is triggered to mobilize storage depots of glycogen and fat. In the postabsorptive state, hepatic glycogen reserves and gluconeogenesis from the liver and kidney directly supply the central nervous system with glucose, which is carried across the blood–brain barrier by a specific glucose transport system, while the mobilization of fatty acids from triglyceride depots provides energy for the large mass of skeletal and cardiac muscle, renal cortex, liver, and other tissues that utilize fatty acids as their basic fuel, thus sparing glucose for use by the tissues of the central nervous system.

The normal lower limit of fasting plasma glucose is typically 70 mg/dL (3.9 mmol/L). Lower values may occur during prolonged fasting, strenuous exercise, or pregnancy or may occur as a laboratory artifact. In normal men, plasma glucose does not fall below 55 mg/dL (3 mmol/L) during a 72-hour fast. However, for reasons that are not clear, normal women may experience a fall to levels as low as 30 mg/dL (1.7 mmol/L) despite a marked suppression of circulating insulin to less than 5 μU/mL. They remain asymptomatic in spite of this degree of hypoglycemia, presumably because ketogenesis is able to satisfy the energy needs of the central nervous system. Basal plasma glucose declines progressively during normal pregnancy, and hypoglycemic levels may be reached during prolonged fasting. This may be a consequence of a continuous fetal consumption of glucose and diminished availability of the gluconeogenic substrate alanine. The cause of these diminished alanine levels in pregnancy is unclear. The greatly increased glucose consumption by skeletal muscle that occurs during prolonged strenuous exercise may lead to hypoglycemia (blood glucose <45 mg/dL) despite increases in hepatic glucose production. Whether the hypoglycemia in this circumstance contributes to fatigue or other symptoms in distance runners is unknown.

In vitro consumption of glucose by blood cell elements has been reported to average 10 mg/dL/h and may give rise to laboratory values in the hypoglycemic range. This can be avoided by adding a small amount of the metabolic inhibitor sodium fluoride to collection tubes used for specimens containing increased numbers of blood cells (as in leukemia, leukemoid reactions, or polycythemia) and keeping samples on ice until separated.

PATHOPHYSIOLOGY OF THE COUNTERREGULATORY RESPONSE TO NEUROGLYCOPENIA

The plasma concentration of glucose that signals the need by the central nervous system to mobilize energy reserves depends on a number of factors, such as the status of blood flow to the brain, the integrity of cerebral tissue, the prevailing arterial level of plasma glucose, the rapidity with which plasma glucose concentration falls, and the availability of alternative metabolic fuels.

A hierarchy of responses has been shown to occur as plasma glucose falls in healthy young volunteers, with hormonal counterregulatory responses being triggered at glucose levels slightly higher (~67 mg/dL [3.7 mmol/L]) than those that induce symptoms of hypoglycemia (Figure 18–1). The first symptoms to appear in healthy people are mediated by autonomic neurotransmitters and occur at plasma glucose levels below 60 mg/dL (3.3 mmol/L). The symptoms consist of tremor, anxiety, palpitations, and sweating, which result from sympathetic discharge; and hunger, which is a consequence of parasympathetic vagal response. Ganglionic blockade and cervical cord section or sympathectomy—but not adrenalectomy—ameliorates these symptoms, indicating that they are due to the release of autonomic neurotransmitters and not dependent on adrenal hormones. As plasma glucose falls below 50 mg/dL (2.8 mmol/L), cerebral neuroglycopenia ensues, consisting of impaired cognition, along with weakness, lethargy, confusion, incoordination, and blurred vision. If counterregulatory responses are inadequate to reverse this degree of profound hypoglycemia, convulsions or coma may occur. This can result in brain damage or death, particularly in those who have not adapted to repeated episodes of hypoglycemia.


In elderly people, however, with compromised cerebral blood supply, neuroglycopenic manifestations may be provoked at slightly higher plasma glucose levels. Patients with chronic hyperglycemia (eg, those with poorly controlled, insulin-treated diabetes mellitus) may experience symptoms of neuroglycopenia at considerably higher plasma glucose concentrations than persons without diabetes. This has been attributed to a down-regulated glucose transport system across the blood–brain barrier. Conversely, in patients exposed to chronic hypoglycemia (eg, those with an insulin-secreting tumor or those with diabetes who are receiving excessively tight glycemic control with insulin), adaptation to recurrent hypoglycemia occurs by upregulation of the glucose transporters, which results in hypoglycemic unawareness, whereby they show greater tolerance to hypoglycemia without manifesting symptoms. Restoring and maintaining an adequate supply of glucose for cerebral function proceeds by a series of neurogenic events that act directly to raise the plasma glucose concentration and to stimulate hormonal responses that augment the adrenergic mobilization of energy stores (Table 18–1).

FIGURE 18–1 Hierarchy of hormonal and neurological responses to progressive stepwise reduction in plasma glucose concentration in healthy volunteers.

TABLE 18–1 Autonomic nervous system response to hypoglycemia.

Alpha-Adrenergic Effects
Inhibition of endogenous insulin release
Increase in cerebral blood flow (peripheral vasoconstriction)

Beta-Adrenergic Effects
Hepatic and muscle glycogenolysis
Stimulation of plasma glucagon release
Lipolysis to raise plasma-free fatty acids
Impairment of glucose uptake by muscle tissue
Increase in cerebral blood flow (increase in cardiac output)

Adrenomedullary Discharge of Catecholamines
Augmentation of all of the above alpha- and beta-adrenergic effects

Cholinergic Effects
Raises level of pancreatic polypeptide
Increases motility of stomach
Produces hunger
Increases sweating

Counterregulatory Response to Hypoglycemia (Figures 18–2 and 18–3)

Insulin   Endogenous insulin secretion is lowered both by reduced glucose stimulation to the pancreatic β cell and by sympathetic nervous system inhibition from a combination of alpha-adrenergic neural effects and increased circulating catecholamine levels. This reactive insulinopenia appears to be essential for glucose recovery, because it facilitates the mobilization of energy from existing energy stores (glycogenolysis and lipolysis); increases hepatic enzymes involved in gluconeogenesis and ketogenesis; increases enzymes of the renal cortex, promoting gluconeogenesis; and at the same time prevents muscle tissue from consuming the blood glucose being released from the liver (see Chapter 17).

Catecholamines   Circulating catecholamines—and norepinephrine produced at sympathetic nerve endings—provide muscle tissue with alternative sources of fuel by activating beta-adrenergic receptors, resulting in mobilization of muscle glycogen, and by providing increased plasma-free fatty acids from lipolysis of adipocyte triglyceride. Metabolism of these free fatty acids provides energy to promote gluconeogenesis in the liver and kidney, thereby adding to plasma glucose levels already raised by the glycogenolytic effect of catecholamines on the liver. Their cardiovascular and other side effects provide a signal that diabetic patients learn to recognize as a warning of their need to ingest rapidly absorbable carbohydrate.

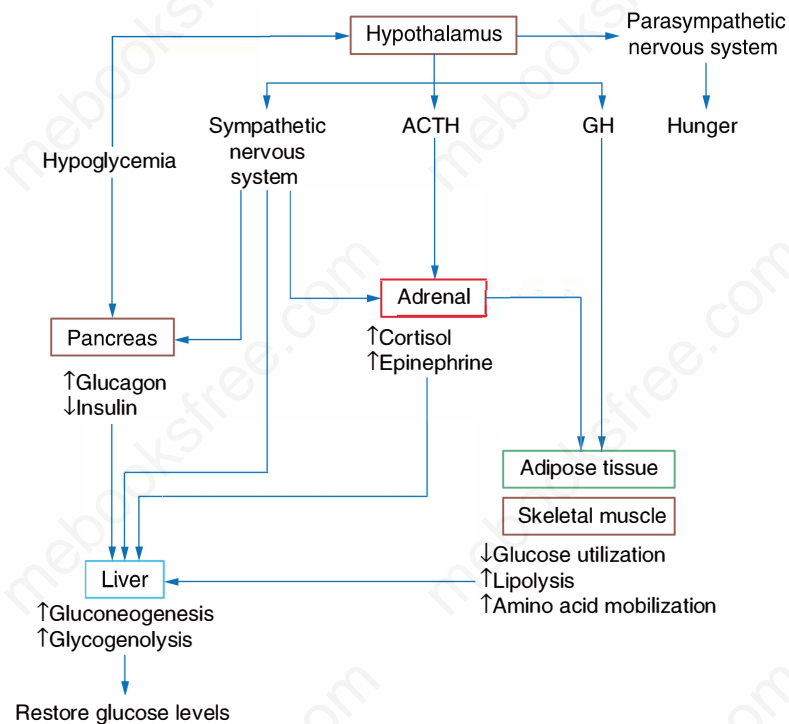
Glucagon   Plasma glucagon is released by the beta-adrenergic effects of both sympathetic innervation and circulating catecholamines on pancreatic α cells as well as by the direct stimulation of α cells by the low plasma glucose concentration. Data are available suggesting that a falling-off of intra-islet insulin concentration in subjects with functioning pancreatic β cells can release pancreatic α cells from insulin inhibition and thus augment glucagon release during hypoglycemia. This glucagon release increases hepatic output of glucose by direct glycogenolysis as well as by facilitating the activity of gluconeogenic enzymes in the liver but not in the kidney. As shown in Figure 18–3, plasma glucagon appears to be the key counterregulatory hormone affecting recovery from *acute* hypoglycemia in nondiabetic humans, with the adrenergic-catecholamine response representing a major backup system. However, in most clinical situations, where hypoglycemia develops *more gradually*, as with inappropriate dosage of insulin or sulfonylureas, or in cases of insulinoma, the role of glucagon may be less influential. When normal volunteers received a prolonged low-dose insulin infusion to produce a gradual decline in plasma glucose levels without waning of insulin levels, the rise of endogenous glucagon contributed much less to counterregulation than after acute hypoglycemia induced by an intravenous insulin bolus, which is followed by rapid waning of insulin levels. This finding suggests that glucagon's role in glucose recovery occurs primarily when the level of insulin wanes.


FIGURE 18–2   Regulatory response to hypoglycemia. A fall in glucose level in the brain activates the sympathetic system; induces hunger (parasympathetic system); releases ACTH and GH. The decline in glucose levels and sympathetic activation inhibits insulin secretion and stimulates glucagon from pancreatic islets. Epinephrine and cortisol are released from the adrenals. These hormonal changes and sympathetic nervous system activation act in concert to facilitate glycogenolysis, gluconeogenesis and lipolysis, to limit peripheral glucose utilization and to restore glucose levels to normal.
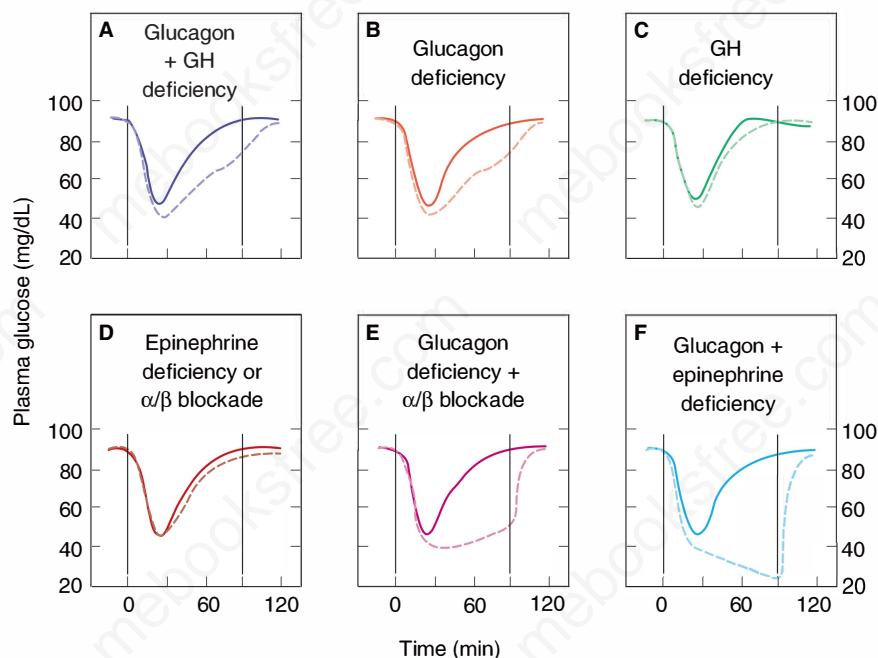

FIGURE 18–3   Solid lines show changes in plasma glucose that occur in normal subjects in response to acute intravenous insulin administration. Note the rapid recovery of glucose levels mediated by intact counterregulatory mechanisms. The dashed lines show the response to insulin-induced hypoglycemia in patients with deficiencies of the counterregulatory mechanisms induced as follows: **A:** Somatostatin infusion (inhibits both glucagon and growth hormone [GH] release). **B:** Somatostatin infusion plus GH infusion (now with functional isolated glucagon deficiency). **C:** Somatostatin infusion plus glucagon infusion (isolated GH deficiency). Note return of glucose response to normal, implying that glucagon is the main counterregulatory hormone. **D:** Bilateral adrenalectomy, leading to epinephrine deficiency, or infusion of phentolamine plus propranolol (alpha and beta blockers, respectively). Note that such deficiencies cause no major abnormality in response to induced hypoglycemia when glucagon is present. **E and F:** Sympathetic modulation (by phentolamine plus propranolol in **E** and by bilateral adrenalectomy in **F**), which seriously impairs the ability to respond to hypoglycemia in the patient made glucagon-deficient by somatostatin infusion. (Data from Clarke WL, Santiago JV, Thomas L, et al. The role of adrenergic mechanisms in recovery from hypoglycemia in man: studies with adrenergic blockade. *Am J Physiol* 236:E147-152, 1979; Gerich J, Davis J, Lorenzi M, et al. Role of glucagon, epinephrine and growth hormone in human glucose counterregulation: effects of somatostatin and adrenergic blockade on plasma glucose recovery and glucose flux rates following insulin-induced hypoglycemia. *J Clin Invest* 64:62-71, 1979.)

Cortisol   Pituitary corticotrophin (ACTH) is released in association with the sympathetic nervous system stimulation by neuroglycopenia. This results in elevation of plasma cortisol levels, which in turn permissively facilitates lipolysis and actively promotes protein catabolism and conversion of amino acids to glucose by the liver and kidney.

Growth hormone   Pituitary growth hormone is also released in response to falling plasma glucose levels. Its role in counteracting hypoglycemia is less well defined, but it is known to antagonize the action of insulin on glucose utilization in muscle cells and to directly activate lipolysis by adipocytes. This increased lipolysis provides fatty acid substrate to the liver and renal cortex which facilitates gluconeogenesis.

Cholinergic neurotransmitters   Acetylcholine is released at parasympathetic nerve endings, and its vagal effects induce the sensation of hunger that signals the need for food to counteract the hypoglycemia. In addition, postsynaptic fibers of the sympathetic nervous system that innervate the sweat glands to signal hypoglycemia also release acetylcholine—in contrast to all other sympathetic postsynaptic fibers, which without exception release norepinephrine.

Maintenance of Euglycemia in the Postabsorptive State

Glucose absorption from the gastrointestinal tract ceases by 4 to 6 hours after a meal. During the postabsorptive state which immediately follows, glucose must be produced endogenously from previously stored nutrients to meet the requirements of the central nervous system and other glucose-dependent tissues. These include 125 mg/min of glucose required by the brain and spinal cord as well as an additional 25 mg/min by red blood cells and the renal medulla. It was previously thought that the liver is the only organ involved in glucose production during an overnight fast, but recent data indicate that the renal cortex also has the requisite enzymes for production and release of glucose.

Liver   The liver initially provides glucose by the breakdown of stored hepatic glycogen. However, because these reserves are limited to 80 to 100 g, they begin to be depleted several hours into the postabsorptive state. Thereafter, hepatic glucose production is augmented by gluconeogenesis—the formation of glucose from amino acids, lactate, and glycerol. These substrates are delivered to the liver and kidney from peripheral stores. Muscle and other

structural tissues supply amino acids, mainly alanine; blood cell elements supply lactate, the end product of glycolytic metabolism; and adipose tissue supplies glycerol from lipolysis of triglyceride. In addition, oxidation of the free fatty acids released from adipose cells during lipolysis supplies the energy required for gluconeogenesis and provides ketone bodies, acetoacetate, and β-hydroxybutyrate, which can serve as alternative metabolic fuels for the central nervous system during periods of prolonged fasting. Studies have shown that an insulin infusion does not reduce hepatic glucose production if elevated levels of fatty acids are maintained by intravenous administration of a fat emulsion and heparin, suggesting that fatty acids may be the major mediator of gluconeogenesis.

The principal mechanisms regulating hepatic glucose output are the availability of gluconeogenic substrates and the regulation of transcription of key regulatory enzymes such as phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase (G-6-Pase). Glucagon and glucocorticoids through signaling intermediates induce the expression of PEPCK and G-6-Pase. Insulin on the other hand suppresses the expression of these enzymes.

Kidney Although it is generally acknowledged that after fasting for 60 hours the kidney contributes up to 20% to 25% of endogenous glucose production, its role after an overnight fast remains controversial. One group has found that it produces as much as 25% of the postabsorptive glucose requirement, yet a second group using different methodology found a contribution of no more than 5% in the postabsorptive state. Despite these conflicting findings, it is clear that because the renal medulla removes almost as much glucose as the renal cortex produces, the net renal contribution is minimal in the short-term postabsorptive state as compared to the liver.

The kidney does not have glycogen stores and is dependent on gluconeogenesis as its only source of glucose production. Glutamine—rather than alanine—is the predominant amino acid substrate for renal gluconeogenesis. In addition to its contribution to glucose homeostasis after an overnight fast, the kidney also has been shown to be an important contributor to glucose counterregulation in the event of hypoglycemia. Although glucagon does not affect the kidney, the counterregulatory rise in catecholamines has been shown to stimulate gluconeogenesis in the renal cortex. As with the liver, insulin inhibits renal gluconeogenesis and glucose release. Hormonal changes that begin early in the postabsorptive state regulate the enzymatic steps necessary for hepatic glycogenolysis and hepatic and renal gluconeogenesis and ensure the delivery of the necessary substrate (Table 18–2). An appropriate fall in circulating insulin levels with a corresponding rise in glucagon is most important; elevations in the counterregulatory hormones, namely cortisol and growth hormone, contribute to it but are less critical. Thus, numerous endocrine and metabolic events interact to provide a continuous source of fuel for proper functioning of the central nervous system. Malfunction of any of these mechanisms can lead to symptomatic hypoglycemia.

TABLE 18–2 Hormonal changes to maintain euglycemia in the postabsorptive state.

Decreased Insulin Secretion
Increases hepatic glycogenolysis
Increases lipolysis
Increases hepatic gluconeogenesis
Decreases muscle uptake of glucose
Increased Glucagon Secretion
Increases hepatic glycogenolysis
Facilitates hepatic gluconeogenesis
Increased Cortisol Secretion
Facilitates lipolysis
Increases protein catabolism
Augments hepatic gluconeogenesis

CLASSIFICATION OF HYPOGLYCEMIC DISORDERS

A clinical classification of the more common causes of symptomatic hypoglycemia in adults is presented in Table 18–3. This classification is useful in directing diagnostic considerations. Symptomatic fasting hypoglycemia is a serious and potentially life-threatening problem warranting thorough evaluation. Conditions that produce inappropriate fasting hyperinsulinism are the most common cause of fasting hypoglycemia in otherwise healthy adults. These include insulin-secreting pancreatic β cell tumors and iatrogenic or surreptitious administration of insulin or sulfonylureas. In patients with illnesses that produce symptomatic fasting hypoglycemia despite appropriately suppressed insulin levels, the clinical picture is generally dominated by the signs and symptoms of the primary disease, with hypoglycemia often only a late or associated manifestation. Hypoglycemia, sometimes severe, can also occur postprandially. In patients with gastric surgery,

TABLE 18–3 Causes of symptomatic hypoglycemia in adults.

Fasting
With hyperinsulinism
Insulins
Oral insulin secretagogues (sulfonylureas, repaglinide, nateglinide)
Other drugs (pentamidine)
Autoimmune hypoglycemia (idiopathic insulin antibodies, insulin receptor autoantibodies)
Pancreatic β cell tumors
Without hyperinsulinism
Severe hepatic dysfunction
Chronic renal insufficiency
Inanition
Hypocortisolism
Alcohol use
Nonpancreatic tumors
Nonfasting
After gastric surgery
Functional
Noninsulinoma pancreatogenous hypoglycemic syndrome (NIPHS)
Occult diabetes
Ethanol ingestion with sugar mixers

overrapid gastric emptying and accelerated glucose absorption may result in excess insulin secretion, rapid disposal of glucose, and hypoglycemia. An uncommon condition of islet hyperplasia or adult nesidioblastosis called noninsulinoma pancreatogenous hypoglycemia syndrome can result in hypoglycemia 4 to 6 hours after meals.

SPECIFIC HYPOGLYCEMIC DISORDERS

1. DIABETES (SEE ALSO CHAPTER 17)

Iatrogenic hypoglycemia is common in type 1 patients and also in insulin treated type 2 patients. Most type 1 patients aiming for HbA_{1c} levels below 7% have on average one to two symptomatic hypoglycemic episodes per week. Severe hypoglycemia is defined as an episode requiring assistance, and in one study, incidence rates were about 12 per 100 patient years for both type 1 and insulin-treated type 2 patients. Sulfonylureas, repaglinide, and nateglinide can also cause hypoglycemia. Increased risk factors include age (70 years and older), renal failure, hepatic failure, and use of the long-acting sulfonylureas. A number of other drug–drug interactions (clarithromycin, salicylates, sulfonamides) can also potentiate the hypoglycemic effects of sulfonylureas. The annual incidence of sulfonylurea-induced hypoglycemia is approximately 0.2 per 1000 patient years.

As β cell failure progresses (early in type 1 and late in type 2 diabetes), patients lose their glucagon response to hypoglycemia. This combination of insulin deficiency and impaired glucagon response makes it harder for patients to achieve HbA_{1c} levels below 7% without occasional hypoglycemia. These hypoglycemic episodes attenuate the sympathoadrenal response to hypoglycemia, with decreased epinephrine release from the adrenal and decreased sympathetic neural responses (hypoglycemic unawareness) and impaired hepatic glucose release. This combination of events is termed hypoglycemia-associated autonomic failure, and it can persist for more than 24 hours after a single episode of hypoglycemia or longer after repeated episodes of hypoglycemia, which in turn increases the risk for recurrent hypoglycemia. About 20% to 25% of type 1 patients have hypoglycemic unawareness. Other factors that increase the risk for hypoglycemia include poor self-management skills. Patients may take too much insulin for the carbohydrates or high glucose adjustment or take the wrong insulin or do not appropriately time insulin administration with food ingestion. They also may not adjust the insulin for acute exercise or take extra carbohydrates for unexpected exercise or reduce insulin doses for improved insulin sensitivity with exercise training. Alcohol can decrease endogenous glucose production and can cause hypoglycemia, especially if it is consumed on an empty stomach. Diabetes complications—gastroparesis, autonomic neuropathy, and renal failure also increase the risk for hypoglycemia.

There are other consequences of hypoglycemia apart from the autonomic and neurogenic symptoms of acute hypoglycemia. In severe cases, hypoglycemia can cause convulsions and coma. Permanent neurological damage is rare. Although cross-sectional studies and case reports have reported intellectual decline with recurrent hypoglycemia, longitudinal studies have not shown significant cognitive dysfunction in adults. In the Diabetes Control and Complications Trial and its follow-up EDIC study, there was no evidence for cognitive decline related to hypoglycemia in 18 years of follow-up. Young children, however, may be more vulnerable to the effects of hypoglycemia on the brain. Hypoglycemia via its autonomic stimulation and catecholamine release increases cardiac output. In patients with cardiac disease, it can also precipitate cardiac arrhythmias, angina, myocardial infarction, and congestive heart failure. Unexpected deaths in type 1 patients are most likely due to hypoglycemia—so-called "dead-in-bed" syndrome. In studies from the United Kingdom and Scandinavian countries, the frequency of such unexplained deaths is about 2 to 6 events per 100,000 patient-years. Hypoglycemia can also exert a psychological toll. Acute hypoglycemia induces mood changes including anxiety and depression. Nocturnal hypoglycemia can lead to fatigue and decreased sense of well-being the following day. Patients who have had severe hypoglycemia may develop a phobia about hypoglycemia and keep their sugars unreasonably high. Hypoglycemia can also impact personal relationships, occupation, driving, and leisure activities. Surveys show that type 1 patients have increased risk of driving mishaps (crashes, moving violations) when compared to nondiabetic spouses; and that these are related to hypoglycemia.

The goal of therapy for hypoglycemia is to restore levels of plasma glucose to normal as rapidly as possible. If the patient is conscious and able to swallow, glucose-containing tablets or gels, or foods such as candy, juices (ie, orange or apple), and cookies should be quickly ingested. Fructose, found in many nutrient low-calorie sweeteners for diabetics, should not be used. While it can be metabolized by neurons, fructose is not transported across the blood–brain barrier.

If the patient is unconscious, rapid restoration of plasma glucose must be accomplished by giving 20 to 50 mL of 50% dextrose intravenously over 1 to 3 minutes (the treatment of choice) or, when intravenous glucose is not available, 1 mg of glucagon intramuscularly or intravenously. Families or friends of insulin-treated diabetics should be instructed in the administration of glucagon intramuscularly for emergency treatment at home. Glucagon should not be given if the hypoglycemia is due to sulfonylurea use. Under these circumstances, glucagon can stimulate insulin secretion and worsen the hypoglycemia. Attempts to feed the patient or to apply glucose-containing gels to the oral mucosa should be avoided because of the danger of aspiration. When consciousness is restored, oral feedings should be started immediately. In patients who have taken massive overdoses of sulfonylureas, the response to intravenous dextrose may be inadequate. For these patients, intravenous boluses of diazoxide (150-300 mg) may be tried but can result in hypotension. Intravenous octreotide (100 μg) has also been reported to be of benefit.

Patients on insulin or sulfonylureas should be instructed on how to recognize and treat hypoglycemia and what measures they can take to prevent such episodes. Patients with type 1 and insulin-treated type 2 diabetes should monitor their blood glucose frequently. Hypoglycemia not infrequently occurs at night and patients should avoid taking large doses of short-acting insulin just

before going to bed. Patients should from time to time also monitor blood glucose levels in the middle of the night. Hypoglycemia can also occur many hours after strenuous exercise, and patients should be advised to monitor at these times and cut back their insulin doses and/or eat more carbohydrate. Continuous glucose monitoring systems are increasingly used by patients to alert them to falling glucose levels and prevent hypoglycemia. Finally, it is important to individualize glycemic goals. Early in the course of both type 1 and type 2 diabetes when there is still some endogenous β cell function, it is easier to achieve HbA_{1c} levels close to normal with low risk of hypoglycemia. As β cell failure progresses, however, aiming for normality may lead to unacceptably high rates of hypoglycemia. Patients who have had frequent hypoglycemia and have hypoglycemia unawareness should be encouraged to temporarily raise their glycemic targets—as little as 2 to 3 weeks of scrupulous avoidance of hypoglycemia reverses hypoglycemia unawareness and improves the attenuated epinephrine response. Diabetes complications, previous incidence of hypoglycemia, and life expectancy should all be considered in the establishment of glycemic goals.

2. FACTITIOUS HYPOGLYCEMIA

Factitious hypoglycemia should be suspected in any patient with access to insulin or sulfonylurea drugs. It is most commonly seen in health professionals and patients with diabetes or their relatives. The reasons for self-induced hypoglycemia vary, with many patients having severe psychiatric disturbances or a pathological need for attention. Inadvertent ingestion of sulfonylureas resulting in clinical hypoglycemia has also been reported, due either to patient error or to a prescription mishap on the part of a pharmacy.

When insulin is used to induce hypoglycemia, an elevated serum insulin level often raises suspicion of an insulin-producing pancreatic β cell tumor. It can be difficult to prove that the insulin is of exogenous origin. The combination of hypoglycemia, high immunoreactive insulin levels, suppressed plasma C-peptide, and suppressed proinsulin level is pathognomonic of exogenous insulin administration in nondiabetic patients. Insulin and C-peptide are secreted into the portal circulation in a 1:1 molar ratio. The liver is the primary site of insulin clearance, and a large fraction of the portal insulin is removed by the liver during first pass transit. C-peptide, on the other hand, is mostly cleared by the kidney at a slower rate than insulin. It follows that normally the molar ratio of insulin to C-peptide is less than 1.0. In the case of factitious hyperinsulinemia, the insulin/C-peptide ratio (pmol/L) will be greater than 1.0. Patients with renal failure may have normal or even high plasma C-peptide levels, but plasma proinsulin levels are suppressed.

When sulfonylurea abuse is suspected, plasma or urine should be screened for its presence. Hypoglycemia with inappropriately elevated levels of serum insulin *and* C-peptide along with detectable sulfonylureas in blood or urine is diagnostic of inadvertent or factitious sulfonylurea overdose. It is important to use assays which measure not only all the sulfonylureas but also repaglinide and nateglinide.

Patients with factitious hypoglycemia should receive psychiatric treatment and/or psychotherapy.

3. DRUGS

Numerous pharmacologic agents may potentiate the effects of insulin and predispose to hypoglycemia. Common offenders include fluoroquinolones such as gatifloxacin and levofloxacin, pentamidine, quinine, angiotensin-converting enzyme (ACE) inhibitors, ethanol, salicylates, and beta-adrenergic–blocking drugs. The fluoroquinolones, especially gatifloxacin, act on ATP-sensitive potassium channels (K_{ATP}) in the β cell and initially cause hypoglycemia and then hyperglycemia after several days into therapy. Intravenous pentamidine is cytotoxic to pancreatic β cells, resulting in acute insulin release and hypoglycemia. This occurs in about 10% to 20% of patients receiving the drug and may be followed later by persistent insulinopenia and hyperglycemia. Fasting patients taking noncardioselective beta blockade can have an exaggerated hypoglycemic response to starvation. Beta blockade inhibits fatty acid and gluconeogenic substrate release and reduces plasma glucagon levels resulting in hypoglycemia. Also the symptomatic response to hypoglycemia is altered—tachycardia is blocked while hazardous elevations of blood pressure may result during hypoglycemia in response to the unopposed alpha-adrenergic stimulation from circulating catecholamines and neurogenic sympathetic discharge. Symptoms of sweating, hunger, and uneasiness are not masked by beta-blocking drugs and remain indicators of hypoglycemia in the aware patient.

Therapy with ACE inhibitors increases the risk of hypoglycemia in diabetic patients who are taking insulin or sulfonylureas, presumably because these drugs increase sensitivity to circulating insulin by increasing blood flow to muscle.

Ethanol-associated hypoglycemia has been proposed to occur as a consequence of hepatic alcohol dehydrogenase activity depleting NAD. The resultant change in the redox state (increase in NADH-to-NAD$^+$ ratio) causes a partial block at several points in the gluconeogenic pathway. These include depressed conversion of citric acid cycle metabolites to oxaloacetate; decreased conversion of lactate to pyruvate; and decreased conversion of L-alpha-glycerophosphate to dihydroxyacetone-phosphate.

In the patient who is imbibing ethanol but not eating, fasting hypoglycemia may occur after hepatic glycogen stores have been depleted (within 8-12 hours of a fast). No correlation exists between the blood ethanol levels and the degree of hypoglycemia, which may occur while blood ethanol levels are declining. It should be noted that ethanol-induced fasting hypoglycemia may occur at ethanol levels as low as 45 mg/dL (10 mmol/L)—considerably below most states' legal standards (80 mg/dL [17.4 mmol/L]) for being *under the influence*. Most patients present with neuroglycopenic symptoms, which may be difficult to differentiate from the neurotoxic effects of the alcohol. These symptoms in a patient whose breath smells of alcohol may be mistaken for alcoholic stupor. Intravenous dextrose should be administered promptly to all such stuporous or comatose patients. Because hepatic glycogen stores have been depleted by the time hypoglycemia occurs, parenteral glucagon is not

effective. Adequate food intake during alcohol ingestion prevents this type of hypoglycemia.

4. AUTOIMMUNE HYPOGLYCEMIA

In recent years, a rare autoimmune disorder has been reported in which patients have circulating insulin antibodies and the paradoxic feature of hypoglycemia. More than 200 cases of insulin-antibody-associated hypoglycemia have been reported since 1970, with 90% of cases reported in Japanese patients. HLA class II alleles (DRB1*0406, DQA1*0301, and DQB1*0302) are associated with this syndrome, and these alleles are 10 to 30 times more prevalent in Japanese and Koreans, which may explain the higher prevalence of this syndrome in these populations. Hypoglycemia generally occurs 3 to 4 hours after a meal and follows an early postprandial hyperglycemia. It is attributed to a dissociation of insulin-antibody immune complexes, releasing free insulin. This autoimmune hypoglycemia, which is due to accumulation of high titers of antibodies capable of reacting with endogenous insulin, has been most commonly reported in methimazole-treated patients with Graves disease from Japan as well as in patients with various other sulfhydryl-containing medications (captopril, penicillamine) and other drugs such as hydralazine, isoniazid, procainamide, and alpha lipoic acid. In addition, it has been reported in patients with autoimmune disorders such as rheumatoid arthritis, systemic lupus erythematosus, and polymyositis, as well as in multiple myeloma and other plasma cell dyscrasias where paraproteins or antibodies cross-react with insulin.

High titers of insulin autoantibodies, usually IgG class, can be detected. Insulin, proinsulin, and C-peptide levels may be elevated, but the results may be erroneous because of the interference of the insulin antibodies with the immunoassays for these peptides.

In most cases the hypoglycemia is transient and usually resolves spontaneously within 3 to 6 months of diagnosis, particularly when the offending medications are stopped. The most consistent therapeutic benefit in management of this syndrome has been achieved by dietary treatment with frequent, low-carbohydrate, small meals. Prednisone therapy (30-60 mg/d) has been used to lower the titer of insulin antibodies.

Hypoglycemia due to insulin receptor autoantibodies is also an extremely rare syndrome; most cases have occurred in women, often with a history of autoimmune disease. Almost all of these patients have also had episodes of insulin-resistant diabetes and acanthosis nigricans. Their hypoglycemia may be either fasting or postprandial and is often severe and is attributed to an agonistic action of the antibody on the insulin receptor. Balance between the antagonistic and agonistic effects of the antibodies determines whether insulin-resistant diabetes or hypoglycemia occurs. Hypoglycemia was found to respond to glucocorticoid therapy but not to plasmapheresis or immunosuppression.

5. PANCREATIC β CELL TUMORS

Spontaneous fasting hypoglycemia in an otherwise healthy adult is most commonly due to an insulinoma, an insulin-secreting tumor of the islets of Langerhans. Eighty percent of these tumors are single and benign; 10% are malignant (if metastases are identified); and the remainder are multiple, with scattered micro- or macroadenomas interspersed within normal islet tissue. (As with some other endocrine tumors, histologic differentiation between benign and malignant cells is difficult, and close follow-up is necessary to ensure the absence of metastases.)

These adenomas may be familial and have been found in conjunction with tumors of the parathyroid glands and the pituitary (multiple endocrine neoplasia type 1; see Chapter 22). It has been reported that about 30% of sporadic insulinoma tumors have a somatic mutation in the YY1 gene (T372R) that encodes the transcriptional repressor YY1. Over 99% of them are located within the pancreas and less than 1% in ectopic pancreatic tissue.

These tumors may appear at any age, although they are most common in the fourth to sixth decades. A slight predominance in women has been reported in some studies. However, others suggest that there is no gender predilection.

Clinical Findings

Symptoms and signs   The most important prerequisite to diagnosing an insulinoma is simply to consider it, particularly when facing a clinical presentation of hypoglycemia with symptoms of central nervous system dysfunction such as confusion or abnormal behavior. Whipple's triad consists of history of symptoms consistent with hypoglycemia, associated low plasma glucose and relief of symptoms upon ingesting carbohydrates and raising the plasma glucose.

Patients typically complain of feeling tired, experiencing blurred vision, and not thinking clearly. Other symptoms include personality changes, amnesia, and loss of consciousness. The preponderance of neuroglycopenic symptoms, rather than those more commonly associated with the adrenergic symptoms of hypoglycemia can lead to misdiagnoses of psychiatric or neurological disorders. Some patients learn to relieve or prevent their symptoms by taking frequent feedings. Eating or drinking readily absorbable carbohydrates improves the symptoms within approximately 15 minutes. Patients may gain weight but obesity is seen in less than 30% of patients with insulin-secreting tumors.

Timing of the symptoms in relation to meals and exercise should be noted. In insulinoma patients, the symptoms are most likely to occur early in the morning before breakfast or if a meal is missed during the day. Patients occasionally present when they attempt to go on a diet to lose weight. Exercise may precipitate the symptoms, especially if the activity occurs while fasting or some hours after a meal. Some patients develop symptoms in the middle of the night and may have to eat. Partners of patients often provide useful information, especially if the patient requires assistance in treating the hypoglycemic symptoms. Occasionally the emergency services are called when the patient gets severely confused, presents with focal weakness, loses consciousness, or has a seizure. There may be documentation of low fingerstick glucose at the time when symptoms are present with recovery following administration of intravenous glucose. With the ready availability of home blood glucose–monitoring systems, patients sometimes present with documented fingerstick blood glucose levels in 40s

and 50s at time of symptoms. Access to diabetic medications (sulfonylureas or insulin) should be explored—does a family member have diabetes, or does the patient or family member work in the medical field? Medication-dispensing errors should be excluded—has the patient's prescription medication changed in shape or color? Other illnesses that cause hypoglycemia such as renal failure, hepatic failure, Addison disease, or nonislet tumor should be considered. Patients with insulinoma or factitious hypoglycemia usually have a normal physical examination.

Diagnostic Testing

If the history is consistent with episodic spontaneous hypoglycemia, patients should be given a home blood glucose monitor and advised to monitor blood glucose levels at the time of symptoms, if it is safe, and before consumption of carbohydrates. Patients with insulinomas frequently will report fingerstick blood glucose levels between 40 mg/dL (2.2 mmol/L) and 50 mg/dL (2.8 mmol/L) at the time of symptoms. The diagnosis, however, cannot be made based on a fingerstick blood glucose since they are not sufficiently accurate—the fingerstick value may differ by as much as 15 mg/dL when the true blood glucose is less than 75 mg/dL. It is necessary to have a low laboratory glucose concomitantly with elevated plasma insulin, proinsulin and C-peptide levels, and a negative sulfonylurea screen. When patients give a history of symptoms after only a short period of food withdrawal or with exercise, then an outpatient assessment can be attempted. The patient should be brought by a family member to the office after an overnight fast and observed in the office. Activity such as walking should be encouraged and fingerstick blood glucose measured repeatedly during observation. If symptoms occur or fingerstick blood glucose is below 50 mg/dL then samples for plasma glucose, insulin, C-peptide, proinsulin, sulfonylurea screen, serum ketones, and antibodies to insulin should be sent. If outpatient observation does not result in symptoms or hypoglycemia and if the clinical suspicion remains high, then the patient should undergo an inpatient, supervised, 72-hour fast.

A suggested protocol for the supervised fast is set forth in Table 18–4. The fast is timed from the last intake of calories. The term *72-hour fast* is actually a misnomer in most cases, because the fast should be immediately terminated as soon as symptoms and laboratory confirmation of hypoglycemia are evident. About 43% of patients with insulinomas are symptomatic within the first 12 hours, 67% by 24 hours and 93% to 95% by 48 hours. Since a minority of patients (~5%-7%) may not demonstrate hypoglycemia after 48 hours of fasting, it is preferable to continue the fast for up to 72 hours. Patients can drink water and decaffeinated, noncaloric drinks. It is important that patients are active (walking) during the fast since exercise may help precipitate hypoglycemia. An intravenous cannula should be placed to allow for blood draws and as a safety precaution, should intravenous dextrose infusion be required. Fingerstick blood glucose levels should be measured at intervals, and blood sent to the laboratory, if the patient is symptomatic or when fingerstick blood glucose levels are below 50 mg/dL. The decision to stop the fast is not always easy. Patients should be carefully monitored for symptoms of hypoglycemia. If the patient

TABLE 18–4 Suggested hospital protocol for supervised rapid diagnosis of insulinoma.

(1) Obtain baseline plasma glucose, insulin, proinsulin, betahydroxybutyrate and C-peptide measurements at onset of fast and place intravenous cannula.

(2) Permit only calorie-free and caffeine-free fluids and encourage supervised activity (such as walking).

(3) Obtain capillary glucose measurements with a reflectance meter every 4 hours until values <60 mg/dL are obtained. Then increase the frequency of fingersticks to each hour, and when capillary glucose value is <45 mg/dL, send a venous blood sample to the laboratory for serum glucose, insulin, proinsulin, betahydroxybutyrate, and C-peptide measurements. Check frequently for manifestations of neuroglycopenia.

(4) If symptoms of hypoglycemia occur *or* if a laboratory value of plasma glucose is <45 mg/dL *or* if 72 hours have elapsed, then conclude the fast with a final blood sample for serum glucose, insulin, proinsulin, C-peptide, β-hydroxybutyrate, and sulfonylurea measurements. Then give oral fast-acting carbohydrate followed by a meal. If the patient is confused or unable to take oral agents, administer 50 mL of 50% dextrose intravenously over 3-5 minutes. Do not conclude a fast based simply on basis of a capillary blood glucose measurement—wait for the laboratory glucose value unless the patient is symptomatic and it would be dangerous to wait.

Glucose sample should be collected in sodium fluoride containing tube on ice to prevent glycolysis and the plasma separated immediately upon receipt at the laboratory. Arrange for the laboratory to run the glucose samples "stat."

is symptomatic and the laboratory glucose is less than 45 mg/dL, then the test can be stopped. If the symptoms are equivocal and the laboratory glucose is in the mid 50s or higher, then the fast should be continued, if the patient is agreeable. At the time of termination of the fast, blood should be sent to the laboratory for plasma glucose, insulin, proinsulin, C-peptide, and serum β-hydoxybutyrate levels and a sulfonylurea screen.

In normal men, the blood glucose value does not fall below 55 mg/dL (3.1 mmol/L) during a 72-hour fast, whereas insulin levels fall below 10 μU/mL; in some normal women, however, plasma glucose may fall below 30 mg/dL (1.7 mmol/L) (lower limits have not been established), but serum insulin levels also fall appropriately to less than 5 μU/mL. These women remain asymptomatic despite this degree of hypoglycemia, presumably because ketogenesis is able to provide sufficient fuel for maintenance of central nervous system function.

The diagnostic criteria for insulinoma after a 72-hour fast are listed in Table 18–5. Virtually all patients with insulin-secreting islet cell tumors fail to suppress their insulin secretion appropriately when the plasma glucose is less than 45 mg/dL (see Table 18–5). It is important to be aware of limitations of the particular insulin assay that is used. When radioimmunoassays (RIAs) with a sensitivity of 5 mU/mL are used, patients with insulinomas have plasma insulin concentrations of 6 mU/mL or more. Immunochemiluminometric assays (ICMA) have sensitivities of less than 1 mU/mL, and with these assays, the cutoff for insulinomas is 3 mU/mL or higher. Previous treatment with insulin may lead to development of autoantibodies to insulin that interfere with the

TABLE 18–5 Diagnostic criteria for insulinoma after a 72-hour fast.

Plasma glucose	<45 mg/dL (2.5 mmol/L)
Plasma insulin (RIA)	≥6 uU/mL (36 pmol/L)
Plasma insulin (ICMA)	≥3 uU/mL (18 pmol/L
Plasma C-peptide	≥200 pmol/L (0.2 nmol/L; 0.6 ng/mL)
Plasma proinsulin	≥5 pmol/L
β-Hydroxybutyrate	≤2.7 nmol/L
Sulfonylurea screen (including repaglinide and nateglinide)	Negative

Conversion factors: insulin uU/mL × 6.0 = pmol/L; C-peptide ng/mL × 0.33 = nmol/L.

Abbreviations: RIA, radioimmunoassay; ICMA, Immunochemiluminometric assays.

assays, leading to falsely low or elevated values depending on the method used. Proper collection of samples is also important. If serum is not separated and frozen within 1 to 2 hours, falsely low values result because the insulin molecule undergoes proteolytic degradation. Plasma insulin levels measured by ICMA may be lower in hemolyzed samples. Calculation of ratios of insulin (μU/mL) to plasma glucose (mg/dL) is not helpful in making the diagnosis.

Factitious use of insulin will result in suppression of endogenous insulin secretion and low C-peptide levels. Elevated circulating proinsulin levels in the presence of fasting hypoglycemia is characteristic of β cell tumors and does not occur in factitious hyperinsulinism. Thus, C-peptide and proinsulin levels (by ICMA) of greater than or equal to 200 pmol/L and greater than or equal to 5 pmol/L, respectively, are characteristic of insulinomas. C-peptide is renally cleared and caution should be used in interpreting elevated levels in the setting of renal failure. Proinsulin normally represents less than 10% of total immunoreactive insulin. Insulinoma cells are poorly differentiated, which affects their ability to process proinsulin to insulin. Thus, most patients with insulinoma have elevated levels of proinsulin, representing as much as 30% to 90% of total immunoreactive insulin. Hyperinsulinemia suppresses ketone production. Plasma β-hydroxybutyrate levels in patients with insulinoma are 2.7 nmol/L or less. A progressive increase in β-hydroxybutyrate levels after 18 hours of fasting is strongly predictive that the fast will be negative. No single hormone measurement (insulin, proinsulin, C-peptide) is 100% sensitive and specific for the diagnosis of insulinoma, and insulinoma cases have been reported with insulin levels below 3 μU/mL (ICMA assay) or proinsulin level below 5 pmol/L. The hormonal assays are also not standardized between labs, and there can be significant variation in the results. Therefore, the diagnosis should be based on multiple biochemical parameters.

A variety of stimulation tests with intravenous tolbutamide, glucagon, or calcium have been devised to demonstrate exaggerated and prolonged insulin secretion in the presence of insulinomas. However, because insulin-secreting tumors have a wide range of granule content and degrees of differentiation, they are variably responsive to these secretagogues. Thus, absence of an excessive insulin-secretory response during any of these stimulation tests does not rule out the presence of an insulinoma. In addition, the tolbutamide stimulation test is extremely hazardous to patients with responsive tumors because it induces prolonged and refractory hypoglycemia. For that reason, it is no longer included in the diagnostic workup of insulinoma.

The hyperinsulinism associated with insulinoma impairs glycogenolysis. Thus, when patients with insulinoma are given 1 mg IV glucagon at the end of the 72-hour fast, there is an increase in plasma glucose within the first 30 minutes. The glucose rise is 25 mg/dL (1.4 mmol/L) or more at 20 to 30 minutes, whereas normal subjects have a lower increment. Intravenous glucagon can also cause an exaggerated release of insulin from insulinomas. Patients are tested after an overnight fast, and serum insulin levels measured every 5 minutes for 15 minutes after 1 mg IV glucagon. A stimulated peak insulin level exceeding 130 μU/mL (780 pmol/L) (~twice upper limit of peak stimulated normals)\suggests an insulin-secreting tumor. However, only about half of patients with insulinomas have insulin levels above 130 μU/mL and so the test is not so helpful. Also, in some patients the exaggerated insulin secretion can lead to severe hypoglycemia. Nausea is an unpleasant side effect, often occurring several minutes after administration of intravenous glucagon.

The oral glucose tolerance test is of no value in the diagnosis of insulin-secreting tumors. A common misconception is that patients with insulinomas have flat glucose tolerance curves because the tumors discharge insulin in response to oral glucose. In fact, most insulinomas respond poorly, and curves typical of diabetes are more common. In those rare tumors that do release insulin in response to glucose, a flat curve may result; however, this also can be seen occasionally in normal subjects.

Low HbA$_{1c}$ values have been reported in patients with insulinoma, reflecting the presence of chronic hypoglycemia. There is however considerable overlap with normal patients and no HbA$_{1c}$ value is diagnostic.

Tumor Localization Studies

After the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings, studies to localize the tumor should be initiated. The focus of attention should be directed at the pancreas only, because virtually all insulinomas originate from this tissue. Ectopic cases are very rare. There are reports of duodenal neuroendocrine tumors secreting insulin. Other ectopic sites include spleen, perisplenic tissue, duodenohepatic ligament, and ligament of Treitz. Ovarian carcinomas and teratomas, small cell carcinomas of the cervix, and bronchial carcinoids have also been reported to secrete insulin. Because of the small size of these tumors (average diameter of 1.5 cm in one large series), imaging studies do not necessarily identify all tumors. A pancreatic dual phase, thin section, helical CT scan can identify 82% to 94% of the lesions. MRI scans with gadolinium can be helpful in detecting a tumor in 85% of cases. One case report suggests that diffusion-weighted MRI can be useful for detecting and localizing small insulinomas, especially those with no hypervascular pattern. ^{111}In-octreotide scans for insulinomas, which typically express somatostatin receptor type 3, are only positive in 50% to 70% of cases. Newer PET/CT scans, using gallium-labeled somtatostatin analogs such as DOTA-1-NaI[3]-octreotide (DOTA-NOC), which
FIGURE 18–4 Responses of serum insulin to selective intra-arterial calcium stimulation in a patient with biochemical confirmation of inappropriate hyperinsulinism. 0.0125 mmol/kg calcium gluconate diluted in 5 mL normal saline were bolused into selectively catheterized arteries as indicated and blood samples collected from the hepatic vein at 0, 30, 50, 90, 120, and 180 seconds. An islet cell tumor was removed from the tail of the pancreas.

has a higher affinity for somatostatin receptor subtypes 2, 3, and 5, have been reported to be useful in localizing the tumors. Insulinomas express GLP1-receptors and radiolabeled GLP1-receptor agonists such as [Lys(40)(Ahx-hydrazinonicotinamide [HYNIC]-(99m)Tc)NH(2)]-exendin-4 for SPECT/CT have also been reported to visualize the tumors. The optimal imaging study used will depend upon local availability and local radiologic skill. If the imaging study is negative, then an endoscopic ultrasound should be performed. In experienced hands, about 80% to 90% of tumors can be detected. Finally, needle aspiration of the identified lesion can be attempted to confirm the presence of a neuroendocrine tumor. If the tumor is not identified or imaging results are equivocal, then the patient should undergo selective calcium-stimulated angiography, which has been reported to localize the tumor to particular regions of the pancreas approximately 90% of the time. In this test, angiography is combined with injections of calcium gluconate into the gastroduodenal, splenic, and superior mesenteric arteries, and insulin levels are measured in the hepatic vein effluent. The procedure is performed after an overnight fast. Ten percent of calcium gluconate, diluted to a volume of 5 mL normal saline, is injected into the individual arteries (discussed earlier) at a dose of 0.0125 mmol Ca^{2+}/kg body weight (0.005 mmol/kg for obese patients). Five milliliter blood samples are taken from the hepatic effluent at times 0, 30, 60, 90, 120, and 180 seconds after calcium injection. Fingerstick blood glucose levels are measured at intervals and a dextrose infusion is maintained throughout the procedure. Calcium stimulates insulin release from insulinomas but not normal islets. A step-up in insulin levels at 30 or 60 seconds (twofold or greater) regionalizes the source of the hyperinsulinism to the head of the pancreas for the gastroduodenal artery, the uncinate process for the superior mesenteric artery, and the body and tail of the pancreas for the splenic artery. A less than twofold elevation of insulin in the 120 second sample may represent effects of recirculating calcium and is not considered a

positive localization. In a single insulinoma, the response is in one artery alone (Figure 18–4) unless the tumor resides in an area fed by two arteries or if there are multiple insulinomas as in multiple endocrine neoplasia, type 1. Patients who have diffuse islet hyperplasia (the noninsulinoma pancreatogenous hypoglycemia syndrome [NIPHS]) will have positive responses in multiple arteries. Because diazoxide may interfere with this test, it should be discontinued for at least 48 to 72 hours before sampling. Patients should be closely monitored during the procedure to avoid hypoglycemia (as well as hyperglycemia), which could affect insulin gradients. These studies combined with careful intraoperative ultrasonography and palpation by a surgeon experienced in insulinoma surgery correctly identify up to 98% of tumors.

Treatment of Insulinoma

The treatment of choice for insulin-secreting tumors is surgical resection (Figure 18–5). While waiting for surgery, patients should be given diazoxide, a potent inhibitor of insulin secretion. It acts by opening the K_{ATP} channel of the pancreatic β cell and hyperpolarizing the cell membrane. This reduces calcium influx through the voltage-gated calcium channel, thereby reducing insulin release. Divided doses of 300 to 400 mg/d usually suffice, but occasionally a patient may require up to 800 mg/d. A liquid preparation of diazoxide (50 mg/mL) is available in the United States. Side effects include edema due to sodium retention (which generally necessitates concomitant thiazide administration), gastric irritation, and mild hirsutism.

Tumor resection should be performed only by surgeons with extensive experience with removal of islet cell tumors, because these tumors may be small and difficult to recognize. The tumors are enucleated whenever possible unless they have malignant features (eg, hardness or an appearance of infiltration). Preoperative imaging studies, including endoscopic ultrasound, can identify
FIGURE 18–5 1.4 cm insulinoma resected from the uncinate process of the pancreas. **A:** CT scan of abdomen; **B:** View of the 3rd part of the duodenum (bottom) and uncinate process with site of enucleation; **C:** tumor sectioned in half.

tumors amenable to laparoscopic surgery. Laparoscopic surgery is associated with faster postoperative recovery. Laparoscopic intra-operative ultrasound should be used to confirm the location and depth of the tumor within the pancreas and also note its relation-ship to the pancreatic duct and splenic vessels. Open surgery is still necessary for some tumors such as those in the head of the pan-creas close to the main pancreatic duct. In the very occasional case where the tumor cannot be found at operation despite the use of intraoperative ultrasound, it is no longer advisable to blindly resect the body and tail of the pancreas since a nonpalpable tumor, missed by ultrasound, is most likely embedded within the fleshy head of the pancreas that is left behind with subtotal resections. Most surgeons prefer to close the incision and treat the patient medically and/or repeat the localization studies. Ultrasound-guided ethanol injection into the tumor has been reported to be effective and should be considered for those patients who are poor surgical candidates.

Diazoxide should be administered on the day of surgery in patients who are responsive to it, because the drug greatly reduces the need for glucose supplements and the risk of hypoglycemia during surgery. Typically, it does not mask the glycemic rise indicative of surgical cure. Blood glucose levels should be moni-tored frequently during the operation, and a 5% or 10% dextrose infusion should be used to maintain euglycemia. Hyperglycemia occurs for a few days postoperatively most likely due to edema and inflammation of the pancreas secondary to its mobilization and

manipulation during surgical resection of the insulinoma. How-ever, other possible contributing factors include high levels of counterregulatory hormones induced by the procedure, chronic downregulation of insulin receptors by the previously high circu-lating insulin levels from the tumor, and, perhaps, suppression of normal pancreatic β cells by long-standing hypoglycemia. Small subcutaneous doses of regular insulin may be prescribed every 4 to 6 hours if plasma glucose exceeds 300 mg/dL (16.7 mmol/L), but in most cases pancreatic insulin secretion recovers after 48 to 72 hours, and very little insulin replacement is required.

In patients with inoperable functioning islet cell carcinoma with or without hepatic metastasis and in approximately 5% to 10% of MEN 1 cases when subtotal removal of the pancreas has failed to produce cure, the treatment approach is the same as for other types of pancreatic neuroendocrine tumors (PNET). Diazoxide is the treatment of choice in preventing hypoglycemia. Frequent carbohydrate feedings (every 2-3 hours) can also be helpful although weight gain can become a problem. If patients are unable to tolerate diazoxide because of gastrointestinal upset, hirsutism, or edema, the calcium channel-blocker verapamil, which inhibits insulin release from insulinoma cells, can be tried. Somatostatin analogs, such as octreotide or lanreotide, should be considered if diazoxide is ineffective or if there is tumor progres-sion. These drugs not only inhibit insulin secretion but also have antiproliferative activity. Surgery or embolization (bland-, chemo-, or radio-embolization) or thermal ablation (radiofrequency,

microwave, or cryoablation) can be used to reduce tumor burden and also provide symptomatic relief. For islet cell carcinomas, chemotherapy regimens can be considered. Representative regimens include combinations of streptozocin, 5–fluorouracil and doxorubicin; capecitabine and oxaliplatin; and capecitabine and temozolomide. There are only limited data regarding efficacy of these regimens. Targeted therapies against multiple steps in the PI3K/AKT/mTor pathway have been shown to be helpful. Everolimus, an inhibitor of mTor, has been approved for treatment of advanced pancreatic neuroendocrine tumors. Sunitinib targets multiple tyrosine kinase inhibitors including vascular endothelial growth factor (VEGF) receptors 2 and 3, platelet-derived growth factor (PDGF) receptors α and β, and c-kit, has been shown to slow growth of pancreatic neuroendocrine tumors. Treatment with radioisotopes (indium-111, yttrium-90, or lutetium-177) linked to a somatostatin analog have been reported to show benefit in a proportion of patients.

6. NONISLET CELL TUMOR HYPOGLYCEMIA (NICTH)

A variety of nonislet cell tumors have been found to cause fasting hypoglycemia. Most are large and mesenchymal in origin, retroperitoneal fibrosarcoma being the classic prototype. However, hepatocellular carcinomas, adrenocortical carcinomas, renal cell carcinomas, gastrointestinal tumors, lymphomas, leukemias, and a variety of other tumors have also been reported.

Laboratory diagnosis depends on fasting hypoglycemia associated with serum insulin levels below 5 μU/mL. In many cases, the hypoglycemia is due to the expression and release of an incompletely processed insulin-like growth factor II (IGF-II) by the tumor (see also Chapter 21). The primary IGF-II translation product is pre-pro-IGF-II consisting of N-terminal signal peptide of 24 amino acids, 67 amino acid mature IGF-II, and an 89 amino acid extension (E-domain) at the C-terminus. Posttranslational processing of pre-pro-IGF-II involves removal of the N-signal sequence, O-glycosylation of one or more threonine residues of the E-domain, and sequential proteolysis of the E-domain. During this process an IGF-II protein with a 21 amino extension of the E-domain (pro-IGF-IIE[68-88]) is a relatively stable intermediate that may be secreted from the cell. Most of the mature IGF-II released from the liver is complexed with IGF-binding protein-3 (IGFBP3) and acid-labile subunit (ALS). This ternary protein complex is generally inactive in adults because it is unable to bind properly to tissue receptors. It is only the free IGF-II (<1%) and that bound in binary complexes (predominantly IGFBP2 and IGFBP3) that is accessible to tissue compartment and available to bind the IGF and insulin receptors. However, in patients with nonpancreatic tumors associated with hypoglycemia, incompletely processed mainly nonglycosylated forms of IGF-II are released—in particular pro-IGF-IIE (68-88) form. These incompletely processed molecules are heterogeneous in size and are also referred to as **big IGF-II** and have molecular mass of 10 to 17 kDa in contrast to mature IGF-II at 7.5 kDa. Pro-IGF-II can form binary complexes with IGFBPs but have reduced affinity

for forming a tertiary complex with ALS. As a consequence, more of the pro-IGF-II is available for binding to the insulin receptors in the muscle to promote glucose transport and to insulin receptors in liver and kidney to reduce glucose output. The increased production of pro-IGF-II by the tumor may also displace processed IGF-II from IGFBPs, increasing free, unbound IGF-II. The IGF-II may bind to receptors for IGF-I in the pancreatic β cell to inhibit insulin secretion and in the pituitary to suppress growth hormone release. With the reduction of growth hormone, there is a consequent lowering of IGF-I levels as well as IGFBP-3 and ALS.

Size exclusion acid chromatography has been the standard method for detection of Pro-IGF-II in NICTH, but the process is time-consuming. Immunoblot analysis after separating the proteins on 16.5% tricine-sodium dodecyl sulphate-polyacrylamide gels is a more rapid and equally sensitive method. The IGF-II antibody used recognizes both mature and pro-IGF-II forms. In normal subjects, most of the IGF-II migrates at 7.5 kDa and a small amount in the 10 to 17 kDa region, whereas with NICTH most of the IGF-II migrates in the 10 to 17 kDa region and a small amount at 7 kDa.

The clinical syndrome of nonislet cell tumor hypoglycemia, therefore, is supported by laboratory documentation of serum insulin levels below 5 μU/mL with plasma glucose measurements of 45 mg/dL or lower. Values for growth hormone and IGF-I are also decreased. Levels of IGF-II may be increased but often are normal in quantity despite the presence of the immature, higher molecular weight form of IGF-II, which can only be detected by special laboratory techniques.

Not all the patients with NICTH have elevated pro-IGF-II. Ectopic insulin production has been described (bronchial carcinoid, ovarian carcinoma, teratoma, and small cell carcinoma of the cervix). Hypoglycemia due to IGF-I released from a metastatic large cell carcinoma of the lung has also been reported.

Treatment is aimed toward the primary tumor, with supportive therapy using frequent feedings. Diazoxide is ineffective in reversing the hypoglycemia caused by these tumors.

7. POSTPRANDIAL HYPOGLYCEMIA

Hypoglycemia Following Gastric Surgery

Hypoglycemia sometimes occurs after gastric surgery (gastrectomy, vagotomy, pyloroplasty, gastrojejunostomy, and laparoscopic Nissen fundoplication, Billroth II procedure, and Roux-en-Y gastric bypass), often after patients consume foods containing high levels of carbohydrates. This late dumping syndrome occurs 1 to 3 hours after a meal and is result of rapid delivery of high concentration of carbohydrates in the small bowel and rapid increase in blood glucose. This is countered by a hyperinsulinemic response. The high insulin levels are responsible for the subsequent hypoglycemia. The hypoglycemic symptoms include lightheadedness, sweating, confusion, and even loss of consciousness. It is likely that excessive release of gastrointestinal hormones—such as glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1)—may play a role in

the hyperinsulinemic response. An increased GLP-1 response has been noted in patients after total gastrectomy, esophageal resection, partial gastrectomy, and Roux-en-Y surgery; and a positive correlation has been noted between the rise in plasma GLP-1 and insulin release. It has been reported that treatment with exendin 9-39, a GLP-1 receptor antagonist can prevent post-gastric bypass hypoglycemia. Decreased need for gastric surgery for peptic ulcer disease and newer gastric operations such as proximal gastric vagotomy had reduced the incidence of postgastrectomy syndromes. There has been a resurgence of cases, however, with the popularity of Roux-en-Y gastric bypass surgery for morbid obesity. The prevalence of the syndrome after Roux-en-Y procedure is not known. The University of Minnesota surgery group identified 14 cases of postprandial hypoglycemia in 3082 procedures (0.4%), but it is unclear how many patients may have eluded detection or failed to maintain follow-up.

Patients typically complain of more severe symptoms after consumption of large amounts of readily absorbable carbohydrates. The mixed meal test can be used to precipitate the symptoms. The composition of the mixed meal has not been standardized, and it is reasonable to request the patient to consume a meal that leads to symptoms during everyday life. The University of Minnesota investigators formalized a high carbohydrate and a low carbohydrate test meal (Table 18–6) and showed that in patients with postgastric bypass hypoglycemia, the high carbohydrate meal resulted in hyperglycemia and concomitant hyperinsulinemia at about 30 minutes after a meal. Glucose levels then fell to a nadir (range 28-62 mg/dL) at 90 to 120 minutes. Eating the low carbohydrate meal, however, resulted in very little change in plasma glucose levels and only a modest increase in plasma insulin. The prolonged (5 hour) oral glucose tolerance test is not recommended for evaluation because a large number of healthy subjects will have a false-positive result. There have been case reports of insulinoma and noninsulinoma pancreatogenous hypoglycemia syndrome occurring in patients who present with hypoglycemia post-Roux-en-Y surgery. It is unclear how often this occurs. A careful history may identify those patients who have history of hypoglycemia with exercise or when meals are missed, and these individuals may require a formal 72-hour fast to rule out insulinoma.

Several different treatments can be tried for the late dumping syndrome. Dietary modification is the best option but may be difficult to sustain for some patients. More frequent meals with smaller portions of less rapidly assimilated carbohydrate and more slowly absorbed fat or protein can be tried. Alpha glucosidase inhibitors (acarbose and miglitol) can be a useful adjunct to a low carbohydrate diet in some patients. Octreotide 50 μg administered subcutaneously two or three times a day 30 minutes prior to each meal has been reported to improve symptoms in patients with severe dumping refractory to other forms of medical interventions. Information regarding long-term octreotide use is however limited. Various surgical procedures to slow down gastric emptying have been reported to improve symptoms, but long-term efficacy studies are lacking. Recently it has been reported that endoscopic gastrojejunal anastomotic reduction to induce delay in gastric pouch emptying in patients with Roux-en-Y surgery improves the dumping syndrome symptoms.

Noninsulinoma Pancreatogenous Hypoglycemia Syndrome (NIPHS)

These are patients with hyperinsulinemic hypoglycemia due to generalized islet hyperplasia. The term adult onset nesidioblastosis has also applied to this clinical entity, and it is very rare. These patients predominantly have symptoms 2 to 4 hours after meals and only rarely while fasting. As in other patients who have frequent hypoglycemia, the symptoms are predominantly those of neuroglycopenia including diplopia, dysarthria, confusion, disorientation, convulsions, and coma. At the time of hypoglycemia, these patients have elevated insulin, C-peptide and proinsulin levels and negative sulfonylurea, repaglinide, and nateglinide screens. Typically these patients have a negative 72-hour fast. Imaging studies are also negative. These patients have a positive selective arterial calcium stimulation test—usually positive for multiple arteries. NIPHS patients do not have mutations in the *KIR6.2* and *SUR1* genes, which have been abnormal in some cases of children with a syndrome of familial hyperinsulinemic hypoglycemia (discussed later) Gradient-guided partial or subtotal pancreatectomy relieves the hypoglycemic symptoms in the majority of patients.

Late Hypoglycemia of Occult Diabetes

This condition occurs in the occasional patient with impaired glucose tolerance or early type 1 or type 2 diabetes. The patient complains of hypoglycemic symptoms after consuming high carbohydrate meals. In response to an oral glucose tolerance test, they have a delayed insulin secretion pattern which produces late hypoglycemia 4 to 5 hours after ingestion of glucose. In the obese patient, treatment is directed at reduction to ideal weight. These patients often respond to reduced intake of refined sugars with multiple, spaced, small feedings that are high in dietary fiber. Those with impaired glucose tolerance should be advised to have periodic assessment for development of diabetes.

TABLE 18–6 Test meals for evaluation of postprandial hypoglycemia after Roux-en-Y gastric bypass surgery.

High Carbohydrate Meal (79% Carbohydrate, 11% Fat, and 10% Protein; 405 kcal)	Low Carbohydrate Meal (2% Carbohydrate, 74% Fat, and 24% Protein; 415 kcal)
8 oz of orange juice 1 slice of toast with 1 tsp of margarine and 2 tsp of jam	Decaffeinated black coffee or tea (without sugar) 1 egg, a 1-oz sausage patty, and a 0.5-oz slice of cheese

After overnight fast (≥8 hours) give high carbohydrate meal on day 1 and low carbohydrate meal on day 2. Measure plasma glucose and serum insulin levels before (fasting) and 30, 60, 90, 120, 150, and 180 minutes after the meal.

Data from Kellogg TA, Bantle JP, Leslie DB, et al. Postgastric bypass hyperinsulinemic hypoglycemia syndrome: characterization and response to a modified diet. *Surg Obes Relat Dis*. 2008 Jul-Aug;4(4):492-499.

Functional Alimentary Hypoglycemia

Patients present with symptoms suggestive of increased sympathetic activity—anxiety, weakness, tremor, sweating, or palpitations after meals. Physical examination and laboratory tests are normal. Previously many of these patients underwent a 5-hour oral glucose tolerance test and the detection of glucose levels in the 50s was determined to be responsible for the symptoms, and the recommendation was to modify the diet. It is now recognized that at least 10% of normal subjects who do not have any symptoms have nadir glucose levels less than 50 mg/dL during a 4- to 6-hour oral glucose tolerance test. In a study comparing responses to an oral glucose tolerance test with the response to a mixed meal test, none of the patients who had plasma glucose levels less than 50 mg/dL on oral glucose testing had low glucose values with the mixed meal. Thus, it is not recommended that these patients undergo either a prolonged oral glucose tolerance test or a mixed meal test. The patients should instead be given home blood glucose monitors (with memories) and instructed to monitor fingerstick glucose levels at the time of symptoms. Only patients who have symptoms when their fingerstick blood glucose is low (<50 mg/dL) and who have resolution of symptoms when the glucose is raised by consumption of readily absorbable carbohydrate need additional evaluation. Patients who do not have evidence for low glucose levels at the time of symptoms are generally reassured by their findings. Counseling and support should be the mainstays of therapy in this group, with dietary manipulation used only as an adjunctive form of therapy.

8. DISORDERS ASSOCIATED WITH LOW HEPATIC GLUCOSE OUTPUT

Reduced hepatic gluconeogenesis can result from a direct loss of hepatic tissue (acute yellow atrophy from fulminant viral hepatitis or toxic damage), from disorders that reduce amino acid substrate for hepatic gluconeogenesis (severe muscle wasting and inanition from anorexia nervosa, chronic starvation, uremia, and glucocorticoid deficit from adrenocortical deficiency), or from inborn errors of carbohydrate metabolism affecting glycogenolytic or gluconeogenic enzymes.

PEDIATRIC HYPOGLYCEMIA

Hypoglycemia is common in children, and prompt diagnosis and effective treatment are required to prevent seizures and brain injury in this vulnerable population. The most common cause of pediatric hypoglycemia is diabetes mellitus. Persistent hypoglycemia, however, is most often the result of a congenital defect in regulation of insulin, cortisol, or growth hormone, or an inborn error of metabolism of glucose, glycogen, or fatty acids. Pediatric hypoglycemia presents a unique challenge of distinguishing between hypoglycemia of the normal transitional glucose metabolism in the newborn and hypoglycemia that persists or presents for the first time after 3 days of life. Diagnosis of the cause of hypoglycemia relies primarily on laboratory investigations (a "critical sample") at the time of a hypoglycemic episode and Figure 18–6 shows an algorithm for elucidating a diagnosis from these results. Persistent hypoglycemia may result from: (1) a deficiency in one or more counterregulatory hormones including hypopituitarism; (2) defects in glycogenolysis, gluconeogenesis, or fatty acid oxidation; or (3) congenital hyperinsulinism.

CONGENITAL HYPERINSULINISM

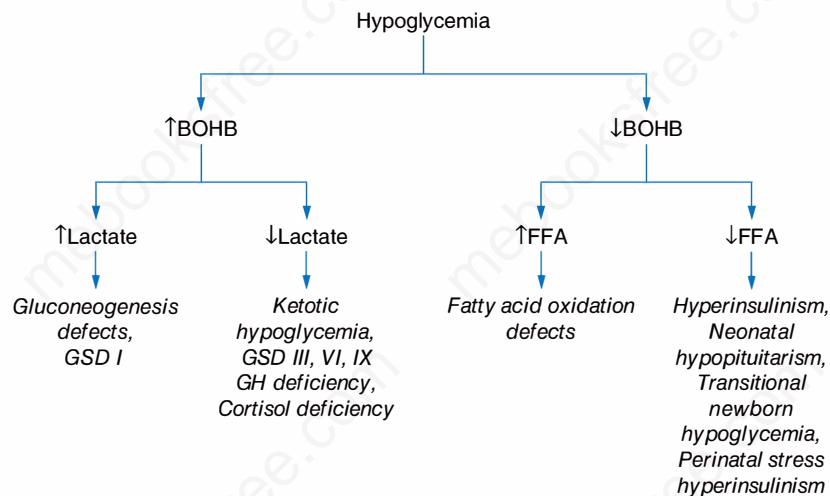
As with adults, hyperinsulinism is the most frequent cause of persistent hypoglycemia in infants and children. As compared to adults, where the most common cause of hyperinsulinism is an insulin-secreting adenoma, in infants hyperinsulinism most likely stems from an underlying genetic disorder. This condition has been referenced in various ways, including persistent hyperinsulinemic hypoglycemia of infancy or islet dysregulation syndrome, but hereafter will be referred to as congenital hyperinsulinism.


FIGURE 18–6 Algorithm to approach hypoglycemia. Shows how information from the critical sample can be used to determine major categories of hypoglycemia. BOHB, beta hydroxybutyrate; FFA, free fatty acids; GH, growth hormone.

TABLE 18–7 Types of congenital hyperinsulinism and their causes.

Transient
  Transitional neonatal hypoglycemia
  Infants of diabetic mothers
  Miscellaneous
    Small or Large for gestational age, asphyxia, and stress in infants
Persistent
  Defects in ATP-dependent potassium channel
    Sulfonylurea receptor (SUR) (ABCC8)
    Kir6.2 (KCNJ11)
  Focal vs diffuse disease
  Metabolic defects
    Glutamate dehydrogenase (GDH)
    Glucokinase (GCK)
    Hexokinase 1 (HK1)
    Pyruvate transporter (MCT1) (Exercise-induced)
    Short-chain L-3-hydroxyacyl-CoA dehydrogenase (SCHAD)
    Hepatocyte nuclear factor (HNF) 1A and HNF 4A
    Uncoupling protein 2 (UCP2)
    Phosphoglucomutase 1 (PGM1)
Syndromes
  Beckwith-Wiedemann
  Soto
  Glycosylation disorders

Transient congenital hyperinsulinism is a common disorder in the immediate neonatal period. Persistent disorders are rarer, occurring in approximately 1 in 50,000. This problem was originally attributed to an anomaly in islet development, termed **nesidioblastosis**, a reference to endocrine cell budding from pancreatic ducts. However, this budding has since been noted to represent a normal developmental process during the first year of life. Recent advances in our understanding of the regulation of insulin secretion have begun to elucidate the underlying pathophysiology of this complex disease (Table 18–7). Monogenic forms of congenital hyperinsulinism have now been attributed to mutations in eleven different genes. However, depending on the series cited, genetic mutation analysis is negative in 50% or more of cases and higher in those who are diazoxide-responsive. Timely diagnosis and aggressive treatment are essential to prevent long-term neurologic sequelae from hypoglycemia in the affected individual.

Transient Hyperinsulinism

A. Transitional neonatal hypoglycemia   It has been long recognized that plasma glucose concentrations are lower in the first few days of life in normal newborns than at older ages. Immediately after birth mean plasma glucose levels drop by 25 to 30 mg/dL and reach a nadir in the first day of life at 55 to 65 mg/dL. These glucose concentrations remain stable and are relatively unaffected by the timing of the first feeding or frequency of feedings in the first day of life. They subsequently increase over the next couple of days to reach the normal range of older children. This hypoglycemia is characterized be suppressed ketogenesis and lipolysis and a large glycemic response to intravenous glucagon injection, consistent with hyperinsulinism due to an apparent incomplete suppression of insulin secretion. This transitional neonatal hyperinsulinism may reflect a persistent reduction of the glucose threshold for insulin secretion, a normal finding in utero thought to optimize fetal growth.

B. Infants of diabetic mothers   The fetuses of mothers with poorly regulated diabetes are exposed to sustained hyperglycemia, leading to increased fetal insulin secretion, with resultant macrosomia. This increased insulin secretion persists postpartum and usually resolves after several days. As a result, infants of diabetic mothers are at high risk of developing hypoglycemia after birth. An added risk of hypoglycemia is associated with being large for gestational age at birth, mothers who required insulin during pregnancy, or mothers who were hyperglycemic during labor. They can usually be managed with early, frequent feedings or intravenous glucose until insulin secretion has normalized, often 1 to 2 days after birth.

C. Small or large for gestational age, asphyxiation, and other conditions in newborns   Various perinatal stresses are known to induce more severe and prolonged hyperinsulinism. Small-for-gestational age as well as large-for-gestational age and asphyxiated newborns, usually from toxemic mothers, frequently experience hyperinsulinism and hypoglycemia. Hyperinsulinism is also reported in erythroblastosis fetalis, sepsis, cerebral hemorrhage, prematurity, and severely stressed newborns (low Apgar scores). Hypoglycemia usually resolves within a period of several days or weeks but may persist in these settings for 6 to 12 months. Some newborns with Beckwith-Wiedemann syndrome and Soto syndrome (also known as cerebral gigantism) show β cell hyperplasia and experience transient hypoglycemia from hyperinsulinism.

Persistent Hyperinsulinism

Persistent hyperinsulinism, continuing for more than several weeks, results from a group of heterogeneous disorders, rather than a single entity, and the various subtypes are discussed below. These forms may be classified in a variety of different ways, including usual time of presentation (shortly after birth vs after months to years of life); mode of genetic transmission (autosomal recessive vs dominant); or anatomic (focal vs diffuse). In this section, the forms are grouped into defects in the pancreatic β cell K_{ATP} channel, defects affecting intracellular metabolism, and several other miscellaneous conditions or syndromes.

A. Channel defects

1. **Sulfonylurea receptor and Kir6.2**—The most common cause and the severe form of congenital hyperinsulinism appears to be related to defects in the pancreatic β cell K_{ATP} channel. This channel consists of a multimer of two proteins, the sulfonylurea receptor (SUR1), a member of the ATP-binding cassette superfamily, and Kir6.2, a member of a family of inwardly rectifying potassium channels. With increases in intracellular ATP, the channel closes, leading to membrane depolarization and insulin secretion (see Chapter 17). Inactivating mutations of either component of the channel result in a non-functional K_{ATP} channel, inappropriate β cell depolarization, and secretion of insulin, even in the face of low glucose concentrations.

The two genes, *ABCC8* and *KCNJ11*, encoding the channel components, SUR1 and Kir6.2, respectively, are located in tandem on chromosome 11p15. Numerous mutations have now been described and appear to occur more frequently in *ABCC8* than *KCNJ11*. They are usually autosomal recessive mutations, which result in complete absence of K_{ATP} channels by blocking trafficking to the plasma membrane. Dominant mutations are missense defects, which allow normal trafficking of the channel to the plasma membrane but act in a dominant negative manner to impair channel activity. The severity of the impairment manifests varying degrees of diazoxide responsiveness. Sequencing of these molecules is available commercially and may not be merely of academic interest: patients harboring some *ABCC8* or *KCNJ11* mutations do not respond well to medical therapy. Thus, knowledge of the underlying defect may influence treatment decisions for a particular patient as well as inform the family about risk to future children. Relative to other forms of congenital hyperinsulinism, patients with defects in the K_{ATP} channel often present early in life, with more marked clinical symptomatology, including macrosomia. They experience early onset and severe hypoglycemia that requires high rates of glucose infusion to normalize serum glucose concentrations and typically require pancreatectomy to restore euglycemia.

2. **Focal versus diffuse disease**—Two histologically distinct forms of congenital hyperinsulinism due to K_{ATP} channel mutations have been described, a diffuse form, mentioned above, which constitutes 35% to 70% of cases, depending on the series cited, and a focal form (focal adenomatous hyperplasia). The clinical differences between the two forms are subtle; children with the focal form are more likely to have a delay in diagnosis and hypoglycemic seizures. Diagnosis of the focal form is made by perioperative palpation and visualization by an experienced surgeon and histologic examination. [18]F DOPA positron emission tomography may also be of utility in preoperative localization of focal lesions. Histologic examination of the focal form reveals focal hyperplasia, with hypertrophied β cells harboring giant nuclei, in contrast to the diffuse form, where all the islets of Langerhans are irregular in size and contain hypertrophied β cells. The molecular explanation for the focal defect is based on a two genetic hit model, in which the child harbors a paternally inherited recessive K_{ATP} mutant allele, in either *ABCC8* or *KCNJ11*, and subsequently has an embryonic pancreas-limited chromosome recombination of 11p15.1 that results in a pancreatic lesion with paternal isodisomy (two copies of the paternally inherited recessive K_{ATP} mutant) and biallelic loss of function of K_{ATP} channel. Paternal isodisomy of the K_{ATP} mutation and the adjacent Beckwith-Weidemann syndrome (BWS) locus leads to islet overgrowth due expression and suppression of imprinted growth regulatory genes (*IGF2, H19, p57/CDKN1C*). The distinction between these two forms of hyperinsulinism has potentially important implications for therapy, because patients with focal disease are not responsive to diazoxide but may be cured with more limited partial pancreatectomy, whereas those with the diffuse form who are not responsive to diazoxide require more aggressive near-total resection, which may result in diabetes. Such patients can only be fully evaluated and treated at centers with a team of endocrinologists, interventional radiologists, pathologists, and surgeons with expertise in this disorder.

B. Metabolic defects The second most common form of congenital hyperinsulinism is the hyperinsulinism-hyperammonemia syndrome, which results from activating mutations of the glutamate dehydrogenase (*GDH*) gene. This condition is inherited in autosomal dominant fashion. This enzyme mediates oxidative deamination of glutamate to alpha ketoglutarate. Activating mutations impair GDH sensitivity to guanosine triphosphate, an allosteric inhibitor, and increase sensitivity to leucine, an allosteric activator. With increased GDH activity, increased production of alpha ketoglutarate with subsequent oxidation in the Krebs cycle generates increased ATP, which in turn activates the K_{ATP} channel and leads to membrane depolarization and insulin secretion. GDH is also expressed in the liver and kidney. Overactivity of GDH in the kidney leads to increased renal ammonia production. Thus, one hallmark of this defect is a chronic mild elevation in serum ammonia concentrations with an increase up to 3 to 5 times normal in response to a protein load. The patients with GDH mutations usually have a milder course than those with defects in the K_{ATP} channel, often presenting outside of the neonatal period. CNS manifestations include absence seizures and behavior disturbances. They often have postprandial hypoglycemia, particularly in response to higher protein loads, but may also manifest fasting hypoglycemia. They usually respond well to diazoxide, and many are able to eventually discontinue treatment.

The third most common form of congenital hyperinsulinism results from mutations in glucokinase, the first and rate-limiting step in glycolysis, and an enzyme that is considered to play an essential role in glucose sensing by the β cell. Dominant activating mutations have been described that result in increased rates of glycolysis at lower glucose concentrations. The resultant increase in the intracellular ATP/ADP ratio increases insulin secretion at any given serum glucose concentration, resulting in fasting hypoglycemia. They usually respond poorly to diazoxide. By contrast, individuals heterozygous for inactivating mutations have a form of maturity onset diabetes of the young (MODY).

Two rare forms of congenital hyperinsulinism involve the expression of genes that are not normally expressed in β cells to ensure appropriate insulin secretion. Hexokinase 1 (HK1) has a higher affinity for glucose than glucokinase, and its absence in β cells prevents insulin release at low glucose concentrations. Expression of hexokinase leads to elevations in basal insulin secretion, even at low glucose concentrations, increasing the potential for hypoglycemia. This dominant form of hyperinsulinism is responsive to diazoxide therapy. The loss of normal suppression of monocarboxylate transporter 1 (MCT1) expression in β cells leads to exercise-induced hyperinsulinism. In the setting of anaerobic exercise, the abnormal expression of MCT1 in the pancreatic beta cell allows pyruvate and lactate influx and subsequently leads to ATP generation and an inappropriate, rapid rise in insulin secretion. Therapy is largely focused on prevention with increased ingestion of carbohydrates during and following exercise.

Another autosomal recessive form of congenital hyperinsulinism results from mutations in the gene encoding the short chain L-3-hydroxyacyl-CoA dehydrogenase (SCHAD). Mutations of SCHAD cause loss of an inhibitory interaction with GDH that results in a hyperinsulinism phenotype similar to that seen with activating GDH mutations but without hyperammonemia and CNS manifestations. This recessive defect is responsive to diazoxide.

For some time, dominant inactivating mutations of the transcription factors hepatocyte nuclear factor (HNF) 1A and HNF 4A have been associated with MODY3 and MODY1, respectively. Recently, individuals bearing these mutations have been shown to manifest hyperinsulinism in early infancy, yet progress to MODY in early adulthood. The mechanism(s) underlying this transition from early hyperinsulinism and to subsequent islet failure remain unknown; animal models suggest that chronic activation of beta cells may herald later beta cell failure.

Dominant inactivating mutations of uncoupling protein 2 (UCP2) have been reported in a small number of cases of hyperinsulinism. UCP2 functions as a carrier to remove 4 carbon intermediates from the mitochondrial matrix and suppress glucose oxidation. It is assumed that reduced activity of UCP2 enhances glucose oxidation and subsequently increases insulin secretion. Phosphoglucomutase 1 (PGM1) plays an important role in regulating insulin response to glucose. Recessive inactivating mutations cause a form of glycogen storage disease that is associated with ketotic, fasting hypoglycemia, post-prandial hyperinsulinemic hypoglycemia, and abnormal protein glycosylation.

Congenital disorders in glycosylation have also been linked with congenital hyperinsulinism. The mechanism is unclear, although hypoglycosylation of the SUR with a resultant defect in trafficking to the cell membrane has been offered as a possible explanation. Nonetheless, these patients appear to be responsive to diazoxide, suggesting that at least some functional K_{ATP} channels reach the cell surface. Affected individuals have multisystem disorders, including neurologic defects.

Clinical Presentation

The cardinal symptoms of congenital hyperinsulinism are recurrent episodes of hypoglycemia and can occur from any time after birth until several years of age, or manifest even later in life, depending on the nature and severity of the defect. However, hyperinsulinism presenting in adolescence is more likely due to an insulinoma. As in adults, the symptoms of hypoglycemia are secondary to adrenergic responses or neuroglycopenia. However, in neonates and infants, symptoms are difficult to detect and may be less specific. They may include tremors, cyanosis, hypothermia, apnea or irregular breathing, lethargy, apathy, limpness, refusal to eat, high-pitched cries, and seizures of any type. Even if newborns appear asymptomatic, hypoglycemia can be severe.

Diagnosis

The differential diagnosis for pediatric hypoglycemia is quite long and includes deficiencies in counterregulatory hormones (eg, growth hormone, ACTH, glucocorticoids); defects in gluconeogenesis, glycogen synthesis, and breakdown; and disorders in fatty acid metabolism. Hyperinsulinism is suspected in hypoglycemic newborns or infants who require unusually high glucose infusion rates (12-30 mg/kg/min) to maintain blood glucose levels in the target range. Macrosomia may be another clue to hyperinsulinism, although it is not always present. The crucial diagnostic step is to obtain a *critical* blood sample for glucose, insulin, growth

hormone, cortisol, blood gases, lactate, free fatty acids, and ketones (β-hydroxybutyrate [BOHB]) during hypoglycemia (see Figure 18–6). Insulin levels must often be measured during several episodes of hypoglycemia because insulin levels at times of hypoglycemia are not always elevated to diagnostic levels. In fact, even if not elevated, insulin levels that are inappropriately measurable during episodes of hypoglycemia are still consistent with the diagnosis. As in adults, the hallmarks of hyperinsulinism include measurable plasma insulin in the face of hypoglycemia (glucose <50 mg/dL), low or unmeasurable ketones (BOHB <15 mg/dL [<1.5 mmol/L]) and free fatty acids (<28-42 mg/dL [<1.0-1.5 mmol/L]), and hyperresponsiveness to glucagon challenge, with the glycemic response to 0.5 to 1 mg (30 µg/kg) of parenteral glucagon of more than 30 mg/dL (with glucose monitored every 15 minutes for up to 45 minutes after glucagon injection).

Treatment

A. Medical therapy   Management of children with congenital hyperinsulinism remains one of the most challenging problems for pediatric endocrinologists, and affected children should be transferred to a tertiary center that has experience in managing such children. Patients may require high glucose infusion rates to maintain euglycemia, and thus a secure central line is usually necessary. They also require frequent glucose monitoring, extensive ongoing laboratory assessment to establish the underlying diagnosis, and a series of medical and/or surgical interventions to effect a cure.

Hypoglycemia in infancy has to be treated aggressively in order to prevent long-term neurologic sequelae. Relative to adults, younger children (up to age 5-6 years) appear to be especially vulnerable to such damage. Those with hyperinsulinism are particularly at risk, because ketone bodies are not present as an alternative fuel source. The therapeutic goal is to achieve glucose levels above 70 mg/dL while the infant is on an appropriate feeding schedule for age. Infants receiving appropriate therapy must be able to support a fast for at least 6 hours without hypoglycemia. In selected cases in which food refusal or intercurrent illness is a problem, hypoglycemia can be prevented by placing a gastrostomy tube to administer enteral feedings on a regular basis or with intermittent low dose intramuscular or subcutaneous glucagon injections until oral feeding resumes.

For acute management of hypoglycemia, stabilization of blood glucoses may require infusion rates of glucose up to 20 to 30 mg/kg/min, well above the 4 to 8 mg/kg/min needed to stabilize most neonates. Some centers employ aggressive enteral feeding, using frequent feeds or continuous feeding via nasogastric or gastrostomy tube, with or without cornstarch, as a means to avoid hypoglycemia. The following drugs are also used in the medical management of hyperinsulinemic hypoglycemia.

1. **Diazoxide**—Diazoxide is the drug of choice in infants who cannot be weaned from intravenous glucose. Diazoxide increases blood glucose by stabilizing the K_{ATP} channel in the open state, thereby inhibiting membrane depolarization and insulin secretion. Functionally intact SUR1 and Kir6.2 proteins are necessary for the full action of the drug, and thus, patients with channel defects often do not respond, whereas

those with other forms of hyperinsulinism do exhibit salutary responses. Diazoxide also increases catecholamine release, which suppresses insulin release and inhibits insulin's actions peripherally. The initial recommended dose is 10 to 15 mg/kg/d divided every 8 hours, up to a maximal dose of 20 mg/kg/d. Positive responses are usually seen within 48 hours if they are going to occur. Diazoxide has several important side effects that should be considered. Fluid retention can be managed by simultaneous administration of thiazide diuretics. Hypertrichosis and coarse facial changes may become quite striking and can be reduced only by decreasing the dose or discontinuing the diazoxide altogether. Hyperuricemia, leukopenia, and thrombocytopenia are rare, but routine serum studies must be monitored while therapy continues. Diazoxide is also an antihypertensive drug, but these effects are rarely encountered with oral administration.

Depending on the study cited, diazoxide appears to be efficacious in only one-fourth to one-half of the patients with hyperinsulinism and appears to be less likely to work in those patients presenting in the immediate newborn period, a population that often has more marked defects in K_{ATP} channel activity. Thus, in those patients with persistent hyperinsulinism, determining whether mutations are present in SUR1 or Kir6.2 may help anticipate the response to medical therapy and predict the need for more definitive surgical intervention.

2. **Somatostatin analogs**—These are usually a second-line approach, for those unresponsive to diazoxide. Somatostatin acts via a G protein–coupled receptor to lower intracellular calcium and to hyperpolarize the β cell membrane, thereby inhibiting insulin release. Somatostatin has a half-life of only 1 to 3 minutes, but the synthetic analog octreotide may be administered at intervals of up to 8 hours or via continuous subcutaneous infusion and is efficacious in some patients with congenital hyperinsulinism. A starting dose of 5 to 10 µg/kg/d, administered either as an intermittent bolus or via continuous subcutaneous infusion in a pump, often produces salutary initial responses, but because of tachyphylaxis due to somatostatin receptor downregulation, the dose sometimes has to be increased to as much as 40 µg/kg/d or dosed intermittently to provide a daily period of time off drug. Some physicians advocate octreotide in patients who fail to respond to diazoxide therapy alone. However, optimal control of blood glucose often cannot be achieved by adding octreotide. Nonetheless, the medication may help stabilize blood glucose concentrations in the period prior to pancreatectomy and may prove efficacious postoperatively in those patients who have persistent hyperinsulinism even with reduced β cell mass. There are some reports of long-term success (>5 years) with octreotide alone.

Short-term side effects are mostly self-limited within the first several weeks of therapy. Octreotide has nonspecific effects on the gastrointestinal tract, including decreased perfusion of the splanchnic circulation, gallbladder contractility, and bile secretion. Short-term effects may include necrotizing enterocolitis in young infants, vomiting, abdominal distension, and steatorrhea, with later risk of cholelithiasis. Possible inhibitory effects of octreotide on other hormonal axes, including effects on the pituitary somatotrope, adrenal, and thyroid, raise concerns about its long-term use, although some centers report successful and uneventful use for years without significant problems.

3. **Glucagon**—Glucagon has a place in the management of hyperinsulinism during initial stabilization of the hypoglycemic infant in the intensive care unit or prior to surgery. This agent stimulates hepatic glycogenolysis and is very effective in these patients with congenital hyperinsulinism because their glycogen stores are replete. A variety of regimens have been shown to be effective, including a bolus of 0.2 mg intravenously in cases of severe hypoglycemia followed by a continuous infusion at a dose of 2 to 10 mg/kg/h. An intramuscular glucagon injection may also be used as an emergency treatment of recurrent hypoglycemic episodes at home. Attempts have been made to administer glucagon continuously via subcutaneous infusion with limited success due to solubility issues. Newer formulations are in various development stages and show promise for sustained outpatient therapy options.

B. Surgical therapy   Pancreatectomy is undertaken when maintenance of euglycemia cannot be achieved with medical treatment alone. The extent of the pancreatectomy required depends on the form of the hyperinsulinism. Some infants may have a focal rather than diffuse form and may require only selective resection of the affected pancreatic tissue in order to effect a cure. Unfortunately, only a limited number of medical centers around the world are now equipped to conduct the pre- and perioperative evaluation to distinguish focal from diffuse disease.

The diffuse form of hyperinsulinism requires more aggressive resections. The β cell mass reduction frequently fails to achieve euglycemia, and medical therapy may have to be continued to address hyper- or hypoglycemia. If hypoglycemia persists, repeated surgical interventions may be required to remove residual and/or ectopic pancreatic tissue. Potential surgical complications include intraoperative injury to the common bile duct and adhesions with intestinal obstruction. Additional complications include exocrine pancreatic insufficiency, often requiring oral supplements at mealtimes, and diabetes mellitus.

NON-INSULIN DEPENDENT HYPOGLYCEMIA

Other remaining causes of persistent hypoglycemia in children are accounted for by deficiencies in one or more counterregulatory hormones or inborn errors of metabolism. Although several hormones are involved in the maintenance of euglycemia and produce hyperglycemic responses in excess, only deficiencies of cortisol or growth hormone have been shown to manifest hypoglycemia, which is characterized by elevated serum ketones levels. Associated physical examination findings are consistent with hypopituitarism, including microphallus, cleft lip and/or palate, neonatal jaundice, and short stature. Glycogen storage diseases (GSD) are inherited defects of glycogen synthesis or degradation. Most cases will manifest in later infancy or childhood. Ketotic hypoglycemia along with failure to thrive and hepatomegaly occur with the hepatic types of GSD (I, III, VI, IX). The most severe hepatic GSD is GSD I, which is a defect in glucose-6-phosphatase activity, the final step in glycogenolytic and gluconeogenic pathways. Lactic academia and hyperuricemia are unique to GSD I due to impaired gluconeogenesis, which is not affected in the other GSD types. Disorders of gluconeogenesis manifest hypoglycemia during episodes of significant metabolic decompensation and are associated with characteristic urine organic acid patterns

and ketosis. Fatty acid oxidation provides a significant energy source for gluconeogenesis and therefore, defects in fatty acid oxidation manifest hypoglycemia during prolonged fasting that is characterized by low ketone levels. The treatment of inborn errors of metabolism to prevent hypoglycemia is focused on decreasing the duration of fasting by frequent or continuous feeding or use of uncooked cornstarch to provide a slowly digested form of carbohydrate.

Outcome

Neurologic sequelae are the major concern with severe hypoglycemia during infancy and childhood. Multiple episodes of hypoglycemia are more often associated with sequelae than one severe hypoglycemic episode with convulsions. At least one-third of patients with congenital hyperinsulinism suffer from developmental delay based on follow-up via a telephone survey.

Patients with the familial form of congenital hyperinsulinism who harbor mutations in the SUR receptor may be at additional neurologic risk. The SUR is expressed in the brain, and defects in this molecule could potentially interfere with neural development. The role of this receptor in the brain, however, has yet to be elucidated.

Affected individuals also appear to be at higher risk for later development of diabetes. This problem may be related to reduced β cell mass following pancreatectomy or from β cell apoptosis following chronic depolarization in subjects who harbor channel defects.

Disorders of Lipoprotein Metabolism

Mary J. Malloy, MD and John P. Kane, MD, PhD

ABCA1	ATP-binding cassette transporter A1		**IDL**	Intermediate density lipoproteins
ABCG1	ATP-binding cassette transporter G1		**Idol**	Inducible degrader of the LDL receptor
ACAT	Acyl-CoA:cholesterol acyltransferase		**LCAT**	Lecithin-cholesterol acyltransferase
ANGPTL3	Angiopoietin-like protein 3		**LDL**	Low-density lipoproteins
Apo	Apolipoprotein		**LMF1**	Lipase maturation factor 1
ARH	Autosomal recessive hypercholesterolemia		**Lp(a)**	Lipoprotein(a)
			LPL	Lipoprotein lipase
CETP	Cholesteryl ester transfer protein		**LRP-1**	LDL receptor-related protein-1
CHD	Coronary heart disease		**MCP-1**	Monocyte chemoattractant protein-1
CK	Creatine kinase		**NAFLD**	Nonalcoholic fatty liver disease
FCH	Familial combined hyperlipidemia		**NASH**	Nonalcoholic steatohepatitis
FFA	Free fatty acids		**PCPE-2**	Procollagen C-proteinase enhancer-2
FH	Familial hypercholesterolemia		**PCSK9**	Proprotein convertase subtilisin/kexin type 9
GPIHBP1	Glycosylphosphatidylinositol-anchored HDL-binding protein 1		**PDGF**	Platelet-derived growth factor
HDL	High-density lipoproteins		**SR-BI**	Scavenger receptor, class B, type I
HMG-CoA	Hydroxymethylglutaryl-CoA		**VLDL**	Very low density lipoproteins

The clinical importance of lipoprotein disorders derives chiefly from the role of lipoproteins in atherogenesis and its associated risk of coronary and peripheral vascular disease. The greatly increased risk of acute pancreatitis associated with severe hypertriglyceridemia is an additional indication for intervention. Disordered lipid metabolism is also a critical element in nonalcoholic fatty liver disease. Characterization of dyslipidemia is important for selection of appropriate treatment and may provide clues to underlying primary clinical disorders.

ATHEROSCLEROSIS

Atherosclerosis is the leading cause of death in the United States. Abundant epidemiologic evidence establishes its multifactorial character and indicates that the effects of the multiple risk factors are at least additive. Risk factors include hyperlipidemia, hypertension, smoking, diabetes, physical inactivity, decreased levels of high-density lipoproteins (HDL), hyperhomocysteinemia, inflammatory, and hypercoagulable states. Atheromas are complex lesions containing cellular elements, collagen, fibrin, and lipids. The progression of the lesion is chiefly attributable to its content of unesterified cholesterol and cholesteryl esters. Cholesterol in the atheroma originates in circulating lipoproteins. Atherogenic lipoproteins include low-density (LDL), intermediate density (IDL), very low density lipoproteins (VLDL), and Lp(a) species, all of which contain the B-100 apolipoprotein (Apo B-100). Chylomicron remnants containing apo B-48 are also atherogenic. All of these are subject to oxidation by reactive oxygen species in the tissues and also by lipoxygenases secreted by macrophages in atheromas. Oxidized lipoproteins cause impairment of endothelial cell-mediated vasodilation and stimulate endothelium to secrete

monocyte chemoattractant protein-1 (MCP-1) and adhesion molecules that recruit monocytes to the lesion. Tocopherols (vitamin E) are natural antioxidants that localize in the surface monolayers of lipoproteins, exerting resistance to oxidation. Increased oxidative stress such as that induced by smoking depletes the tocopherol content. Oxidation of lipoproteins stimulates their endocytosis via scavenger receptors on macrophages and smooth muscle cells, leading to the formation of foam cells. Recent studies strongly support a role of vitamin D in prevention of atherosclerosis, probably by influencing inflammatory activity of macrophages.

Hypertension increases access of lipoproteins to the subintima. Smoking accelerates atherogenesis by reducing HDL and increasing thrombogenesis by platelets—in addition to its pro-oxidant effect. Activated platelets release platelet-derived growth factor (PDGF), stimulating proliferation and migration of cells of smooth muscle origin into the lesion.

Activated macrophages secrete cytokines that drive an inflammatory and proliferative process. Metalloproteases secreted by macrophages weaken the atheroma so that fissuring and rupture can occur. Exposure of blood to subintimal collagen and tissue factor stimulates thrombogenesis, precipitating acute coronary events. The inverse relationship between HDL levels and atherogenesis probably reflects the role of certain species of HDL in cholesterol retrieval and in protecting lipoproteins against oxidation.

Reversal of Atherosclerosis

Angiographic intervention trials have shown that regression of atherosclerotic lesions can occur with lipid-lowering therapy. Large trials have demonstrated striking reductions in the incidence of new coronary events in individuals with hyperlipidemia who have had no prior clinical coronary disease (primary prevention) as well as in patients with antecedent disease (secondary prevention). Thus, timely hypolipidemic therapy appropriate to the lipid disorder decreases the incidence of coronary disease and reduces the need for angioplasty, stenting, and bypass surgery. Side-effects of treatment have been minimal in comparison with the magnitude of this benefit.

Average levels of LDL in the United States and northern Europe are higher than in many other nations, where the levels appear to approach the biologic norm. This probably accounts in large part for the higher incidence of coronary disease in industrialized Western nations and suggests that dietary changes that reduce levels of atherogenic lipoproteins would be beneficial.

OVERVIEW OF LIPID TRANSPORT

The Plasma Lipoproteins

Because lipids are relatively insoluble in water, they are transported in association with proteins. The simplest complexes are those formed between unesterified, or free fatty acids (FFA) and albumin, which serve to carry the FFA from peripheral adipocytes to other tissues.

Aside from some HDL species, the remainder of the lipids are transported in spherical lipoprotein complexes (Table 19–1), with core regions containing hydrophobic lipids. The principal core lipids are cholesteryl esters and triglycerides. Triglycerides predominate in the cores of chylomicrons, which transport newly absorbed lipids from the intestine, and in VLDL, which originate in liver. The relative content of cholesteryl ester is increased in the cores of remnants derived from these lipoproteins. Cholesteryl esters are the predominant core lipid in LDL and HDL. Surrounding the core in each lipoprotein is a monolayer containing amphiphilic phospholipids and unesterified (free) cholesterol. Apolipoproteins, noncovalently bound to the lipids, are located on this surface monolayer (Figure19–1).

B Apolipoproteins

Lipoproteins, excluding HDL, contain very high molecular weight B proteins that behave like intrinsic proteins of cell membranes. Unlike the smaller apolipoproteins, the B proteins do not migrate from one lipoprotein particle to another. VLDL contain the B-100 protein, which is retained in the formation of LDL from VLDL remnants by liver. Apo B-100 has a ligand domain for binding to the LDL receptor. The ligand is conformed as VLDL are transformed into LDL. Lipoprotein (a) consists of an LDL particle bound covalently to one copy of the (a) protein. The intestinal B protein, B-48, is found only in chylomicrons and their remnants.

Other Apolipoproteins

In addition to the B proteins, the following proteins are present in lipoproteins (see Table 19–1).

C apolipoproteins are lower molecular weight proteins that equilibrate rapidly among the lipoproteins. There are four distinct species: C-I, C-II, C-III, and C-IV. Apo C-II is a requisite cofactor

TABLE 19–1 Lipoproteins of human serum.

	Density Interval (g/cm^3)	Core Lipids	Diameter (nm)	Apolipoproteins in Order of Quantitative Importance
High density (HDL)	1.21-1.063	Cholesteryl ester	7.5-10.5	A-I, A-II, C, E (many others)
Low density (LDL)	1.063-1.019	Cholesteryl ester	21.5	B-100
Intermediate density (IDL)	1.019-1.006	Cholesteryl ester, triglyceride	25-30	B-100, some C and E
Very low density (VLDL)	<1.006	Triglyceride cholesteryl ester	39-100	B-100, C, E
Chylomicrons	<1.006	Triglyceride	60-500	B-48, C, E, A-I, A-II, A-IV
Lp(a)	1.04-1.08	Cholesteryl ester	21-30	B-100, (a)

FIGURE 19–1 Metabolism of chylomicrons (A-I, A-II, B-48, and C proteins, apolipoproteins; CE, cholesteryl esters; TG, triglycerides). See text for details.

for lipoprotein lipase, and Apo C-III is an inhibitor of that enzyme.

Three isoforms of Apo E—E-2, E-3, and E-4—are the products of allelic genes. Unlike Apo E-3 and Apo E-4, Apo E-2 does not contain a functional ligand for the LDL receptor. The Apo E-4 alleles are associated with early-onset Alzheimer disease and and other neurodegenerative disorders, and with increased risk of coronary disease.

Apo A-I is the major apolipoprotein of HDL. It is also present in chylomicrons and is the most abundant of the apolipoproteins of human serum (about 125 mg/dL). It is a cofactor for lecithin-cholesterol acyltransferase (LCAT). Mutations in this apolipoprotein can be amyloidogenic.

Apo A-II is an important constituent of HDL. It contains cysteine, which permits the formation of disulfide-bridged dimers with Apo E.

Apo A-IV is chiefly associated with chylomicrons.

Apo A-V plays a significant role in the removal of triglycerides from plasma.

The (a) protein is a glycoprotein that has a high degree of sequence homology with plasminogen, resulting in binding affinity for tissue plasminogen activator. It is found as a disulfide-bridged dimer with Apo B-100 in LDL-like species of lipoproteins (Lp[a] lipoproteins).

Absorption of Dietary Fat; Secretion of Chylomicrons

Dietary triglycerides are hydrolyzed in the intestine to β-monoglyceride and fatty acids by pancreatic lipase, which is activated by bile acids and a protein cofactor. The partial glycerides and fatty acids form micelles that are absorbed by intestinal epithelium. The fatty acids are reesterified with β-monoglycerides to form triglycerides, and free cholesterol is esterified with fatty

acids by acyl-CoA:cholesterol acyltransferase-2 (ACAT-2). Droplets of triglyceride with small amounts of cholesteryl esters, associated with B-48, acquire a monolayer of phospholipid and free cholesterol. Apo A-I and Apo A-II are added, and the nascent chylomicron emerges into the extracellular lymph space (see Figure 19–1). The new chylomicron begins to exchange surface components with HDL, acquiring Apo C and Apo E and losing phospholipids. This process continues as the chylomicron is carried via the intestinal lymphatics to the thoracic duct and thence into the bloodstream.

Formation of Very Low Density Lipoproteins

The liver exports triglycerides to peripheral tissues in the cores of VLDL (Figure 19–2). These triglycerides are synthesized in liver from FFA abstracted from plasma and from fatty acids synthesized *de novo.* Release of VLDL by liver is augmented by any condition that results in increased flux of FFA to liver in the absence of compensating ketogenesis. Obesity, increased caloric intake, ingestion of ethanol, and estrogens stimulate release of VLDL and are important factors in hypertriglyceridemia.

Metabolism of Triglyceride-Rich Lipoproteins in Plasma

A. Hydrolysis by lipoprotein lipase   Fatty acids derived from the triglycerides of chylomicrons and VLDL are delivered to tissues through a common pathway involving hydrolysis by the lipoprotein lipase (LPL) system. Five other gene products participate in this process. Apoproteins C-II and A-V act as cofactors for LPL, and glycosylphosphatidylinositol-anchored HDL-binding protein 1 (GPIHPB1) organizes the complex. Lipase maturation factor 1 (LMF1) is a chaperone essential for the conformation of
FIGURE 19–2 Metabolism of VLDL (A-I, A-II, B-48, and C proteins, apolipoproteins; CE, cholesteryl esters; TG, triglycerides). See text for details.

LPL, hepatic and endothelial lipases. Apo C-III suppresses the activity of LPL and promotes increased production of VLDL by liver. Members of a family of fatty acid transfer proteins facilitate FFA uptake in tissues. LPL is bound to capillary endothelium in heart, skeletal muscle, adipose tissue, mammary gland, and other tissues.

B. Biologic regulation of lipoprotein lipase   When glucose levels in plasma are elevated and the release of insulin is stimulated, LPL is transcriptionally upregulated in adipose tissue, and fatty acids derived from triglycerides of circulating lipoproteins are stored. During prolonged fasting, and in diabetic ketoacidosis, LPL activity of adipose tissue falls, preventing storage of fatty acids. Heparin is a cofactor for LPL. When it is given intravenously (0.1-0.2 mg/kg over 10 minutes), LPL activity is displaced into plasma, permitting its measurement.

C. Formation of lipoprotein remnants   Hydrolysis by LPL results in depletion of triglycerides in the cores of chylomicrons and VLDL, producing progressive decreases in particle diameter. Lipids from the surface and C proteins are transferred to HDL. The remnant lipoproteins thus formed contain their original complement of Apo B, significant amounts of Apo E, and little Apo C. They have lost about 70% of their triglycerides and are enriched in cholesteryl esters.

D. Fate of lipoprotein remnants   Chylomicron remnants are removed from blood quantitatively by high-affinity, receptor-mediated endocytosis in the liver. The receptors include the LDL (B-100:E) receptors and the LDL receptor-related protein-1 (LRP-1). Endocytosis of chylomicron remnants by both requires the presence of Apo E-3 or Apo E-4. The lipids enter hepatic pools, and B-48 protein is degraded. Cholesterol derived from chylomicron remnants exerts feedback control of cholesterol biosynthesis in liver.

VLDL remnants: Some are removed from blood via the B-100:E receptors (discussed later) and are degraded. Those that escape uptake are transformed into LDL. Thus, the rate of removal of VLDL remnants is a determinant of LDL production. Formation of LDL involves the removal of residual triglycerides by hepatic lipase, facilitated by Apo E. LDL contain cholesteryl esters in their cores and retain Apo B-100. In normal individuals, a major fraction of VLDL is converted to LDL, and all of the LDL Apo B comes from VLDL. In certain hypertriglyceridemic states, conversion of VLDL to LDL is decreased. In the absence of impaired conversion, increased secretion of VLDL results in increased production of LDL. This precursor-product relationship explains the clinical phenomenon referred to as the **beta shift**, an increase of LDL (beta-lipoprotein) as hypertriglyceridemia resolves. An example of this occurs temporarily following institution of insulin treatment in uncontrolled diabetes with lipemia. Insulin induces LPL activity, resulting in rapid conversion of

VLDL to LDL. Because of its longer half-life, LDL accumulates in plasma. Elevated levels of LDL may persist beyond the time when levels of triglyceride-rich lipoproteins have returned to normal. A similar phenomenon may occur when patients with familial combined hyperlipidemia (FCH) are treated with fibric acid derivatives.

E. Half-lives of lipoproteins   Normally, the half-life of chylomicrons is 5 to 20 minutes; that of VLDL is 0.5 to 1 hour; and that of LDL is about 2½ days. At triglyceride levels of 800 to 1000 mg/dL, LPL is at kinetic saturation. Increased input of triglycerides into plasma at those levels rapidly augments the hypertriglyceridemia.

F. Effect of dietary fat restriction   Individuals consuming a typical North American diet transport 75 to 100 g or more of triglyceride per day in chylomicrons, whereas the liver exports 10 to 30 g in VLDL. When LPL is saturated and triglycerides are measured in thousands of milligrams per deciliter, acute restriction of dietary fat produces a significant reduction in levels. This intervention is especially important in the lipemic patient with impending pancreatitis. If symptoms suggest that pancreatitis is imminent, oral intake should be eliminated, gastric acid should be suppressed with H_2 blockade, and the patient should not be fed by mouth until the symptoms subside and triglycerides decrease to less than 800 to 1000 mg/dL.

Catabolism of Low-Density Lipoproteins

LDL catabolism is mediated by high-affinity receptors on the cell membranes of virtually all nucleated cells but, most importantly, hepatocytes. Ligands for these LDL receptors exist in Apo B-100 and Apo E. After endocytosis, Apo B is degraded, and the receptor returns to the cell membrane. The cholesteryl esters of LDL are hydrolyzed to free cholesterol for production of cell membrane bilayers. Free cholesterol down-regulates hydroxymethylglutaryl-CoA (HMG-CoA) reductase and other rate-limiting enzymes in the biosynthetic pathway for cholesterol. Cholesterol in excess of need for membrane synthesis is esterified by ACAT-2 for storage, a process inhibited by saturated and trans fats. In addition to suppression of cholesterol biosynthesis, the entry of cholesterol via the LDL pathway leads to downregulation of LDL receptors. Further regulatory mechanisms involve shortening of the residence time of LDL receptors in cell membranes. The PCSK9 protein increases the proteolytic degradation of LDL receptors, decreasing the ability of cells to endocytose LDL. Another mechanism that leads to receptor degradation involves ubiquitination of the receptors by Idol (inducible degrader of the LDL receptor).

Metabolism of High-Density Lipoproteins

When isolated by ultracentrifugation, HDL appear to comprise two major classes: HDL_2 and HDL_3. Similar quantities of HDL_3 are isolated from serum of men and women, but about twice as much HDL_2 is found in premenopausal women. Immunochemical studies indicate that there are as many as 20 discrete species of HDL that are obscured by ultracentrifugation. One of these, the

67-kDa prebeta-1 HDL, is the primary acquisitor of cholesterol in the retrieval pathway from peripheral tissues.

A. Sources of HDL   Both liver and intestine produce HDL apolipoproteins, which organize with lipids into the native species of HDL in lymph and plasma. Excess free cholesterol and phospholipids are liberated from the surface monolayers of chylomicrons and VLDL as hydrolysis of triglycerides proceeds. Phospholipids are transferred to HDL by phospholipid transfer protein. Free cholesterol acquired by HDL is esterified by LCAT. This enzyme transfers 1 mol of fatty acid from a lecithin molecule to the hydroxyl group of unesterified cholesterol, forming cholesteryl esters. LCAT is secreted by liver. In severe hepatic parenchymal disease, levels in plasma are low and esterification of cholesterol is impeded, leading to the accumulation of free cholesterol in lipoproteins and in membranes of erythrocytes. This transforms them into the target cells classically associated with hepatic disease.

B. Metabolic roles for HDL   HDL serve as carriers for the C apolipoproteins, transferring them to nascent VLDL and chylomicrons. HDL as well as LDL deliver cholesterol to the adrenal cortex and gonads in support of steroidogenesis. HDL play a major role in the centripetal transport of cholesterol. Unesterified cholesterol, exported by the ATP-binding cassette transporter A1 (ABCA1), is acquired from the membranes of peripheral tissues by prebeta-1 HDL and is esterified by LCAT, passing through other HDL species before the cholesteryl esters are incorporated into HDL of alpha-electrophoretic mobility. Cholesterol effluxed from macrophages by the ATP-binding cassette transporter G1 (ABCG1) is acquired by larger HDL. The cholesteryl esters are then transferred to LDL and to triglyceride-rich lipoproteins mediated by cholesteryl ester transfer protein (CETP). Cholesteryl esters are also transferred from HDL to hepatocytes by scavenger receptor, class B, type I (SR-BI) receptors.

C. Catabolism of HDL   The pathways of catabolism of HDL are not yet known. Radiochemical studies indicate that Apo A-I and Apo A-II are removed from plasma synchronously and that a portion of the degradation occurs in liver and in kidney.

The Cholesterol Economy

Cholesterol is an essential constituent of the plasma membranes of cells and of myelin. It is required for adrenal and gonadal steroidogenesis and for production of bile acids by liver. Cells synthesize cholesterol, commencing with acetyl-CoA. The first committed step, mediated by HMG-CoA reductase, is the formation of mevalonic acid, which is then metabolized via a series of isoprenoid intermediaries to squalene. The latter cyclizes to form a series of sterols leading to cholesterol. A small amount of the mevalonate is converted to the isoprenoid substances ubiquinone, dolichol, and isopentenyl pyrophosphate. This pathway also yields the isoprenoid intermediaries, geranyl and farnesyl pyrophosphates, that are involved in prenylation of proteins. Prenylation provides an anchor

so that proteins such as the low molecular weight G proteins can bind to membranes. Cholesterol synthesis is tightly regulated by cholesterol or its metabolites, which down-regulate HMG-CoA reductase. Thus, cells can produce cholesterol not provided by circulating lipoproteins. Hepatocytes and intestinal epithelial cells use cholesterol for secretion of lipoproteins. In addition, cells constantly transfer cholesterol to circulating lipoproteins, chiefly HDL. Cholesterol is converted to bile acids in liver via a pathway initiated by cholesterol 7α-hydroxylase. Most of the bile acids are reabsorbed from the intestine, but the small amount that is lost in stool provides a means of elimination of cholesterol. Activity of cholesterol 7α-hydroxylase is decreased in hypothyroidism, as are the expression of LDL receptors and hepatic lipase.

At usual levels of cholesterol intake, about one-third of the amount ingested is absorbed. Most is transported to liver in chylomicron remnants, suppressing hepatic cholesterogenesis. Individuals may differ substantially in the effect of dietary cholesterol on levels of serum lipoproteins.

DIFFERENTIATION OF DISORDERS OF LIPOPROTEIN METABOLISM

Laboratory Analyses of Lipids and Lipoproteins

Chylomicrons may be secreted into plasma up to 10 hours after a meal, or longer, if alcohol is also consumed. Thus, serum lipids should be measured after a 10-hour fast. If blood glucose is not to be measured, patients may have a small non-fat meal. Because triglyceride-rich lipoproteins, their remnants, and Lipoprotein (a) are atherogenic, determination of non-HDL cholesterol by precipitation of HDL yields useful initial information.

A. Inspection   Diagnostic insights can be gained from inspection of serum or plasma before and after overnight refrigeration. Opalescence is due to light scattering by large triglyceride-rich lipoproteins. A sample begins to appear hazy when triglycerides reach 200 mg/dL (2.3 mmol/L). Chylomicrons are readily detected, because they form a white supernatant layer after refrigeration. Uncommon cases in which binding of immunoglobulins to lipoproteins takes place can be detected by the formation of a curd-like lipoprotein aggregate or a snowy precipitate as the sample cools. If one of these disorders is suspected, blood should be kept at 37°C during the formation of the clot and separation of the serum, because the critical temperatures for precipitation of the cryoglobulin complex may be higher than room temperature.

B. Laboratory techniques   Several chemical techniques provide reliable measures of cholesterol and triglycerides, an essential minimum for differentiation of disorders of lipoproteins. Unesterified and esterified cholesterol are usually measured together, so that the reported value is the total content of cholesterol in serum. A more complete characterization of lipoproteins is achieved by measurement of the cholesterol and triglyceride contents of individual lipoprotein fractions, separated by preparative ultracentrifugation. Other methods, employing magnetic resonance or electrophoresis, afford assessment of lipoprotein concentrations and particle diameters. HDL can be measured using a technique in which they are the only lipoproteins that remain in solution after treatment of the serum with heparin and manganese or other precipitants. Prognostic implications of small changes in HDL cholesterol make rigid quality controls necessary. An important determinant of the content of cholesteryl esters in HDL is the amount of triglyceride-rich lipoproteins to which the HDL are exposed in plasma. Cholesteryl esters from HDL transfer into triglyceride-rich lipoproteins, leading to an inverse dependence of HDL cholesterol on plasma triglycerides. HDL cholesterol cannot be interpreted without knowledge of the level of serum triglycerides. Elevated triglycerides can lead to erroneous diagnosis of primary HDL deficiency.

Enrichment of VLDL by cholesteryl esters is typical of familial dysbetalipoproteinemia that is due to homozygosity for Apo E-2. The Apo E genotype can be determined by PCR analysis. Clinically useful immunoassays are available for Apo B and Lp(a).

Some epidemiologic evidence suggests that LDL particles of smaller than normal diameter are associated with an increased risk of atherosclerosis. Small, dense LDL particles are a constant finding when triglyceride levels are elevated even marginally. Laboratory measurement of LDL diameters is therefore uninformative in patients with hypertriglyceridemia. LDL particle number can be assessed and elevated numbers are associated with increased risk of cardiovascular disease.

Clinical Differentiation of Abnormal Patterns of Plasma Lipoproteins

A. Preliminary screening   Epidemiologic studies in Europe and the United States have shown a progressive increase in risk of coronary disease as levels of cholesterol increase. Over the last decade, a number of objective placebo-controlled trials have demonstrated significant reduction in fatal and non-fatal outcomes with respect to coronary disease, associated with treatments that reduced the levels of atherogenic lipoproteins, chiefly LDL.

The 2013 American Heart Association/American College of Cardiology (AHA/ACC) guidelines suggest lipoprotein treatment goals based on calculated risk for individual patients. The National Lipid Association (NLA) and the International Atherosclerosis Society (IAS) have published alternate recommendations. Lipoprotein treatment goals should be individualized and based on global risk assessment that includes all the known lipoprotein and non-lipoprotein risk factors. For patients at high risk (coronary heart disease or risk equivalents, including diabetes), a suggested LDL cholesterol goal is less than 70 mg/dL (1.8 mmol/L). An LDL cholesterol goal of 100 mg/dL (2.6 mmol/dL) or below is considered appropriate for primary prevention when multiple risk factors are present. Fasting triglyceride levels above 150 mg/dL (1.7 mmol/L) merit investigation. One abnormality commonly associated with increased risk of coronary disease that is not detected if screening is limited to hyperlipidemia

is hypoalphalipoproteinemia, or deficiency of HDL. Lp(a), an important and independent risk factor, should be measured. HDL deficiency and elevated levels of Lp(a) underscore the importance of controlling other risk factors.

B. Identification of abnormal patterns   The second step in investigation of hyperlipidemia is determination of the molecular species of lipoproteins involved. In some cases, this may include multiple species; in others, qualitative properties of the lipoproteins are of diagnostic importance. Secondary hyperlipidemias of similar pattern may be the sole cause of the lipoprotein abnormality or may aggravate primary disorders of lipoprotein metabolism. The differentiation of specific primary disorders usually requires additional clinical and genetic information.

The following diagnostic protocol, based on initial measurement of cholesterol, triglycerides, and HDL in serum after a 10-hour fast, supplemented by observation of serum and by additional laboratory measurements where essential, serves as a guide to identifying abnormal patterns. The term **hyperlipidemia** denotes high levels of any class of lipoprotein; **hyperlipemia** denotes high levels of any of the triglyceride-rich lipoproteins.

Case 1: Serum Cholesterol Levels Increased; Triglycerides Normal

If the serum cholesterol level is modestly elevated (up to 260 mg/dL [6.72 mmol/L]), elevated levels of HDL may account for the observed increase. This is usually not associated with disease processes. The LDL cholesterol (in mg/dL) may be estimated by subtracting the HDL cholesterol and the estimated cholesterol contribution of VLDL from the total cholesterol level. The VLDL cholesterol is approximated as one-fifth of the serum triglyceride level (Friedewald formula).

$$\text{LDL cholesterol} = \text{total cholesterol} - \left(\frac{\text{TG}}{5} + \text{HDL cholesterol} \right)$$

Very high levels of HDL cholesterol measured by the precipitation technique can signal the presence of the abnormal lipoprotein of cholestasis (Lp-X). This disorder is characterized by elevated alkaline phosphatase activity. Rarely, deficiency of CETP or hepatic lipase can cause high levels of HDL.

Case 2: Predominant Increase of Triglycerides; Moderate Increase in Cholesterol May Be Present

Here it is apparent that the primary abnormality is an increase in triglyceride-rich VLDL or chylomicrons or both (mixed lipemia). Because both contain free cholesterol in their surface monolayers and a small amount of cholesteryl ester in their cores, the total cholesterol may be increased, although to a much smaller extent than triglycerides. Low levels of LDL often seen in hypertriglyceridemia may offset the increase in cholesterol due to the triglyceride-rich lipoproteins, especially in primary chylomicronemia.

Because VLDL and chylomicrons compete as substrates in a common removal pathway, chylomicrons are nearly always present when triglyceride levels exceed 1000 mg/dL (11.5 mmol/L).

Case 3: Cholesterol and Triglyceride Levels Both Elevated

This pattern can be the result of either of two abnormal phenotypes. One is a combined increase of VLDL and LDL. This pattern is termed combined hyperlipidemia and is one of the three phenotypic patterns encountered in kindreds with the disorder Familial Combined Hyperlipoproteinemia (FCH). The second phenotype is an increase of remnant lipoproteins derived from VLDL and chylomicrons. These particles have been partially depleted of triglyceride by LPL and enriched with cholesteryl esters by the LCAT system, such that the total content of cholesterol in serum is similar to that of triglycerides. This pattern is almost always an expression of Familial Dysbetalipoproteinemia. Diagnosis of this disorder is confirmed by a genotype demonstrating absence of the normal E-3 and E-4 alleles.

CLINICAL DESCRIPTIONS OF PRIMARY AND SECONDARY DISORDERS OF LIPOPROTEIN METABOLISM

THE HYPERTRIGLYCERIDEMIAS

Atherogenicity

Epidemiologic evidence supports the atherogenicity of VLDL, chylomicrons, and their remnants. They have been demonstrated in atherosclerotic plaques from humans. Impaired capacity of the VLDL of some individuals to accept cholesteryl esters from the LCAT reaction may also contribute to atherogenesis by impeding centripetal transport of cholesterol.

Cause of Pancreatitis

Very high levels of triglycerides in plasma are associated with a risk of acute pancreatitis, probably from the local release of FFA and lysolecithin from lipoprotein substrates in the pancreatic capillary bed. When these lipids exceed the binding capacity of albumin, they could lyse membranes of parenchymal cells, initiating a chemical pancreatitis. Many patients with lipemia have intermittent episodes of epigastric pain during which serum amylase does not reach levels commonly considered diagnostic for pancreatitis especially in patients who have had previous attacks. These episodes frequently evolve into classic pancreatitis suggesting that they represent incipient pancreatic inflammation. The progression of pancreatitis often can be prevented by rapid reduction of triglycerides, usually accomplished by restriction of all dietary fat for at least 72 hours or until symptoms disappear. In some cases, parenteral feeding, excluding fat emulsions, may be required for a few days.

Clinical Signs (Figure 19–3)

When triglyceride levels in serum exceed 3000 to 4000 mg/dL (34.5-46 mmol/L), light scattering by these particles in the blood lends a whitish cast to the venous vascular bed of the retina, a sign known as **lipemia retinalis**. Markedly elevated levels of VLDL or chylomicrons may be associated with the appearance of eruptive cutaneous xanthomas (see Figure 19–3E). These lesions, filled with foam cells, appear as yellow morbilliform eruptions 2 to 5 mm in diameter, often with erythematous areolae. They usually occur in clusters on extensor surfaces such as the elbows, knees, and buttocks. They are transient and disappear within a few weeks after triglyceride levels are reduced.

Effects of Hypertriglyceridemia on Laboratory Measurements

Light scattering from high levels of triglyceride-rich lipoproteins can cause erroneous results in most chemical determinations

FIGURE 19–3 Clinical manifestations of hyperlipidemias. **A.** Xanthelasma involving medial and lateral canthi. **B.** Severe xanthelasma and arcus corneae. **C.** Tuberous xanthomas. **D.** Large tuberous xanthoma of elbow. **E.** Eruptive xanthomas, singly and in rosettes. **F.** Xanthomas of extensor tendons of the hands. **G.** Xeroradiogram of Achilles tendon xanthoma. **H.** Xanthoma of Achilles tendon. (Normal Achilles tendons do not exceed 7 mm in diameter in the region between the calcaneus and the point at which the tendon fibers begin to radiate toward their origins.)

involving photometric measurements. Amylase activity in serum may be inhibited; therefore, lipemic specimens should be diluted for measurement of this enzyme. Because the lipoproteins are not permeable to ionic or polar molecules, their core regions constitute a second phase in plasma. When the volume of this phase becomes appreciable, electrolytes and other hydrophilic species are underestimated with respect to their true concentration in the aqueous phase. A practical rule for correcting these values is as follows: For each 1000 mg/dL (11.5 mmol/L) of triglyceride, the measured concentrations of all hydrophilic molecules and ions should be adjusted upward by 1%.

PRIMARY HYPERTRIGLYCERIDEMIA

1. DEFICIENCY OF LIPOPROTEIN LIPASE ACTIVITY

Clinical Findings

A. Symptoms and signs   The activity of LPL is dependent upon the integrity of the enzyme and its cofactor, Apo C-II. In addition, defects in Apo A-V, GPIHBP1, and LMF1 proteins can result in severe impairment of LPL activity. Because the clinical expressions of these defects are similar, they are considered together. On a typical North American diet, lipemia is usually severe (triglycerides of 2000-25,000 mg/dL) (23-287.5 mmol/L). Hepatomegaly and splenomegaly are frequently present. Foam cells laden with lipid are found in liver, spleen, and bone marrow. Splenic infarct has been described and may be a source of abdominal pain. Hypersplenism with anemia, granulocytopenia, and thrombocytopenia can occur. Recurrent epigastric pain and overt pancreatitis are frequently encountered. Eruptive xanthomas may be present. These disorders may be recognized in early infancy or may go unnoticed until an attack of acute pancreatitis occurs or lipemic serum is noted on blood sampling as late as middle age. Patients with these disorders are usually not obese and have normal carbohydrate metabolism unless pancreatitis impairs insulinogenic capacity. Estrogens intensify the lipemia by stimulating hepatic production of VLDL. Therefore, in pregnancy and lactation or during the administration of estrogenic steroids, the risk of pancreatitis increases.

B. Laboratory findings   There is a preponderance of chylomicrons in serum. Many patients have a moderate increase in VLDL, however, and in pregnant women or those receiving estrogens, a pattern of mixed lipemia is usually present. Levels of LDL are decreased, reflecting catabolism of VLDL by pathways that do not involve the production of LDL.

A presumptive diagnosis of these disorders can be made by restricting oral intake of fat to 10 to 15 g/d. Triglycerides drop precipitously, usually reaching 200 to 600 mg/dL (2.3-6.9 mmol/L) within 3 to 4 days unless the patient has significant hepatic steatosis, in which case there may be continued excretion of VLDL. Confirmation of deficiency of LPL is obtained by measurement of the lipolytic activity of plasma 10 minutes after injection of heparin (0.2 mg/kg over 10 minutes) intravenously. Analysis of lipolysis is done with or without 0.5 mol/L sodium chloride, which

inhibits LPL but does not suppress the activity of hepatic lipase. Abnormalities in LMF-1, GPIHBP, Apo A-V, and Apo C-II are identified by genotyping.

Treatment

Treatment of chylomicronemia is primarily dietary. Plasmapheresis may be helpful in the initial management of acute or incipient pancreatitis. Intake of total fat should be limited in most adult patients to 15 g/d. Because the defect involves lipolysis, both saturated and unsaturated fats must be curtailed. The diet should contain at least 5 g of polyunsaturated fat as a source of essential fatty acids, and fat-soluble vitamins must be provided. Administration of 500 mg daily of marine omega-3 fatty acids is also recommended. Adherence to this diet invariably maintains triglycerides below 1000 mg/dL (11.2 mmol/L) in the absence of pregnancy, lactation, the administration of exogenous estrogens, or alcohol. Because this is below the level at which pancreatitis usually occurs, compliant patients are at low risk. Pregnant women with these disorders require particularly close monitoring. Antisense oligonucleotide knockdown strategy for Apo C-III, currently under active investigation, may prove to be useful in management of severe hypertriglyceridemia.

2. ENDOGENOUS AND MIXED LIPEMIAS

Etiology and Pathogenesis

Endogenous lipemia (elevated VLDL) and mixed lipemia probably both result from several genetically determined disorders. Because VLDL and chylomicrons are competing substrates in the intravascular lipolytic pathway, saturating levels of VLDL impede the removal of chylomicrons. Therefore, as the severity of endogenous lipemia increases, a pattern of mixed lipemia may supervene. In other cases, the pattern of mixed lipemia appears to be present continuously. Although specific pathophysiologic mechanisms remain obscure, certain familial patterns are known. In all forms, factors that increase the rate of secretion of VLDL aggravate the hypertriglyceridemia (ie, obesity with insulin resistance, appearance of fully developed type 2 diabetes mellitus, alcohol, and exogenous estrogens). Studies of VLDL turnover indicate that either increased production or impaired removal of VLDL may be operative in different individuals. A substantial number of patients with mixed lipemia have partial defects in catabolism of triglyceride-rich lipoproteins, often due to heterozygosity for mutations in LPL. Most patients with significant endogenous or mixed lipemia have centripetal obesity.

Clinical Findings

Clinical features of these forms of hypertriglyceridemia depend on their severity and include eruptive xanthomas, lipemia retinalis, recurrent epigastric pain, and acute pancreatitis.

Endogenous lipemia is frequently an element in a constellation of metabolic abnormalities termed the **metabolic syndrome**. Insulin resistance, usually associated with central obesity, is a core feature of this syndrome. Patients may or may not have hyperglycemia. Low levels of HDL cholesterol largely reflect increased transfer of CE into circulating VLDL and, therefore, are not a

primary component of the syndrome. Hypertension and hyperuricemia are frequently present.

Treatment

The first element of treatment is severe restriction of total fat intake. The objective of long-term dietary management is reduction to ideal body weight. Because alcohol causes significant augmentation of VLDL production, abstinence is important. If weight loss is achieved, the triglycerides almost always show a marked response, often approaching normal values. When the fall in triglycerides is not satisfactory, a fibrate or nicotinic acid (in the absence of insulin resistance), singly or in combination, usually produces further reductions. When insulin resistance is present, metformin may be a useful adjunct.

3. FAMILIAL COMBINED HYPERLIPIDEMIA

Etiology

This inherited disorder, which is the most common form of hyperlipidemia, occurs in 1% to 2% of the population. The underlying process involves overproduction of VLDL. Some affected individuals have increased levels of both VLDL and LDL (combined hyperlipidemia); some have predominantly increased levels of either VLDL or LDL. The level of Apo B-100 is increased. Patterns in the serum of an individual may change with time. It is known that the offspring of an individual having any one of the three phenotypic patterns can have one of the other patterns. Affected children often have hyperlipidemia. If the child is obese, hypertriglyceridemia is likely present, whereas a child of normal weight may have only an elevated LDL.

Clinical Findings

Neither tendinous nor cutaneous xanthomas other than xanthelasma occur. This disorder appears to be inherited as a Mendelian dominant trait involving alternative loci. Modifying genes have been published, but major loci have not been identified. Factors that increase the severity of hypertriglyceridemia in other disorders aggravate the lipemia in this syndrome as well.

Treatment

The risk of coronary disease is significantly increased, and patients should be treated aggressively with diet and drugs. Because LDL levels often increase with fibrate therapy in these patients and because resins increase triglycerides, the recommended treatment is an HMG-CoA reductase inhibitor. The addition of niacin or fenofibrate may be required if triglycerides remain elevated. Fenofibrate may be used cautiously with rosuvastatin.

4. FAMILIAL DYSBETALIPOPROTEINEMIA (TYPE III HYPERLIPOPROTEINEMIA)

Etiology and Pathogenesis

A permissive genetic constitution for this disease (homozygosity for Apo E-2) occurs in about 2% of the U.S. population but the expression of hyperlipidemia apparently requires environmental and possibly additional genetic determinants. The molecular basis is the presence of isoforms of Apo E that are poor ligands for high-affinity receptors. In its fully expressed form, the lipoprotein pattern is dominated by the accumulation of remnants of VLDL and chylomicrons. Levels of LDL are decreased, reflecting interruption of the transformation of VLDL remnants to LDL. The primary defect is impaired hepatic uptake of remnants of triglyceride-rich lipoproteins. The remnant particles are enriched in cholesteryl esters such that the level of cholesterol in serum is often as high as that of triglycerides. Absence of the E-3 and E-4 alleles in genomic DNA confirms the diagnosis. Additional ligand defective mutations of Apo E are now known to result in dysbetalipoproteinemia. Some of these cause hyperlipidemia in the heterozygous state, a disorder termed **dominant dysbetalipoproteinemia**.

Clinical Findings

Hyperlipidemia and clinical signs are not usually evident before age 20. In younger patients with hyperlipidemia, hypothyroidism or obesity is likely to be present. Adults frequently have tuberous or tuberoeruptive xanthomas (see Figure 19–3C). Both tend to occur on extensor surfaces, especially elbows and knees. Tuberoeruptive xanthomas are pink or yellowish skin nodules 3 to 8 mm in diameter that often become confluent. Tuberous xanthomas— shiny reddish or orange nodules up to 3 cm or more in diameter— are usually moveable and nontender. Another type, planar xanthomas of the palmar creases, strongly suggests dysbetalipoproteinemia. The skin creases assume an orange color from deposition of carotenoids. They occasionally are raised above the level of adjacent skin and are not tender. (Planar xanthomas are also seen in cholestasis.)

Some patients have impaired glucose tolerance, which is usually associated with higher levels of blood lipids. Obesity is commonly present and tends to aggravate the lipemia. Patients with the genetic constitution for dysbetalipoproteinemia often develop severe hyperlipidemia if they are hypothyroid. Atherosclerosis of the coronary and peripheral vessels occurs with increased frequency, and the prevalence of disease of the iliac and femoral vessels is especially high.

Treatment

Management includes a weight reduction diet providing a reduced intake of cholesterol, fat, and alcohol. When the hyperlipidemia does not respond satisfactorily to diet, a fibrate or niacin in low doses (if the patient does not have insulin resistance) is usually effective. These agents can be used together in resistant cases. Some patients respond to the more potent reductase inhibitors alone, and the addition of niacin normalizes the lipid levels in most.

SECONDARY HYPERTRIGLYCERIDEMIA

1. DIABETES MELLITUS

In patients with diabetes, levels of VLDL in plasma are frequently elevated. The severe lipemia associated with absence or marked

insufficiency of insulin is attributable to decreased transcription of the *LPL* gene. The administration of insulin usually restores triglyceride levels to normal within a few days. However, if massive fatty liver is present, weeks may be required for the VLDL to return to normal while the liver secretes its triglycerides. Conversion of massive amounts of VLDL to LDL as the impedance of VLDL catabolism is relieved leads to marked accumulation of LDL that may persist for weeks, leading to a spurious diagnosis of primary hypercholesterolemia.

The moderately elevated VLDL seen in type 2 diabetes under average control probably reflects chiefly an increased flux of FFA to liver that stimulates production of triglycerides and their secretion in VLDL. In addition to VLDL, LDL levels are also somewhat increased in diabetic individuals under poor control, probably accounting in part for their increased risk of CHD. Some have much higher levels of VLDL, suggesting that an additional genetic factor predisposing to lipemia is present. Still another cause of lipemic diabetes is the compromised insulinogenic capacity that can result from acute pancreatitis. The deficiency may be severe enough to require exogenous insulin, often only in small doses. In diabetic individuals who develop nephrosis, the secondary lipemia of nephrosis compounds their hypertriglyceridemia. In the presence of hyperglycemia, lipoproteins become glycosylated, leading to their uptake by macrophages.

Lipemia may be very severe, with elevated levels of both VLDL and chylomicrons when control is poor. Lipemic patients usually have ketoacidosis when they are insulin-deficient, but lipemia can occur in its absence. Patients with type 1 diabetes who have been chronically undertreated with insulin may have mobilized most of the triglyceride from peripheral adipose tissue, so that they no longer have sufficient substrate for significant ketogenesis. These emaciated individuals may have severe lipemia and striking hepatomegaly.

In type 1 diabetes, the rigid control of blood glucose levels, which can be attained with continuous subcutaneous insulin infusion, is associated with sustained normalization of levels of both LDL and VLDL. The lipemia of type 2 diabetes usually responds well to control of the underlying disorder. In obese insulin-resistant individuals, weight loss is essential. Diets containing slowly absorbed carbohydrates are well tolerated, allowing a decrease in the burden of chylomicron triglycerides in plasma (see Chapter 17).

2. UREMIA

Uremia is associated with modest isolated increases in VLDL. The most important underlying mechanisms are probably insulin resistance and impairment of catabolism of VLDL. Many uremic patients are also nephrotic. The additional effects of nephrosis on lipoprotein metabolism may produce a combined hyperlipidemia. Patients who have had renal transplants may be receiving glucocorticoids, which induce elevation of LDL.

3. HUMAN IMMUNODEFICIENCY VIRUS INFECTION

HIV infection per se is associated with hypertriglyceridemia (see Chapter 25). A syndrome of partial lipodystrophy and insulin resistance, often with marked lipemia, occurs with multidrug treatment that includes certain inhibitors of viral proteases. Acute pancreatitis can ensue. Limited clinical experience suggests that fibric acid derivatives are of some value. Alcohol must be avoided.

4. CORTICOSTEROID EXCESS

In endogenous Cushing syndrome and with corticosteroid treatment, insulin resistance is present, and levels of LDL are increased. It appears that the hyperlipidemia is primarily due to increased secretion of VLDL, which is then catabolized to LDL. More severe lipemia ensues when steroidogenic diabetes appears, reducing catabolism of triglyceride-rich lipoproteins via the LPL pathway.

5. EXOGENOUS ESTROGENS

When estrogens are administered to normal women, triglyceride levels may increase by as much as 15%, reflecting increased production of VLDL. Paradoxically, estrogens increase the efficiency of catabolism of triglyceride-rich lipoproteins. Whereas estrogens tend to induce insulin resistance, it is not clear that this is an important mechanism, because certain nortestosterone derivatives decrease plasma triglycerides despite the induction of appreciable insulin resistance.

Certain individuals, usually those with preexisting mild lipemia, develop marked hypertriglyceridemia when receiving estrogens even in relatively small doses. Thus, triglycerides should be monitored during estrogen therapy. Contraceptive combinations with predominantly progestational effects produce less hypertriglyceridemia than purely estrogenic compounds. Transdermal delivery of estrogen probably results in lesser increases in VLDL secretion because it avoids the hepatic first-pass effect.

6. ALCOHOL INGESTION

Ingestion of appreciable amounts of alcohol does not necessarily result in significantly elevated levels of triglycerides, but many alcoholics are lipemic. Alcohol profoundly increases triglycerides in patients with primary or secondary hyperlipemias. In Zieve syndrome, the alcohol-induced lipemia is associated with hemolytic anemia and hyperbilirubinemia. Because LCAT originates in liver, severe hepatic parenchymal dysfunction may lead to deficiency in the activity of this enzyme. A resultant accumulation of unesterified cholesterol in erythrocyte membranes may account for the hemolysis seen in Zieve syndrome.

Alcohol is converted to acetate, exerting a sparing effect on the oxidation of fatty acids that are then incorporated into triglycerides. This results in hepatomegaly due to fatty infiltration and in marked enhancement of secretion of VLDL. In many individuals, there is sufficient adaptive increase in the removal capacity for triglycerides so that plasma levels are normal.

7. NONALCOHOLIC FATTY LIVER DISEASE AND NONALCOHOLIC STEATOHEPATITIS

These conditions are characterized by hepatic steatosis and abnormalities of liver enzymes in the absence of alcohol ingestion.

The cause is not yet understood, but it is likely that misdirection of fatty acids from oxidative pathways to hepatic triglyceride synthesis is involved. Five to ten percent of patients with nonalcoholic fatty liver disease (NAFLD) progress to more severe liver disease, including cirrhosis, end-stage liver disease, and hepatocellular carcinoma. In NAFLD, spontaneous improvement can occur. About 80% of patients with NAFLD or nonalcoholic steatohepatitis (NASH) have features of the metabolic syndrome, including abdominal obesity, hypertension, insulin resistance/glucose intolerance, and hypertriglyceridemia. They are at increased risk for atherosclerosis. Weight reduction with exercise and diet in overweight or obese patients is a central element in treatment. Bariatric surgery has proven effective in a large percentage of morbidly obese patients with NASH. Studies to date reveal only marginal benefit attributable to metformin. Treatment of coexisting dyslipidemia, diabetes, and hypertension is important. Statins, fenofibrate, and marine omega-3 fatty acids do not appear to increase the risk of further hepatic injury in most patients. Mixed tocopherols are beneficial.

8. NEPHROSIS

The hyperlipidemia of nephrosis is biphasic. Before serum albumin levels fall below 2 g/dL, LDL increases selectively. The synthesis and secretion of VLDL appear to be coupled to that of albumin. The increased flux of VLDL from liver increases production of LDL. As albumin falls below 1 to 2 g/dL, lipemia ensues. Impaired hydrolysis of triglycerides by LPL is due to lack of albumin as an FFA receptor. FFA bind to lipoproteins when albumin levels are low, impairing their ability to undergo lipolysis.

Because coronary disease is prevalent in patients with long-standing nephrotic syndrome, treatment of the hyperlipidemia is indicated, although few studies of the effect of treatment have been reported. The hyperlipidemia is resistant to diet. Fibrates may precipitate myopathy even in small doses. Bile acid–binding resins, niacin, and reductase inhibitors may be useful.

9. GLYCOGEN STORAGE DISEASE

In type I glycogenosis, insulin secretion is decreased, leading to increased flux of FFA to liver and increased secretion of VLDL. The low levels of insulin in plasma are the probable cause of reduced activity of LPL. The fatty liver in these patients tends to progress to cirrhosis.

Frequent small feedings, including during the night, help maintain blood glucose levels and ameliorate the lipemia. Other forms of hepatic glycogen storage disease may be associated with elevated levels of VLDL and LDL in serum.

10. HYPOPITUITARISM AND ACROMEGALY

Part of the hyperlipidemia of hypopituitarism is attributable to secondary hypothyroidism, but hypertriglyceridemia may persist after thyroxine replacement. Deficiency of growth hormone is associated with elevated levels of both LDL and VLDL. Decreased insulin levels may be the major underlying defect; however, deficiency of growth hormone may impair the disposal of FFA by oxidation and ketogenesis in the liver, favoring synthesis of triglycerides. Mild hypertriglyceridemia is often associated with acromegaly, probably resulting from insulin resistance. Although growth hormone acutely stimulates lipolysis in adipose tissue, FFA levels are normal in acromegaly.

11. HYPOTHYROIDISM

Whereas significant hypothyroidism produces elevated levels of LDL in nearly all individuals, only a few develop hypertriglyceridemia. The increase in LDL results in part from decreased conversion of cholesterol to bile acids and downregulation of LDL receptors. Lipemia, when present, is usually mild, although serum triglycerides in excess of 3000 mg/dL (34.5 mmol/L) can occur in myxedema reflecting decreased activity of hepatic lipase. Increased content of cholesteryl esters and Apo E in the triglyceride-rich lipoproteins suggests accumulation of remnant particles. Hypothyroidism often causes expression of hyperlipidemia in individuals with dysbetalipoproteinemia.

12. IMMUNOGLOBULIN-LIPOPROTEIN COMPLEX DISORDERS

Both polyclonal and monoclonal hypergammaglobulinemias may cause hypertriglyceridemia. IgG, IgM, and IgA have each been involved. Monoclonal antibodies associated with myeloma, macroglobulinemia, lymphomas, and lymphocytic leukemias have been implicated. Lupus erythematosus and other autoimmune disorders have been associated with the polyclonal type. Binding of heparin by immunoglobulin, with resulting inhibition of LPL, can cause severe mixed lipemia. More commonly, the triglyceride-rich lipoproteins have an abnormally high density, probably as a result of bound immunoglobulin, although some may be remnant-like particles. These complexes usually have gamma mobility on electrophoresis.

Xanthomatosis associated with immunoglobulin complex disease includes tuberous and eruptive xanthomas, xanthelasma, and planar xanthomas of large areas of skin. The latter are otherwise seen only in patients with cholestasis. Deposits of lipid-rich hyaline material can occur in the lamina propria of the intestine, causing malabsorption and protein-losing enteropathy. Circulating immunoglobulin-lipoprotein complexes can fix complement, leading to hypocomplementemia. In such patients, administration of whole blood or plasma can cause anaphylaxis. Hence, washed red cells or albumin are recommended when blood volume replacement is required.

Treatment is directed at the underlying disorder. The critical temperature of cryoprecipitation of some of these complexes is close to body temperature. Therefore, if plasmapheresis is indicated to remove offending immunoglobulins, it should be done at a temperature above the critical temperature measured in serum.

FAMILIAL HYPERCHOLESTEROLEMIA (FH)

LDL RECEPTOR DEFICIENCY

Etiology and Pathogenesis

This disorder occurs in approximately 1 in 500 or fewer individuals in its heterozygous form. It is a codominant trait with high penetrance. Because half of first-degree relatives may be affected, all members of a family should be screened. A selective increase in LDL exists from birth and tends to increase during childhood and adolescence such that total cholesterol in adult heterozygotes usually varies from about 250 to 400 mg/dL (6.7-10.4 mmol/L). Some individuals—especially those in kindreds in which hypertriglyceridemia is present—may have higher than normal levels of VLDL and IDL.

The underlying defect is a deficiency of normal LDL receptors on cell membranes. A number of defects in the LDL receptor gene affecting the structure, translation, modification, or transport of the receptor protein have been identified.

Some individuals have combined heterozygosity. In cases in which a kinetic mutant is combined with an ablative mutant, the hypercholesterolemia is greater than that seen in simple heterozygosity, usually in the range of 500 to 800 mg/dL (13-20.8 mmol/L). Those patients who are homozygous for null alleles have extremely severe hypercholesterolemia (approaching 1000 mg/dL [26 mmol/L] or greater) and fulminant atherosclerosis.

Production rates for LDL are moderately increased in heterozygotes and are higher in homozygotes because of increased conversion of VLDL to LDL. In the heterozygote, a greater fraction of LDL is removed by nonreceptor-dependent mechanisms than in normal subjects. In homozygotes, all removal of LDL proceeds through such pathways.

Clinical Findings

Tendon xanthomas are frequently present, causing a broadening or fusiform mass in the tendon. They can occur in almost any tendon but are most readily detected in the Achilles and patellar tendons and in the extensor tendons of the hands (see Figures 19–3F, 19–3G, and 19–3H). Patients who are physically active may complain of achillodynia. Arcus corneae (see Figure 19–3B) may occur as early as the third decade. Xanthelasma (see Figure 19–3A) may also be present. Both arcus and xanthelasma are seen in some individuals who do not have hyperlipidemia, however. Coronary atherosclerosis tends to occur prematurely in heterozygotes. It is particularly prominent in individuals who are relatively deficient in HDL or have an elevated level of Lipoprotein (a). It is probable that this represents a coincident inheritance of both traits. The homozygous form is catastrophic. Xanthomatosis progresses rapidly. Patients may have tuberous xanthomas (see Figures 19–3C and 19–3D) and elevated plaque-like xanthomas of the extremities, buttocks, interdigital webs, and aortic valves. Coronary disease may be evident in the first decade of life.

Serum cholesterol in excess of 300 mg/dL (7.8 mmol/L) in the absence of significant hypertriglyceridemia and conditions known to cause secondary hypercholesterolemia makes the diagnosis of the heterozygous disorder likely. The presence of affected first-degree relatives is supportive of this diagnosis, especially if no other phenotypes of hyperlipidemia are present in the family that would suggest FCH. The finding of tendon xanthomas is nearly pathognomonic—phytosterolemia, cerebrotendinous xanthomatosis (cholestanolosis), and autosomal recessive hypercholesterolemia (ARH) are exceptions. Although the cholesterol content of umbilical cord blood is usually elevated, the diagnosis is most easily established by measuring LDL cholesterol after the first year of life.

Treatment

Treatment of heterozygotes with HMG-CoA reductase inhibitors may normalize LDL levels. However, achieving optimal levels may require one of the binary or ternary combinations involving reductase inhibitors, niacin, bile acid sequestrants, or ezetimibe. Levels of LDL cholesterol less than 100 mg/dL (2.6 mmol/L) can be obtained with combinations of these drugs in most patients. Treatment of individuals with homozygosity or combined heterozygosity is extremely difficult. Partial control may be achieved with medications including antisense oligonucleotide directed at Apo B-100 synthesis, inhibition of microsomal triglyceride transfer protein, and ezetimibe. Statins and monoclonal antibodies directed at proprotein convertase subtilisin/kexin type 9 (PCSK9) protein are useful if some residual receptor activity is present. LDL apheresis in conjunction with medications can be very effective. Striking reduction of LDL levels is observed after liver transplantation, illustrating the important role of hepatic receptors in LDL clearance.

FAMILIAL COMBINED HYPERLIPIDEMIA (FCH)

In some individuals in kindreds with FCH (see "Primary Hypertriglyceridemia," discussed earlier), LDL are the only lipoproteins that are elevated. This pattern may vary in an individual over time. Predominant elevation of VLDL or combined elevations of LDL and VLDL may be observed in the patient's relatives. Some affected children express hyperlipidemia. In contrast to most cases of LDL receptor deficiency, the total cholesterol level may be as low as 250 mg/dL (6.5 mmol/L) and xanthomas are absent in FCH. Studies of kindreds with the FCH phenotype suggest codominant transmission. Coronary atherosclerosis is accelerated, accounting for about 15% of all coronary events in the United States. The underlying mechanism involves increased secretion of VLDL.

Treatment of the hypercholesterolemia should begin with diet and either a reductase inhibitor or niacin. It may be necessary to use a combination of these agents, or fenofibrate with a statin, to normalize levels of LDL and triglyceride.

FAMILIAL LIGAND-DEFECTIVE APO B-100

Mutations involving the ligand domain in Apo B-100 impair the ability of LDL to bind to its receptor. Two prevalent mutations at codon 3500 or 3531 occur in about one in 500 individuals and may be found in compound states with LDL receptor mutations. The hypercholesterolemia with ligand defects alone is generally less severe than in LDL receptor defects because the removal of VLDL remnants is normal, resulting in a lower production of LDL. Patients are at increased risk of coronary disease. Response to reductase inhibitors varies. Many show some resistance because upregulation of receptors cannot correct the defect completely. Receptor upregulation can decrease LDL production because IDL particles are endocytosed by liver via interaction of the LDL receptor with Apo E.

CHOLESTEROL 7α-HYDROXYLASE DEFICIENCY

Loss of function mutations in cholesterol 7α-hydroxylase result in diminished catabolism of cholesterol to bile acids and accumulation of cholesterol in hepatocytes. Downregulation of LDL receptors causes elevated LDL in plasma. VLDL may also be increased. Homozygous patients have early coronary disease, marked resistance to reductase inhibitors as single agents, and may have premature cholesterol gallstones. Heterozygous patients have moderately elevated LDL. The hyperlipidemia responds well to niacin with a reductase inhibitor.

AUTOSOMAL RECESSIVE HYPERCHOLESTEROLEMIA (ARH)

In this very rare disorder, LDL levels are markedly elevated, resulting in total cholesterol levels between 400 and 700 mg/dL (10.4-18.1 mmol/L). It is attributed to mutations in the gene for the ARH protein that is involved in endocytosis of the LDL receptor. Very large xanthomas (tuberous, tendinous, and planar) are frequently present. Arcus and xanthelasma are also common. Statins and bile acid sequestrants appear to be effective.

PROPROTEIN CONVERTASE SUBTILISIN/KEXIN TYPE 9 (PCSK9) VARIANTS

The protease PCSK9 plays a role in processing the LDL receptor. It is expressed at a high level in liver. Rare gain-of-function mutations are associated with hypercholesterolemia, due to reduction in the number of effective receptors. Hypercholesterolemia is observed in the heterozygous state.

LP(a) HYPERLIPOPROTEINEMIA

Lp(a) normally comprises a very minor fraction of circulating lipoproteins, but it may be present in high concentrations in some individuals. It contains Apo B-100 and the (a) protein, a homolog of plasminogen that can inhibit fibrinolysis. It has been demonstrated in atherosclerotic plaques, and several large studies confirm its importance as an independent risk factor for coronary disease. The Ile4399Met polymorphism is particularly associated with increased risk. Plasma levels of Lp(a) can be measured by immunoassay. Levels of Lp(a) primarily reflect genetic determinants but can also be elevated in disorders such as nephrosis because the (a) gene contains an inflammatory response element in its promoter. Niacin is effective in many but not all patients. Monoclonal antibodies directed at PCSK9 can also reduce levels of Lp(a). Decreasing plasma levels of LDL appears to reduce the risk attributed to the elevated Lp(a), at least to some extent.

SECONDARY HYPERCHOLESTEROLEMIA

HYPOTHYROIDISM

In hypothyroidism, LDL and IDL are elevated. Some patients may have lipemia, as described in the section on secondary hyperlipemia. Hyperlipidemia may occur with no overt signs or symptoms of decreased thyroid function. Biliary excretion of cholesterol and bile acids is depressed. Cholesterol stores in tissues appear to be increased, although the number of LDL receptors on cells is decreased. Activity of hepatic lipase is markedly decreased, and atherogenesis is accelerated by myxedema. The hyperlipidemia responds dramatically to treatment with thyroxine.

NEPHROSIS

As described in the section on secondary hypertriglyceridemias, nephrosis produces a biphasic hyperlipoproteinemia. The earliest alteration of lipoproteins in nephrosis is elevation of LDL. Increased secretion of VLDL by liver is probably involved. Because the lipids of the lipoprotein surfaces are altered by enrichment with sphingomyelin, lysolecithin, and FFA, the catabolism of LDL could be impaired. Perhaps the low metabolic rate in affected patients introduces metabolic changes similar to those associated with hypothyroidism. The hyperlipidemia may be an important element in the markedly increased risk of atherosclerosis in these patients. The treatment of choice is a reductase inhibitor. Ezetimibe, a bile acid–binding resin, and niacin are alternatives.

IMMUNOGLOBULIN DISORDERS

One of the lipoprotein abnormalities that can be associated with monoclonal gammopathy is elevation of LDL. A gamma lipoprotein that is a stable complex of immunoglobulin and lipoprotein may be observed on electrophoresis. Cryoprecipitation, often in the temperature range encountered in peripheral tissues when the environmental temperature is low, may occur. Patients may have symptoms from the vascular effect of complement fixation resulting from complex formation and may have hyperviscosity syndrome from the elevated immunoglobulins per se. Planar xanthomas may be present.

Treatment is directed at the underlying process. Plasmapheresis is often effective. If cryoprecipitation occurs at critical temperatures near or above room temperature, the procedure must be carried out in a special warm environment. Transfusion of whole blood or serum may be dangerous in these patients because of rapid production of anaphylatoxins from fresh complement in the serum, resulting from interaction with circulating antibody-antigen complexes. This risk can be minimized by the use of packed red blood cells and albumin in place of whole blood.

ANOREXIA NERVOSA

About 40% of patients with anorexia nervosa have elevated LDL, and levels of cholesterol may reach 400 to 600 mg/dL (10.4-15.6 mmol/L). The hyperlipidemia, which persists despite correction of hypothyroidism, is probably a result of decreased fecal excretion of bile acids and cholesterol. Serum lipoproteins return to normal when proper nutrition is restored.

CHOLESTASIS

The hyperlipidemia associated with obstruction of biliary flow is complex. Levels of cholesterol in these patients exceeding 400 mg/dL (10.4 mmol/L) usually are associated with extrahepatic obstruction or with intrahepatic tumor. Several types of abnormal lipoproteins are present. The most abundant, termed Lp-X, is a bilayer vesicle composed of unesterified cholesterol and lecithin, with associated apolipoproteins but no Apo B. Lp-X is apparent on electrophoresis as a band of zero to gamma mobility that shows metachromatic staining with Sudan black. It is these vesicular particles that cause the serum phospholipid and unesterified cholesterol content to be extremely high. Another abnormal species, called Lp-Y, contains appreciable amounts of triglycerides and Apo B. The LDL in cholestasis also contains an unusually large amount of triglycerides.

Patients may have planar xanthomas, especially at sites of minor trauma, and xanthomas of the palmar creases. Occasionally, eruptive xanthomas are present. Xanthomatous involvement of nerves may lead to symptoms of peripheral neuropathy, and the abnormal lipoproteins may be atherogenic. Whereas bilirubin levels are nearly normal in some patients with chronic cholestasis, all have elevated serum alkaline phosphatase activity.

Neuropathy or evidence of atherosclerosis is the chief indication for treatment of the hyperlipidemia. Bile acid–binding resins are of some value, whereas fibric acid derivatives may cause an increase in cholesterol. Plasmapheresis is the most effective treatment. Large doses of vitamin E are indicated to overcome severe impairment of absorption. Deficiency of other fat-soluble vitamins also occurs.

THE PRIMARY HYPOLIPIDEMIAS

Although the clinician is confronted less frequently by the problem of a striking deficiency in plasma lipids, it is important to recognize the primary and secondary hypolipidemias. A serum cholesterol less than 110 mg/dL (2.9 mmol/L) is noteworthy.

Because levels of triglycerides in normal fasting serum may be as low as 25 mg/dL (0.29 mmol/L), significance is limited to cases in which they are virtually absent.

PRIMARY HYPOLIPIDEMIA DUE TO DEFICIENCY OF HIGH-DENSITY LIPOPROTEINS

1. TANGIER DISEASE
Etiology and Pathogenesis

Severe deficiency of HDL occurs in Tangier disease. Heterozygotes lack clinical signs but have about one-half or less of the normal complement of HDL and Apo A-I in plasma. Homozygotes lack normal HDL, and Apo A-I and Apo A-II are present at extremely low levels. Serum cholesterol is usually below 120 mg/dL (3.12 mmol/L) and may be half this value. Mild hypertriglyceridemia is usually present, and LDL is greatly enriched in triglycerides. Mutations in the ATP-dependent transporter ABCA1 underlie this disorder, causing defective efflux of cholesterol from peripheral cells.

Clinical Findings

The clinical features of this rare autosomal recessive disease include large, orange-colored, lipid-filled tonsils, accumulation of cholesteryl esters in the reticuloendothelial system, and an episodic and recurrent peripheral neuropathy with predominant motor weakness in the later stages. The course of the disease is benign in early childhood, but the neuropathy may appear as early as age 8 years. Cholesteryl ester accumulates most prominently in peripheral nerve sheaths. Carotenoid pigment may be apparent in pharyngeal and rectal mucous membranes. Splenomegaly and corneal infiltration may also be present. There is some increase in risk of coronary atherosclerosis.

Treatment

Because some of the lamellar lipoprotein material in plasma is believed to originate in chylomicrons, restriction of dietary fats and cholesterol is suggested.

2. FAMILIAL HYPOALPHALIPOPROTEINEMIA
Etiology and Pathogenesis

This phenotypic pattern is a partial deficiency of HDL that may involve heterogeneous mechanisms. These presumed constitutional disorders must be differentiated from the condition in which moderately low levels of HDL are seen in individuals consuming a diet very low in fat. White and Asian men on such diets usually have HDL cholesterol levels of 38 to 42 mg/dL (1-1.1 mmol/L) by ultracentrifugal analysis, in contrast to a median value of 49 mg/dL (1.3 mmol/L) when consuming a typical North American diet. Lower levels are common in Asiatic populations and among vegetarians, where the risk of coronary disease is usually small.

HDL cholesterol must also be interpreted in the light of the amount of triglyceride-rich lipoproteins in plasma. Because cholesteryl esters are progressively transferred to the cores of triglyceride-rich lipoproteins as triglyceride levels rise, HDL cholesterol decreases as an inverse function of the triglyceride level.

Etiologic Factor in Coronary Disease

Familial hypoalphalipoproteinemia is fairly common and is an important risk factor in atherosclerosis. This abnormality may be the only apparent risk factor in many cases of premature coronary or peripheral vascular disease and accelerates the appearance of coronary disease in patients with hyperlipidemias. Hypoalphalipoproteinemia shows a strong familial incidence. Mutations in several genes have been associated, including *Apo A-I* (the principal protein of HDL), which can be amyloidogenic, *PCPE-2* (a protease involved in the maturation of Apo A-I), and the WW domain oxidoreductase (a transcriptional regulator involved in HDL metabolism). Although several mechanisms and modes of transmission may be involved, many kindreds show distributions consistent with autosomal dominance. HDL cholesterol levels are usually below 35 mg/dL (0.9 mmol/L).

Treatment

Increases in HDL cholesterol in several coronary intervention trials have been independently associated with plaque regression. Only limited means of raising HDL levels are at hand. Findings that HDL is composed of as many as 20 discrete species further complicate this problem. It is not yet known which of these species may be involved in protecting against atherosclerosis or whether their levels can be increased. Although alcohol ingestion may increase total HDL, it appears that the effect is primarily on the HDL_3 ultracentrifugal fraction, which correlates poorly with decreased risk. No recommendation for increased alcohol consumption should be made.

Heavy exercise is associated with increases in HDL in some individuals but must be approached with caution in patients who may have coronary disease. Niacin increases total HDL in many subjects, chiefly the HDL_2 ultracentrifugal fraction. Smaller increments in HDL occur with reductase inhibitors and fibric acid derivatives.

The most important reason for measuring HDL cholesterol is to identify patients who are at increased risk. Thus, just as with patients who have premature vascular disease or a family history of early arteriosclerosis, patients with low HDL should be treated more aggressively for elevated levels of the atherogenic lipoproteins. Furthermore, vigorous efforts should be directed at the control of other risk factors such as hypertension. Smoking and obesity are known to decrease HDL significantly.

3. DEFICIENCY OF LECITHIN-CHOLESTEROL ACYLTRANSFERASE

This rare autosomal recessive disorder is not expressed in clinical or biochemical form in the heterozygote. In the homozygote, clinical characteristics are variable. The primary defect is the inability to esterify free cholesterol, leading to a total deficiency of mature, spherical HDL particles. HDL species that are present include bilayer discs, small spherical particles, and prebeta-1 HDL. The diagnosis is usually made in adults, although corneal opacities may begin in childhood. Proteinuria may be an early sign. Deposits of unesterified cholesterol and phospholipid in the renal microvasculature lead to progressive loss of nephrons and ultimate renal failure. Many patients have mild to moderate normochromic anemia with target cells. Hyperbilirubinemia or peripheral neuropathy may be present. Red blood cell lipid composition is abnormal, with increased content of unesterified cholesterol and lecithin. Most patients have elevated plasma triglycerides (200-1000 mg/dL [2.3-11.2 mmol/L]), and levels of serum cholesterol vary from low normal to about 500 mg/dL (13 mmol/L), only a small fraction of which is esterified. The large triglyceride-containing lipoproteins are unusually rich in unesterified cholesterol and appear to have abnormal surface monolayers. LDL are rich in triglycerides, and abnormal vesicular lipoproteins are present in the LDL density interval. Marked restriction of dietary fat and cholesterol delays the onset of renal disease.

PRIMARY HYPOLIPIDEMIA DUE TO DEFICIENCY OF APO B–CONTAINING LIPOPROTEINS

1. RECESSIVE ABETALIPOPROTEINEMIA
Etiology and Pathogenesis

This disorder could represent a number of mutations involving the processing of Apo B or the secretion of Apo B–containing lipoproteins. The predominant cause is mutations involving the microsomal triglyceride transfer protein. Patients heterozygous for mutations have no abnormalities of lipoproteins or clinical signs. In homozygotes, no chylomicrons, VLDL, or LDL are found in plasma, leaving only HDL. Plasma triglycerides are usually less than 10 mg/dL (0.12 mmol/L) and fail to rise after a fat load. Total cholesterol is usually less than 90 mg/dL (2.3 mmol/L). There is a defect in the incorporation of newly synthesized triglycerides into chylomicrons. However, at low levels of fat intake, about 80% of the ingested triglycerides are absorbed, probably by direct absorption of fatty acids via the portal vein.

Clinical Findings

Clinical features include a paucity of adipose tissue associated with malabsorption of long-chain fatty acids due to failure of the intestine to secrete chylomicrons. Red blood cells may be acanthocytic, with a high cholesterol-phospholipid ratio. There may be progressive degeneration of the central nervous system, including cerebellar degeneration and posterior and lateral spinal tract disease. Retinal degeneration may be severe. Levels of fat-soluble vitamins in plasma may be very low. The neurologic and ophthalmologic defects are due to deficiency of vitamin E (normally transported largely in LDL). Patients are apparently normal at birth and develop steatorrhea with impaired growth in infancy.

The neuromuscular disorder often appears in late childhood with ataxia, night blindness, decreased visual acuity, and nystagmus. Cardiomyopathy with arrhythmias has been reported and may be a cause of death.

Treatment

Treatment includes administration of fat-soluble vitamins and essential fatty acids. Very large doses of mixed tocopherols (vitamin E; 100-150 IU/kg) limit the progressive central nervous system degeneration. Although vitamin A seems to correct the night blindness, it may not alter the course of retinitis pigmentosa. Vitamins D and K may also be indicated. Restriction of dietary fat minimizes steatorrhea.

2. FAMILIAL HYPOBETALIPOPROTEINEMIA

This disorder is usually attributable to defects at the Apo B locus, resulting in decreased production of protein or in the production of truncated gene products. LDL and Apo B in heterozygotes are often present at about half of normal levels. If a mutant allele resulting in the complete interdiction of Apo B synthesis is present in the homozygous state, the clinical and biochemical features may be indistinguishable from those of recessive abetalipoproteinemia, and treatment is the same as for that disorder. Very short truncations of Apo B-100 only allow the formation of abnormally dense, small LDL. Longer truncations permit the formation of larger lipoproteins, even including VLDL-like particles. Mutations in the Angiopoietin-like protein 3 (ANGPTL3) gene can cause deficiency of LDL, HDL, and triglycerides.

Clinical features may be absent in patients who produce at least low levels of LDL-like particles. However, signs and symptoms of tocopherol deficiency may be present. Treatment with mixed tocopherols (800 IU/d) is recommended for all patients.

3. CHYLOMICRON RETENTION DISEASE

This disorder presents in the neonate and appears to be based on the selective inability of intestinal epithelial cells to secrete chylomicrons due to mutations in the Secretion Associated Ras related GTPase 1B (SAR1B) gene. Affected individuals have severe malabsorption of triglycerides with steatorrhea. Levels of LDL and VLDL are about half of normal, presumably secondary to malnutrition. Tocopherol levels may be very low and may be associated with neurologic abnormalities. Clinical symptoms diminish somewhat with time if the patient is managed with a low-fat diet and tocopherol supplementation.

4. PCSK9 LOSS OF FUNCTION MUTATIONS

Loss of function mutations that result in longer residence time of the LDL receptor on the cell surface are associated with low levels of LDL cholesterol and protection from atherosclerotic vascular disease. Approximately 1 in 50 African Americans carries one of two such mutations. Other loss of function mutations are also found less commonly among Caucasians.

SECONDARY HYPOLIPIDEMIA

Hypolipidemia may be secondary to a number of diseases characterized by chronic cachexia (eg, advanced cancer). Myeloproliferative disorders can lead to extremely low levels of LDL, probably owing to increased uptake related to rapid proliferation and membrane synthesis. A wide variety of conditions leading to intestinal malabsorption produces hypolipidemia. In these situations, levels of chylomicrons, VLDL, and LDL in serum are low but never absent. Because most of the lipoprotein mass of fasting serum is of hepatic origin, massive parenchymal liver failure (eg, in Reye syndrome) can cause severe hypolipidemia. A precipitous fall in lipoprotein levels during drug treatment of hyperlipidemia can signal hepatic toxicity. Secondary hypobetalipoproteinemia occurs in oroticaciduria.

The hypolipidemias associated with immunoglobulin disorders result from diverse mechanisms. Affected patients usually have myeloma or macroglobulinemia but may have lymphomas or lymphocytic leukemia. Isolated HDL deficiency can be associated with chronic lymphocytic leukemia. Any of the major classes of immunoglobulins may be involved. In many cases, the immunoglobulins are cryoprecipitins; thus, the diagnosis may be missed if blood is not drawn and serum prepared at 37°C and observed for cryoprecipitation. Immunoglobulin-lipoprotein complexes may precipitate in various tissues. When this occurs in the lamina propria of the intestine, a syndrome of malabsorption and protein-losing enteropathy may result. Monoclonal IgA in myeloma may precipitate with lipoproteins, causing xanthomas of the gingiva and cervix. Xanthomas in the skin are usually planar and may involve intracutaneous hemorrhage, producing a classic purple xanthoma. Planar xanthomas occurring in cholestasis may be confused with this condition because the abnormal lipoprotein of cholestasis (Lp-X), like the circulating lipoprotein complex of immunoglobulin and lipoprotein, has gamma mobility on electrophoresis.

OTHER DISORDERS OF LIPOPROTEIN METABOLISM

THE LIPODYSTROPHIES

Classification

Classification of the lipodystrophies is based on their familial or acquired origin and the regional or generalized nature of the loss of adipose tissue. Mutations in a number of loci (including caveolin, peroxisome proliferator activated receptor (PPAR) gamma, lamin A/C, perilipin, seipin, and others) have been associated with various phenotypes of lipodystrophy. Insulin resistance is a common feature.

Familial generalized lipodystrophy (Seip-Berardinelli syndrome) is a rare recessive trait associated with mutations in the gene for seipin. It may be diagnosed at birth and is associated with macrosomia. Genital hypertrophy, hypertrichosis, acanthosis nigricans, hepatomegaly, insulin resistance, hypertriglyceridemia, and glucose intolerance are regularly observed.

Familial lipodystrophy of limbs and trunk (Köbberling-Dunnigan syndrome) appears to be transmitted as a dominant trait associated with mutations in the *lamin A* gene. Because sequence anomalies in other regions of the gene are associated with muscular dystrophy, cardiac conduction defects, cardiomyopathy, or axonal neuropathies, overlapping phenotypes may occur. It affects women predominantly and is not evident until puberty. The face, neck, and upper trunk are usually spared. Growth is normal, but otherwise this syndrome shares features of the generalized form noted earlier. It is frequently associated with Stein-Leventhal syndrome and often progresses to fatal cirrhosis.

Acquired forms of lipodystrophy, generalized (Lawrence syndrome) and partial (Barraquer-Simmons syndrome), usually begin in childhood, affect females predominantly, and often follow an acute febrile illness. The generalized type commonly shares the features described earlier, invariably involving the trunk and extremities but sometimes sparing the face. A sclerosing panniculitis, as seen in Weber-Christian syndrome, may appear at the outset. The partial type usually begins in the face and then involves the neck, upper limbs, and trunk. In this disorder, reduced levels of C3 complement are frequently encountered. Most patients have proteinuria, and some develop overt vascular nephritis.

Associated Disorders

Because a number of patients with disorders resembling both familial and acquired types of lipodystrophy have tumors or other lesions of the hypothalamus, appropriate neurologic evaluation should be obtained. Similarly, the physician should be alert to the association of HIV disease and collagen-vascular disorders, including scleroderma and dermatomyositis, with some cases of acquired lipodystrophy.

RARE DISORDERS

Werner Syndrome, Progeria, Infantile Hypercalcemia, Sphingolipidoses, and Niemann-Pick Disease

These disorders may be associated with hypercholesterolemia, but levels of triglycerides may be normal. Among the sphingolipidoses, HDL deficiency is typical of Gaucher disease, in which hypertriglyceridemia may also occur. Niemann-Pick disease is attributable in most cases to mutations in the *Niemann-Pick type C1* (*NPC1*) gene and may be associated with hypercholesterolemia or hypertriglyceridemia. However, a similar disorder results from mutations in the *NPC2* locus. The *NPC1* gene product is involved in the post-lysosomal transport of lipids. The neurological manifestations of Niemann-Pick disease type C are mitigated by inhibitors of glycosphingolipid synthesis.

Wolman Disease and Cholesteryl Ester Storage Disease

These recessive lipid storage disorders involve the absence and partial deficiency, respectively, of lysosomal acid lipase, resulting in abnormal cholesteryl ester and triglyceride stores in liver, spleen, adrenals, small intestine, and bone marrow. Diagnosis is established by measuring the activity of lysosomal acid lipase in plasma. Most patients have elevated levels of both LDL and VLDL. These disorders respond to the administration of recombinant lysosomal acid lipase. Statin therapy is contraindicated because it increases delivery of cholesteryl esters to hepatocytes.

Cerebrotendinous Xanthomatosis

In this recessive disorder, impaired synthesis of bile acids due to mutations in the *sterol 27-hydroxylase* gene results in increased production of cholestanol that accumulates in tissues. Plasma levels of cholestanol are elevated. Cataracts, extensive tendinous xanthomas, progressive neurologic dysfunction, and premature coronary atherosclerosis are hallmarks of this disease. Its central nervous system effects include dementia, spasticity, and ataxia. Death usually ensues before age 50 from neurologic degeneration or coronary disease. The treatment is administration of chenodeoxycholic acid.

Phytosterolemia

Mutations in the cassette half transporters ABCG5 or ABCG8 underlie this disorder, which is characterized by normal or elevated plasma cholesterol levels; high concentrations of plant sterols in serum, adipose tissue, and skin; and prominent tendinous and tuberous xanthomas. Substantially larger fractions of phytosterols and cholesterol are absorbed from the intestine than in normal individuals. Serum cholesterol levels may be as high as 700 mg/dL (18.2 mmol/L), reflecting an increase in LDL that contain phytosterol esters in addition to cholesteryl esters. Diagnosis is established by quantitation of phytosterols in plasma by gas-liquid chromatography. Premature coronary disease is common, as is polyarteritis and leukocytoclastic vasculopathy. Treatment consists of a diet restricted in plant sterols and cholesterol, and the use of ezetimibe. Bile acid–binding resins and reductase inhibitors may also be helpful.

Cholesteryl Ester Transfer Protein (CETP) Deficiency

Mutations have been identified that impair the function of CETP, resulting in the retention of cholesteryl esters in HDL. Total HDL cholesterol is increased by 30% to 50% in heterozygotes and by as much as 200 mg/dL in homozygotes. The risk of atherosclerosis may be moderately increased in homozygotes.

TREATMENT OF HYPERLIPIDEMIA

Initial therapy in all forms of hyperlipidemia is an appropriate diet. In most cases, a universal diet (discussed later) is indicated. In many subjects with lipemia or with mild hypercholesterolemia, compliance with diet is sufficient to control lipoprotein levels. Most patients with severe hypercholesterolemia or lipemia require drug therapy. Diet must be continued to achieve the full potential

of the medications. LDL cholesterol and triglycerides should be below 70 mg/dL (1.8 mmol/L) and 120 mg/dL (1.5 mmol/L), respectively, in patients with known atherosclerosis. C-reactive protein, lipoprotein-associated phospholipase A2, and other emerging biomarkers are useful in predicting risk.

Caution Regarding Drug Therapy

Women of childbearing age should be advised of the potential risk of teratogenicity of hypolipidemic agents. Treatment should be given only if pregnancy is being actively avoided. Nursing mothers should not be treated. Estrogen-containing contraceptives should be avoided or used with caution in patients with hypertriglyceridemia.

In children, hyperlipidemias other than primary hypercholesterolemias and severe cases of the metabolic syndrome may not require medication before age 16 years. Factors in the decision to start drug treatment include: the child's age and levels of lipoproteins; the severity and age at onset of symptomatic coronary disease in the child's family; and the presence in the child of other risk factors, especially diabetes or compound dyslipidemias [including hypoalphalipoproteinemia or hyper-Lp(a)lipoproteinemia in addition to a primary hypercholesterolemia]. Dietary treatment is indicated for all children with hyperlipidemia and should be started after the second year. The exception is primary chylomicronemia, in which an appropriate diet should be instituted as soon as the disease is detected.

DIETARY FACTORS IN THE MANAGEMENT OF LIPOPROTEIN DISORDERS

Restriction of Caloric Intake

The secretion of VLDL by the liver is greatly stimulated by caloric intake in excess of requirements for physical activity and basal metabolism. Therefore, the total caloric content of the diet is of greater importance than its specific composition in treating endogenous hyperlipemia. There is a positive correlation between serum levels of VLDL triglyceride and various measures of obesity, but many obese patients have normal serum lipids. On the other hand, many patients with hypertriglyceridemia—except most with chylomicronemia syndrome—are obese. As obese patients lose weight, VLDL stabilizes at lower levels. There is a modest correlation of LDL levels with body weight in the general population.

Restriction of Fat Intake

In primary chylomicronemia, all types of fats must be restricted. In the acute management of mixed lipemia with impending pancreatitis, elimination of dietary fat leads to a rapid decrease in triglycerides.

The cholesterol-lowering effect of a significant reduction in total fat is well known. It has also been shown that a 10% to 15% fall in cholesterol is achieved when individuals who have been consuming a typical North American diet restrict their intake of saturated fats to 8% of total calories. Trans-fatty acids increase

LDL cholesterol and should be avoided. Most saturated fatty acids cause increased levels of LDL cholesterol by downregulating hepatic LDL receptors. Whereas polyunsaturated fatty acids do not have this effect, they may reduce levels of HDL. Monounsaturated fatty acids increase HDL but do not increase LDL. Moderate use of monounsaturated fats such as olive oil, oleic acid–rich safflower oil, or canola oil is indicated.

Marine Omega-3 Fatty Acids

The omega-3 fatty acids are ligands for PPAR alpha. Those found in fish oils have special properties relevant to the treatment of hypertriglyceridemia and may protect against fatal arrhythmias in ischemic myocardium. Substantial decreases in triglyceride levels can be induced in some patients with severe endogenous or mixed lipemia at doses of 3 to 4 g/d of eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids, combined. This should be given in divided doses with meals. EPA and DHA are potent inhibitors of platelet reactivity.

Reduction of Cholesterol Intake

The amount of cholesterol in the diet affects serum cholesterol levels, but individual responses vary. Restriction of dietary cholesterol to less than 200 mg/d (5.2 mmol/d) in normal individuals can result in a decrease of up to 10% to 15% in serum cholesterol, primarily reflecting a decrease in LDL. Dietary cholesterol and saturated or trans fat content have independent effects.

Role of Carbohydrate in Diet

When a high-carbohydrate diet is consumed, hypertriglyceridemia often develops within 48 to 72 hours, and levels of triglycerides rise to a maximum in 1 to 5 weeks. Persons with higher basal triglycerides and those consuming hypercaloric diets show the greatest effect. Because the conversion of fructose to fatty acids proceeds unregulated, it contributes disproportionally to hypertriglyceridemia compared to other saccharides. In persons with type 2 diabetes, a high-carbohydrate diet tends to increase insulin resistance. Substitution of monounsaturated fats for the carbohydrate improves insulin resistance and lipoprotein levels.

Alcohol Ingestion

Ingestion of alcohol is a common cause of secondary hypertriglyceridemia owing to overproduction of VLDL. Some individuals with familial hypertriglyceridemia are particularly sensitive to the effects of alcohol, and abstinence may normalize their triglycerides. Occasionally, chronic alcohol intake may also be associated with hypercholesterolemia. Increased cholesterol synthesis and decreased conversion to bile acids have been observed. Alcohol may account for alimentary lipemia persisting beyond 12 to 14 hours. This possibility should be excluded by the history or a repeat lipid analysis. A positive correlation has been found between alcohol intake and HDL cholesterol levels in some individuals. Because alcohol-induced changes in HDL appear primarily to involve the HDL_3 subfraction, there is no justification for the use of alcohol to increase the protective effect of HDL against atherosclerosis.

If the low HDL cholesterol is secondary to hypertriglyceridemia, alcohol must be avoided.

Antioxidants

Both alpha and gamma tocopherols (vitamin E) have recognized roles in the elimination of free radicals. Vitamin C assists this activity by restoring the tocopheroxyl radical to active tocopherol. These vitamins have been shown to restore normal vascular reactivity in hyperlipidemic patients, and some epidemiologic evidence suggests that they have an antiatherogenic effect. It is therefore reasonable to include at least 50 IU of mixed natural tocopherols and 250 mg of vitamin C in the diet each day. Larger doses may partially vitiate the effects of certain hypolipidemic drug regimens and have not been shown to have antiatherogenic potential. Selenium may also be important because it is a cofactor for one species of superoxide dismutase. Diets rich in fruits and vegetables appear to be important, providing isoflavones, quinols, and a number of carotenoid species.

B Vitamins

A significant percentage of Americans carry at least one allele for mutations in the methylene tetrahydrofolate reductase gene that diminishes its efficiency by reducing its affinity for folic acid. This, and certain other mutations, may lead to significantly elevated levels of a metabolite of methionine—homocysteine—that has toxic effects on endothelium. Supplementation with 0.4 mg of folic acid mitigates this problem. Vitamins B_6 and B_{12} participate in the metabolism of homocysteine. Thus, a B complex supplement should be used. Dietary protein should be restricted to the amount required for replacement of essential amino acids (about 0.5-1 g/kg) in patients with hyperhomocysteinemia. Oral administration of betaine, a methyl donor, can reduce homocysteine levels in severely affected patients (2 g 3 times daily). Homocysteine liberates the (a) protein from the Lp(a) complex, increasing its inhibition of fibrinolysis by plasminogen. Thus, the detection and management of hyperhomocysteinemia is important in patients with elevated Lp(a).

Other Dietary Substances

Several other nutrients have been studied in relation to atherosclerosis. Caffeine and sucrose have negligible effects on serum lipids, and their statistical relationship to coronary heart disease is generally unimpressive when data are corrected for cigarette smoking. However, when coffee is prepared by protracted boiling of the grounds, a lipid substance (cafestol) is extracted that contributes to hypercholesterolemia. Lecithin has no effect on plasma lipoproteins. A minor reduction in LDL cholesterol is associated with the addition of oat bran and certain other brans to the diet.

The Universal Diet

Dietary treatment is an important aspect of the management of all forms of lipoprotein disorders and may in some cases be all that is required. An exception is phytosterolemia in which the specific exclusion of dietary phytosterols and commercial products containing phytosterols is indicated. Knowledge of the dietary factors

mentioned earlier allows selection of appropriate modifications for an individual. However, a basic diet is useful in the treatment of most patients, the elements of which are as follows:

(1) A normal BMI should be achieved and maintained.
(2) Fat should provide less than 35% and saturated fat less than 8% of total calories. Monounsaturated oils should predominate. Olive oil contains a potent antioxidant, tyrosol that may be an important micronutrient. It is unstable when heated so should not be used for high-temperature cooking.
(3) Cholesterol should be reduced to less than 200 mg/d.
(4) Complex carbohydrates should predominate among total carbohydrates.
(5) Alcohol should be avoided in patients with hypertriglyceridemia or those requiring weight loss.
(6) Intake of trans-fatty acids should be avoided.
(7) Peroxidized fats resulting from protracted heating should be avoided.

Caloric restriction and reduction of adipose tissue mass are particularly important for patients with increased levels of VLDL and IDL. During periods of substantial weight loss, levels of VLDL and LDL tend to be lower than they would be under isocaloric conditions.

DRUGS USED IN TREATMENT OF HYPERLIPOPROTEINEMIA

BILE ACID SEQUESTRANTS

Mechanism of Action and Efficacy

Cholestyramine, colestipol, and colesevelam are cationic resins that bind bile acids in the intestinal lumen. They are not absorbed and, therefore, increase the excretion of bile acids in the stool up to tenfold. LDL levels decrease as a consequence of increased expression of high-affinity LDL receptors on hepatic cell membranes. These agents are useful only in disorders involving elevated LDL. Patients who have increased levels of VLDL may have further increases in triglycerides during treatment with resins. In combined hyperlipidemia, where the resins may be given to reduce LDL, a second agent such as fenofibrate or niacin may be required to control the hypertriglyceridemia. Levels of LDL fall 15% to 30% in compliant patients with heterozygous LDL receptor deficiency who are receiving maximal doses of the resins. These agents can contribute an incremental effect in the management of insulin resistance by an incretin-mediated mechanism. When given as a single agent, a modest reduction in new coronary events can result. When given in combined regimens with a statin and/or niacin, regression of coronary artery plaques has been demonstrated by quantitative angiography.

Drug Dosage

In disorders involving moderately high levels of LDL, 20 g of cholestyramine or colestipol daily may reduce cholesterol levels effectively. Treatment should commence at one-half this dosage to

minimize gastrointestinal side-effects. Maximum doses (30 g colestipol, 32 g cholestyramine, 3.75 g colesevelam daily) are required in more severe cases. These agents are only effective if taken with meals.

Side-Effects

Because the resins are not absorbed, systemic side-effects are absent. Patients frequently complain of a bloated sensation and constipation, both of which may be relieved by the addition of psyllium to the resin mixture. Malabsorption of fat or fat-soluble vitamins with a daily dose of resin up to 30 g occurs only in individuals with preexisting bowel disease or cholestasis. Hypoprothrombinemia has been observed in patients with malabsorption due to these causes. Cholestyramine and colestipol bind thyroxine, digitalis glycosides, and warfarin and impair the absorption of iron, thiazides, beta-blockers, ezetimibe, and other drugs. Absorption of all these (except ezetimibe) is ensured if they are administered 1 hour before or at least 2 hours after the resin. Colesevelam does not bind digoxin, warfarin, or reductase inhibitors. Because they change the composition of bile micelles, bile acid sequestrants theoretically may increase the risk of cholelithiasis, particularly in obese subjects. In practice, this risk appears to be very small. The resins should not be used as single agents in patients with hypertriglyceridemia and should be avoided in those with diverticulitis.

NIACIN (NICOTINIC ACID)

Mechanism of Action and Efficacy

Niacin (but not its amide) is able to effect major reductions in triglyceride-rich lipoproteins and, to a lesser extent, in LDL. It inhibits secretion of VLDL. It increases sterol excretion acutely, mobilizes cholesterol from tissue pools until a new steady-state is established, and decreases cholesterol biosynthesis. That it can cause a continued decrease in hepatic cholesterol production even when given with bile acid–binding resins is probably an important feature of the complementary action of these agents. Levels of HDL, particularly HDL_2, are usually significantly increased, reflecting a decrease in their fractional catabolic rate. Niacin stimulates production of tissue plasminogen activator, an effect that may be of value in preventing thrombotic events. Small, dense LDL are converted to particles of larger diameter during treatment. Niacin can reduce levels of Lp(a) significantly but variably. As a single agent, it was given in only one large intervention study which found a significant decrease in nonfatal, recurrent coronary events. In four angiographic studies in which niacin was given with a resin, a statin, or both, significant regression or decreased progression of coronary lesions was reported.

Drug Dosage

The dose of crystalline niacin required varies with the diagnosis. Optimal effect on LDL in heterozygous hypercholesterolemia is usually achieved only when 4.5 to 6 g of niacin daily is combined with a resin or reductase inhibitor. For other forms of hypercholesterolemia, dysbetalipoproteinemia, hypertriglyceridemia, and

hypoalphalipoproteinemia, 1.5 to 3.5 g/d often has a dramatic effect. Because niacin causes cutaneous flushing, it is usually started at a dosage of 100 mg 3 times daily with meals, increasing to the desired dose within 7 to 10 days. Many patients have no or only occasional flushing when stabilized on a given dose, but most must reach about 3 g/d before flushing ceases. Because the flush is prostaglandin mediated, 0.3 g of aspirin given 20 to 30 minutes before each dose when treatment is initiated or the dose increased (or equivalent doses of other cyclooxygenase inhibitors) may mitigate this symptom. It is important to counsel the patient that the flushing is a harmless cutaneous vasodilation and that the drug should be taken with meals 2 or 3 times daily. A daily dose of 6.5 g is the maximum under any circumstances. Niaspan, a prescription extended-release niacin, appears to be safe in doses up to 2 g daily.

Side-Effects

Some patients have reversible elevations of serum glutamic aminotransferase or alkaline phosphatase activities up to 3 times the upper limit of normal that do not appear to be clinically significant. In a group of patients treated continuously for up to 15 years, no significant liver disease developed despite such enzyme abnormalities. Rarely, patients develop a chemical hepatitis signaled by malaise, anorexia, and nausea. Aminotransferase levels are significantly elevated, and levels of lipoproteins may fall precipitously. Treatment should be stopped immediately. About one-fifth of patients have mild hyperuricemia that tends to be asymptomatic unless the patient has had gout. In such cases, allopurinol can be added to the regimen. Some patients have moderate elevations of blood glucose during treatment. Again, this is reversible except in those who have latent type 2 diabetes. The use of niacin should be considered carefully in patients with insulin resistance. Diabetic patients receiving insulin can often be treated successfully. A more common side-effect is gastric irritation, which responds well to H_2 blockers and antacids. Antacids that contain aluminum should be avoided. Rarely, patients develop acanthosis nigricans, which usually clears if the drug is discontinued. Some patients can have cardiac arrhythmias, mostly atrial, while taking niacin. Reversible macular edema has been described rarely. A principal metabolite of niacin is N-methylnicotinamide, the formation of which consumes methyl groups resulting in the production of macrocytic erythrocytes that are without apparent inimical effect.

Niacin should be avoided in patients with peptic ulcer or hepatic parenchymal disease. Liver function, uric acid, and blood glucose should be evaluated before commencing treatment and periodically thereafter.

Most over-the-counter sustained-release preparations should be avoided because of the risk of fulminant hepatic failure. However, if the daily dose is limited to 2 g or less, this rare consequence is probably unlikely.

FIBRIC ACID DERIVATIVES

Mechanism of Action and Efficacy

Gemfibrozil and fenofibrate, which are ligands for PPAR alpha, decrease lipolysis in adipose tissue, reduce levels of circulating

triglycerides, and cause modest reductions in LDL. However, in some patients, reductions in VLDL levels are attended by increased LDL levels. They cause moderate increases in levels of HDL, including the protein moiety. One primary prevention, and one secondary prevention trial using gemfibrozil as monotherapy showed reduction in new coronary events.

Drug Dosage

The fibrates may be useful in the treatment of patients with severe endogenous lipemia, familial dysbetalipoproteinemia, and some patients with combined hyperlipidemia. The usual dose of gemfibrozil is 600 mg twice daily. That of fenofibrate varies with the preparation.

Side-Effects

Skin eruptions, gastrointestinal symptoms, and muscle symptoms have been described as well as blood dyscrasias and elevated levels of aminotransferases and alkaline phosphatase. These drugs enhance the effects of the coumarin and indanedione anticoagulants and increase lithogenicity of bile. Concomitant use of fibrates with certain reductase inhibitors increases the risk of myopathy. Fenofibrate is most compatible with pravastatin or rosuvastatin with respect to cytochrome metabolism. Fibrates should be avoided during pregnancy and lactation and are contraindicated if renal or severe hepatic disease is present.

HMG-CoA REDUCTASE INHIBITORS (TABLE 19–2)

Mechanism of Action and Efficacy

Several closely related structural analogs of HMG-CoA act as competitive inhibitors of HMG-CoA reductase, a key enzyme in the cholesterol biosynthetic pathway. Of these, lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, pitavastatin, and rosuvastatin are approved for use in the United States. Inhibition of cholesterol biosynthesis induces an increase in high-affinity LDL receptors in the liver, increasing removal of LDL from plasma and decreasing production of LDL. Modest increases in HDL cholesterol and limited decreases in VLDL levels can be achieved. These drugs have no appreciable effect in patients with severe

TABLE 19–2   Reductase inhibitors.

Drugs (in Increasing Order of Potency)	Dose Range (mg)
Fluvastatin	20-80
Pravastatin	10-80
Lovastatin	10-80
Simvastatin	5-80
Atorvastatin	5-80
Resuvastatin	5-40
Pitavastatin	1-4

hypertriglyceridemia. Some of the cholesterol-independent effects of reductase inhibitors appear to involve enhanced stability of atherosclerotic lesions and decreased oxidative stress and vascular inflammation, with improved endothelial function. Institution of treatment with a reductase inhibitor should begin immediately in all patients with acute coronary syndromes regardless of cholesterol level. A number of primary and secondary trials with statins as monotherapy have demonstrated significant reduction in endpoints including primary or recurrent myocardial infarction, coronary revascularization, atherosclerotic stroke, or cardiac death. Reduction of LDL cholesterol levels to or below currently accepted goals produced an approximate 35% reduction in new coronary events over the 3 to 5 year duration of the trials. Longer term follow-up suggests that the impact on new coronary events will deepen over time, consistent with observations on individuals with familial hypobetalipoproteinemia or loss of function variants in the *PCSK9* gene.

Drug Dosage

These drugs are the most effective individual oral agents for treatment of hypercholesterolemia. Their effects are amplified significantly when combined with niacin, ezetimibe, or resin. Daily dosage ranges are presented in Table 19–2. Patients with LDL receptor defects usually require higher doses. Because information on long-term safety is lacking, use of these agents in children should be restricted to those with homozygous hypercholesterolemia and selected heterozygotes who are at particularly high risk. Women who are lactating, pregnant, or likely to become pregnant should not be given these drugs.

Side-Effects

These agents are generally well tolerated. Side-effects, often transient, include rashes and changes in bowel function. Myopathy with markedly elevated creatine kinase (CK) levels occurs infrequently and is often associated with mutations in the Solute Carrier Organic anion transporter family, member 1B1 (SLCO1B1) gene. Rarely, myopathy can progress to rhabdomyolysis with myoglobinuria and renal shutdown. Among the rare hypersensitivity syndromes (Lupus-like syndromes and dermatomysitis) associated with statin treatment, is a more recently described autoimmune myopathy. This presents as severe proximal muscle weakness and pain that does not diminish after the statin is discontinued, is HMGCoA reductase antibody positive, and requires immunosuppressive treatment, usually with good results. There is an increased incidence of myopathy in patients receiving certain reductase inhibitors with cyclosporine, fibric acid derivatives, macrolides, HIV protease inhibitors, nefazodone, verapamil, and ketoconazole. Other drugs that compete for metabolism by cytochrome P450 3A4 can be expected to have the same effect. Because pravastatin and rosuvastatin do not compete with these agents for metabolism by cytochrome P450 enzymes, they appear to be compatible with them. Fluvastatin is chiefly metabolized by cytochrome P450 2C9. Thus, competitors for that pathway may cause accumulation of this reductase inhibitor. Moderate myopathy is usually rapidly reversible on cessation of statin therapy.

Minor elevations of CK activity in plasma are noted more frequently, especially with unusual physical activity. CK levels should be measured before starting therapy and monitored at regular intervals in selected patients. Older patients, those taking higher doses and multiple other drugs, those who have diabetes or renal insufficiency, and those with baseline elevated CK levels should be observed more frequently. A form of statin-associated myopathy can occur in the absence of CK elevations.

Moderate, often intermittent elevations of serum aminotransferases (up to 3 times normal) occur in some patients. If the patient is asymptomatic, therapy may be continued if activity is measured frequently (at 1- to 2-month intervals) and the levels are stable. In about 2% of patients, some of whom have underlying liver disease or a history of alcohol use, aminotransferase activity may exceed 3 times the normal limit. This can occur after 3 or more months of continuous therapy and may portend more severe hepatic toxicity such as that described in the section on niacin. The reductase inhibitor should be discontinued promptly in these patients. These agents are contraindicated in the presence of active liver disease and should be used with caution in patients with a history of liver disease. They should be discontinued temporarily during hospitalization for major surgery.

Large scale intervention trials have revealed an increased incidence of type 2 diabetes in individuals treated with statins compared with those receiving placebo. A meta-analysis revealed the increment of risk to be 9%. Patients who developed diabetes derived the same benefit in cardiovascular outcome as those receiving statins who did not develop diabetes. This effect was greater among older subjects. Periodic assessment of HgbA1c is indicated in patients receiving statins.

CHOLESTEROL ABSORPTION INHIBITORS

Mechanism of Action and Efficacy

Ezetimibe, the first of this class, inhibits the absorption of cholesterol and phytosterols by enterocytes. By interrupting the enterohepatic circulation of sterols secreted in bile, it increases sterol elimination. Recent trials indicate that ezetimibe contributes to reduction of new coronary events.

Drug Dosage

Ezetimibe is useful in treating primary hypercholesterolemias and phytosterolemia. Concomitant use of fibric acid derivatives can increase the blood concentration of this drug. Resins can decrease its absorption. It should be avoided in pregnant or lactating women and in patients with liver disease, and used with caution in patients receiving cyclosporine. A dose of 10 mg daily reduces cholesterol by 15% to 20%.

Side-Effects

Very few side-effects have been reported. The prevalence of elevated liver enzymes may be modestly increased when ezetimibe is given with a reductase inhibitor. Biopsy-proven myopathy has been described rarely.

PCSK9 MONOCLONAL ANTIBODY

Mechanism of Action and Efficacy

PCSK9 is a resident protein in the cell membrane that binds to the LDL receptor and carries it to the lysosome for destruction, preventing it from recycling to the membrane. Naturally occurring loss of function mutations lead to very low levels of circulating LDL that are associated with significant reduction in morbidity and mortality from coronary vascular disease. Humanized monoclonal antibodies to PCSK9 inhibit its activity leading to major reductions in LDL levels in individuals with at least some LDL receptor activity. These agents have applications in individuals who have clinical cardiovascular disease or primary hypercholesterolemia with statin intolerance or whose LDL-C is not at goal. They can be given with other lipid-lowering agents. Preliminary results from placebo-controlled trials reveal a reduction in aggregate new coronary events.

Drug Dosage

Two preparations are available, alirocumab and evolocumab. Dose of the former is 75 or 150 mg SQ every 2 weeks; dose of the latter is 140 mg SQ every 2 weeks.

Side-Effects

Hypersensitivity reactions, injection site reactions, a transient flu-like syndrome, upper respiratory infection, increased liver enzymes, muscle pain, and other side-effects have been reported.

INHIBITION OF MICROSOMAL TRIGLYCERIDE TRANSFER PROTEIN (MTP)

Mechanism of Action and Efficacy

A requisite step in the secretion of VLDL by liver is the lipidation with triglyceride of Apo B-100. This is mediated by MTP and is inhibited by the agent, lomitapide. Reduction in the secretion of VLDL results in lower levels of its metabolic product, LDL. Use of this MTP inhibitor is currently limited to patients with homozygous LDL receptor deficiency. It can be used with a statin.

Drug Dosage

Dosage begins at 5 mg orally daily and is increased to tolerance or a maximum of 40 mg daily.

Side-Effects

The most significant adverse effect is hepatic steatosis that reverses spontaneously in some patients.

TABLE 19–3   **The primary hyperlipoproteinemias and their drug treatment.**

	Single Drug[a]	Drug Combination
Primary Chylomicronemia Chylomicrons (VLDL may be increased)	Niacin, fibrate[b] if VLDL increased	Niacin plus fibrate[b] if VLDL increased
Familial Hypertriglyceridemia VLDL and perhaps chylomicrons increased	Niacin, fibrate	Niacin plus fibrate
Familial Combined Hyperlipoproteinemia VLDL increased LDL increased VLDL, LDL increased	Niacin, fibrate, reductase inhibitor Reductase inhibitor, niacin, ezetimibe Reductase inhibitor, niacin, fibrate	Two or three of the single drugs
Familial Dysbetalipoproteinemia VLDL remnants, chylomicron remnants increased	Niacin, fibrate, reductase inhibitor	Fibrate plus niacin or niacin plus reductase inhibitor
Familial Hypercholesterolemia LDL increased	Reductase inhibitor, ezetimibe, niacin, resin	Two or three of the single drugs
Familial Ligand-Defective Apo B LDL increased	Reductase inhibitor, niacin, ezetimibe	Niacin plus reductase inhibitor or ezetimibe
Lp(a) Hyperlipoproteinemia Lp(a) increased	Niacin	

[a]Single-drug therapy should be tried before drug combinations are used.

[b]Fibric acid derivative.

APO B ANTISENSE OLIGONUCLEOTIDE

Mechanism of Action and Efficacy

Mipomersen is an oligonucleotide directed at the messenger RNA for Apo B-100. It lowers LDL-C levels by about 25% and would be expected to be effective in the absence of LDL receptor activity. Its use is limited to patients with homozygous LDL receptor deficiency.

Drug Dosage

The dose is 200 mg SQ once weekly.

Side-Effects

Elevated transaminases and hepatic steatosis have been reported. It is contraindicated in individuals with liver disease.

COMBINED DRUG THERAPY (TABLE 19–3)

Combinations of drugs may be useful (1) when LDL and VLDL levels are both elevated; (2) in cases of hypercholesterolemia in which significant increases of VLDL occur during treatment with a bile acid–binding resin; (3) where a complementary effect is required to normalize LDL levels; and (4) when a hyperlipidemia is accompanied by primary HDL deficiency or an elevated level of Lp(a).

Niacin with Other Agents

The combination of a fibrate with niacin may be more effective than either drug alone in managing marked hypertriglyceridemia.

Niacin usually normalizes triglycerides in individuals who have increased levels of VLDL while taking resins. The combination of niacin and resins is more effective than either agent alone in decreasing LDL levels in familial hypercholesterolemias. The combination is also very useful in the treatment of FCH. The absorption of niacin from the intestine is unimpeded by the resin. Niacin is complementary with ezetimibe in treating combined hyperlipidemia.

HMG-CoA Reductase Inhibitors with Other Agents

The addition of resin or niacin to a reductase inhibitor further decreases plasma levels of LDL in patients with primary hypercholesterolemias. Liver function and plasma CK activity should be monitored frequently when the combination includes niacin. These three drugs used together are more effective, frequently at lower doses, than any of their binary combinations in reducing LDL. Ezetimibe is synergistic with reductase inhibitors. The compatibility of rosuvastatin or pravastatin with fenofibrate makes these combinations useful in combined hyperlipidemia.

DEFINITION AND EPIDEMIOLOGY

Definition

Obesity and overweight categories have been defined by examining longitudinal study data that associate a given weight with future adverse health effects. The currently accepted surrogate measure of body fatness is body mass index (BMI) which is measured as weight in kilograms divided by height in meters squared. For adults, a BMI less than 18.5 kg/m^2 is underweight, 18.5 to 24.9 kg/m^2 is healthy weight, 25.0 to 29.9 kg/m^2 is overweight, and greater than or equal to 30 kg/m^2 is obese. For children and adolescents, a BMI between the 85th and 95th percentile for age

and sex is considered at risk of overweight, and BMI at or above the 95th percentile is considered overweight or obese.

However, BMI does not account for ethnic differences in skeletal structure or musculature. Body frame size varies dramatically by race/ethnicity from small-framed East Asian adults to larger framed Pacific Islanders. Moreover, conventional cut-points for adult overweight (BMI ≥25 kg/m^2) and obesity (BMI ≥30 kg/m^2) do not correspond to similar absolute or relative metabolic risk in all ethnic group. As a result, the World Health Organization (WHO) and International Obesity Task Force proposed a lower BMI cut-point to define obesity in South and East Asian adults: 23 kg/m^2 for overweight and 25 kg/m^2 for obesity.

Prevalence and Projections

National surveys performed by the Centers for Disease Control and Prevention in the United States have found a significant increase in the prevalence of overweight and obesity over the past 30 years. In 2003 to 2004, according to data from the National Health and Nutrition Examination Survey (NHANES), 32.2% of adults were obese. Trends among adults have been tracked by repeat NHANES surveys, showing that the percent of overweight or obese has climbed from 47.0% in 1976 to 1980 to 66.2% in 2003 to 2004, and the prevalence of obesity alone has more than doubled from 15.0% to 32.9% overall. In 2015, the prevalence of obesity was 48.1% among non-Hispanic blacks, 42.5% among Hispanics, and 34.5% among non-Hispanic whites.

The trends in obesity have been most striking among children and adolescents with two- to threefold increases in rates over the past three decades in all age groups. In the NHANES 2003 to 2004 survey, a total of 17.1% of U.S. children and adolescents were overweight (BMI ≥95th percentile). However, the newest trend reports by the Centers for Disease Control show that no change in obesity prevalence has been observed between the 2011-2012 and 2013-2014 data collection period.

While the United States leads most of the world with high prevalence of overweight and obesity, these conditions are becoming more prevalent worldwide, even in developing countries. In China, overweight prevalence in adults increased from 14.6% to 21.8% between 1992 and 2002, with greatest increases seen among men, urban residents, and high-income groups. In India, the prevalence of overweight ranged from 9.4% in rural men to 38.8% in urban women in 2003 to 2005.

Globally, according to a pooled analysis, in 2005 there were an estimated 937 million (95% CI, 922-951 million) overweight adults and 396 million (388-405 million) obese adults. Using conservative projections, by 2030 the number of overweight adults was estimated to be 1.35 billion and 573 million obese individuals without adjusting for secular trends. The authors warned that if recent secular trends continue unabated, the absolute numbers may total 2.16 billion overweight and 1.12 billion obese adult individuals. Among U.S. residents, projections forecast that by 2030, 86.3% adults will be overweight or obese (51.1%) with black women (96.9%) and Mexican American men (91.1%) being most affected. Wang et al estimate that by 2048, all American adults would become overweight or obese, and in children, the prevalence of overweight (BMI ≥95th percentile) would almost double to 30%.

Possible Explanations for the Increased Obesity Rates

Several hypotheses have been proposed to explain the rapid rise in overweight/obesity in developed and developing countries. The simple explanations start with changes in lifestyle behaviors, primarily the lack of regular physical activity and increased caloric intake that tip the energy balance equilibrium. The reality of the factors promoting the obesity epidemic is clearly more complex and involves multiple layers of determinants including social norms and values, several sectors of influence from governmental to media to the food/entertainment industries, behavioral settings including the work/home/neighborhood environment, to individual factors that include genetic/epigenetic, microbiomic, socioeconomic, cultural, and psychosocial factors. In a novel social network analysis of the Framingham cohort, investigators found that weight status (gain, loss, or stability of weight) for an individual was highly influenced by his/her friends and family extending out to three degrees of separation. A multifaceted approach will be required to meaningfully curb the obesity epidemic globally.

PATHOPHYSIOLOGY AND GENETICS OF OBESITY

Regulation of Food Intake and Energy Expenditure

Obesity is an increase of energy stored as fat that occurs when caloric intake exceeds caloric expenditure. What causes this imbalance is less clear, but recent advances in our understanding of the physiological systems responsible for the maintenance of energy stores in response to variable access to nutrition and demands for energy expenditure have provided some insights into the pathophysiology of obesity. The physiological system controlling food intake and energy expenditure is composed of (1) long-term and short-term afferent signals that allow for sensing the energy status of the individual; (2) integrating brain centers, most importantly within the hypothalamus, where the level of the efferent response is determined; and (3) efferent signals including those regulating the intensity of hunger and the level of energy expenditure.

One common misconception is that this physiological system is dedicated to the prevention of obesity. Instead this system's essential role is in the prevention of starvation (ie, ensuring adequate energy intake to compensate for the energy requirements of basal metabolism, physical activity, growth, and reproduction). As a result, this physiological system is more strongly biased toward prevention of energy deficiency rather than excess storage.

Informing the Brain of the Energy Status: Leptin and Short-Term Gastrointestinal Signals

Leptin   The major afferent signal allowing the brain to sense the level of energy stores is the hormone leptin. Discovered in 1994, this cytokine-like 167 amino acid protein is released by adipocytes. Under basal conditions the circulating levels of serum leptin are correlated with fat mass (r = 0.8) and decrease after weight loss. Decreasing leptin levels inform the brain of diminishing fat storage resulting from negative energy balance. This results in compensatory effects on appetite and energy expenditure, aimed at replenishing the stores and reestablishing energy balance. The role of leptin is best understood from the phenotype of rare cases of humans with complete leptin deficiency. Despite early-onset, extremely severe obesity, these patients show behaviors and

physiological signs of starvation. This includes hyperphagia, decreased immune function, and hypogonadotropic hypogonadism. The latter reflects deficiency of the leptin signal informing the brain that sufficient energy stores are available for reproduction. Hormonal replacement of leptin-deficient patients corrects all these abnormalities, abolishing the hyperphagia leading to normalization of weight and maturation of the reproductive axis.

Leptin's action is mediated by the leptin receptor (LepR). This receptor is a member of the class I cytokine receptor family which also includes the growth hormone, prolactin and erythropoietin receptors (see Chapter 1). These receptors have a single transmembrane domain and homodimerize upon binding of the ligand. Leptin binding to LepR leads to phosphorylation of the JAK2 receptor-associated kinase followed by recruitment and phosphorylation of the signal transducer and activator of transcription STAT3. Upon activation STAT3 dimerizes and translocates to the nucleus, where it activates transcription of target genes. The LepR is expressed in almost every tissue but only one of five isoforms, LepRb, contains the STAT3 recruitment domain. This isoform is expressed specifically in leptin-responsive brain regions.

In summary, leptin functions as a long-term signal of energy balance by informing the brain of changes in the level of energy stored as fat. A perceived decrease in leptin levels increases the amount of food consumed and minimizes energy expenditure. Leptin levels do not change with meals, and leptin does not acutely change meal size.

Signals from the gastrointestinal tract In addition to leptin, which represents a long-term adiposity signal, a number of other hormones, most of which are secreted by the gastrointestinal (GI) system, regulate appetite on a short-term basis (ie, in response to a meal) (Table 20–1). These hormones act on **satiation** (the feeling of fullness that contributes to the decision to stop eating) rather than on **satiety** (the prolongation of the interval until hunger or a drive to eat reappears). Some of these hormones have been shown to act on the same brain centers as leptin does. Altered secretion of or response to these GI hormones may directly contribute to the pathogenesis or the maintenance of obesity. Cholecystokinin (CCK) is secreted by duodenal I cells into the bloodstream. Its secretion is stimulated by the presence of fat and protein in the duodenum. CCK stimulates gut motility, contraction of the gallbladder, pancreatic enzyme secretion, gastric

emptying, and acid secretion. CCK acts locally, stimulating vagal sensory nerves through the CCK 1 receptor (CCK-1R) and informs the brain that fat and proteins are being processed and will soon be absorbed. This message is conveyed to the hypothalamus via the hindbrain. Circulating CCK levels increase after meals and infusion of a CCK-1R agonist (CCK33), to postprandial levels, suppresses food intake. Conversely, infusion of a CCK-1R antagonist increases calorie intake. CCK is also a proximal mediator of the broader satiation process, attenuating meal-induced changes of more distal GI hormones, such as ghrelin and peptide YY (PYY).

Glucagon-like peptide 1 (GLP1) is a 30 amino acid peptide derived from the proglucagon gene. GLP1 is secreted into the bloodstream by the intestinal L-cells of the ileum and colon in response to the presence of nutrients in the lumen. GLP1 has a very short half-life (2 minutes), and is degraded by dipeptidyl peptidase-4. It increases insulin secretion in a glucose-dependent manner, decreases glucagon secretion, increases beta cell mass, inhibits gastric emptying, and decreases food intake. GLP1 is thought to signal through the hindbrain via stimulation of the GLP1 receptor (GLP1R) on the vagus nerve.

PYY, a 36 amino acid peptide is released into the bloodstream by intestinal endocrine L-cells of the distal gut (ileum and colon) after food ingestion and in response to the presence of fat in the lumen. PYY3-36, the major form of circulating PYY, binds to the hypothalamic NPY-Y2 receptor, and reduces food intake. Obese individuals have lower PYY levels after a test meal than nonobese controls.

Ghrelin, a 28 amino acid octanoylated peptide, is secreted into the bloodstream by endocrine cells lining the fundus of the stomach. Ghrelin secretion is stimulated by fasting, increases preprandially, and is suppressed by food intake. Ghrelin is orexigenic, increasing food intake when administered peripherally, and acts in part by directly modulating the activity of the NPY (neuropeptide Y)/ AGRP (agouti-related peptide) neurons in the arcuate nucleus of the hypothalamus.

Central Integration of Energy Homeostasis Signals

The major challenge of adapting food intake to energy expenditure lies in the discontinuous availability of the first and the continuous

TABLE 20–1 Selected GI and pancreatic peptides that regulate food intake.

	Main Site of Synthesis	Secretion Pattern	Effect on Food Intake
Ghrelin	Gastric X/A-like cells	Increases prior to meal; decreased by food intake	Stimulates food intake
Cholecystokinin (CCK)	Proximal intestinal I cells	Stimulated by duodenal presence of fat and protein	Promotes meal termination and reduces meal size
Peptide YY3-36 (PYY)	Distal-intestinal L cells	Stimulated by presence of fat in the lumen	Reduces appetite and food intake
Glucagon-like peptide 1 (GLP-1)	Distal-intestinal L cells	Stimulated by presence of nutrients in the lumen	Short-term inhibition of food intake
Pancreatic polypeptide (PP)	Pancreatic F cells	Released in proportion to calories ingested	Reduces appetite and food intake

and variable levels of the second required for survival, growth, and reproduction. The current prevailing model is that the concentration of circulating adiposity signals, primarily leptin, influences the response to short-term satiation signals thereby allowing for sufficient energy intake to maintain a constant level of stored energy. Genetic studies in mice and humans have outlined several critical neuronal populations and circuits that translate information provided by afferent circulating hormonal signals into neural responses that regulate appetite and energy expenditure. The primary locus for the integration of peripheral signals that influence energy balance is the hypothalamus (Figure 20–1). Specifically, two adjacent groups of neurons in the arcuate nucleus (ARC) of the hypothalamus, characterized by their production of specific neuromediators, act as the primary site in the brain for receiving the humoral signals that reflect body energy status. The AGRP/NPY neurons are orexigenic. They are inhibited by leptin and their activity is also modulated by GI hormones, such as ghrelin and PYY. The proopiomelanocortin (POMC) neurons are anorexigenic and are activated by leptin. In these neurons, POMC is processed by the specific proteases proconvertase-1 and proconvertase-2 to the anorexigenic neuropeptide α-melanocyte–stimulating hormone (α-MSH). Interactions between these neurons within the ARC allows for cross talk and modulation of the neuronal output.

These first-order neurons send projections to second-order neurons in other regions of the hypothalamus, specifically the paraventricular nucleus (PVN) and the lateral hypothalamic area (LHA), as well as to the hindbrain. Both α-MSH and AGRP act on a common receptor, the melanocortin-4 receptor (MC4R) expressed on PVN neurons. α-MSH binds to and activates the melanocortin 4 receptor (MC4R) and by competing with α-MSH for the MC4R, AGRP inhibits MC4R-bearing neurons. The MC4R neurons then innervate neurons in other areas of the hypothalamus and brain stem to produce an integrated inhibition of appetite and increase in energy expenditure.

Leptin Resistance in Obesity

While recombinant leptin can correct the exceptionally rare cases of obesity due to genetic leptin deficiency, all other obese patients have leptin levels that are proportional to their fat mass. In addition, recombinant leptin injections in obese patients do not lead to weight loss. Therefore, despite the presence of elevated leptin concentrations, which should reduce food intake and body fat, obese patients appear to be insensitive or resistant to leptin. Both genetic and environmental factors have been shown to contribute to this leptin resistance, and a number of specific alterations in the downstream leptin effector pathways have been suggested to participate in this obesity-associated leptin resistance. Understanding the nature of this leptin resistance may allow for the development of novel obesity treatments, but the molecular basis of obesity is probably heterogenous and different in each patient.

Genetics of Obesity

Excess caloric intake and the tendency toward a more sedentary lifestyle are certainly to blame for the increased prevalence
FIGURE 20–1 Leptin-melanocortin system of energy balance. Information about the body's energy stores is conveyed to the brain by hormones such as leptin. Leptin is secreted by adipocytes in proportion to the body's fat mass. Leptin binds to its receptors on two populations of neurons in the arcuate nucleus of the hypothalamus: the orexigenic AGRP/NPY–expressing neurons, and the anorexigenic POMC-expressing neurons. These two groups of neurons have projections to the paraventricular nucleus of the hypothalamus, as well as to other regions of the brain. The PVN has a dense neuronal population that expresses MC4R. When leptin binds its receptors on POMC neurons, α-MSH, a cleavage product of POMC, is released. Activation of MC4R in the PVN by α-MSH relays a satiety signal and causes a decrease in food intake. AGRP is an antagonist of MC4R, and competes with α-MSH for binding to MC4R. Binding of AGRP to MC4R leads to increased food intake. Leptin activates POMC neurons and inhibits AGRP neurons. Therefore, by activating its receptors on these two neuronal populations, leptin acts in a concerted way to increase MC4R activation by α-MSH and decrease its antagonism by AGRP resulting in a net decrease in food intake. (α-MSH, α-melanocyte–stimulating hormone; AGRP, agouti-related peptide; ARC, arcuate nucleus; MC4R, melanocortin 4 receptor; NPY, neuropeptide Y; POMC, pro-opiomelanocortin; PVN, paraventricular nucleus; LepR, leptin receptor.)

of obesity, but individuals exposed to the same environmental pressures have different levels of vulnerability. Indeed, genetic epidemiologic studies, such as twin studies and adoption studies have implicated genetic factors in the susceptibility to obesity. These studies have shown that genetic factors account for 40% to

TABLE 20–2 Common variants increasing the risk of obesity.[a]

Chromosomal Localization	Nearby Genes	Odds Ratio of Obesity in Adults

70% of the population variation in BMI and that the heritability of obesity increases with its severity. Emphasis has, therefore, now shifted from the question of whether human obesity has a genetic component to how many and which genetic variants underlie this susceptibility. While the majority of genes that contribute to the predisposition to obesity are still unknown, both common genetic variants, with small effects on the BMI at the level of the population, and single gene defects, causing Mendelian forms of obesity, have been described.

Large and comprehensive genome-wide association studies find that a number of common genetic variants are associated with obesity (Table 20–2). These variants are near genes that are expressed in the central nervous system, further suggesting a role for an alteration of central regulatory pathways in the pathogenesis of obesity. However, since these variants are not located within the protein-coding regions of these genes, the exact mechanism by which they predispose to obesity remains to be elucidated. More importantly, the individual as well as the combined effects of these common variants only explain a small fraction of the inherited variability in obesity (10%-20%), suggesting that rare variants may contribute more significantly to the genetic predisposition to this condition.

Indeed a number of single gene defects that cause human obesity have been uncovered. These defects have provided more insight into the genetic predisposition and pathophysiology of obesity. Certain mutations can cause obesity as part of a complex syndrome, in which developmental phenotypes are prominent (Table 20–3). However, most single gene defects causing Mendelian forms of obesity are in genes of the leptin-melanocortin system (Table 20–4). The description of patients with these mutations has both provided insight into the genetic predisposition to obesity and has confirmed that the hypothalamic leptin-melanocortin system is critical for energy balance in humans. Mutations in leptin and the LepR cause severe obesity associated with hypogonadotropic hypogonadism. Mutations in POMC cause severe obesity, due to absent synthesis of α-MSH in the hypothalamus, and neonatal adrenal insufficiency, due to lack of ACTH production in the anterior pituitary gland. These recessive syndromes are extremely rare. In contrast, mutations in MC4R represent the most common genetic cause of severe obesity accounting for 2.5% of all cases. Patients who carry such mutations do not have specific clinical or biological characteristics that differentiate them from other patients with severe obesity; genetic testing is the only reliable method to identify these patients. At present, such testing is not recommended since the presence or absence of one of these mutations carries no specific implications for the clinical management of these patients.

HEALTH CONSEQUENCES OF OBESITY

Mechanism Underlying Obesity Complications: Adipose Tissue as an Endocrine Organ

The massive public health burden of obesity is due to the psychological, behavioral, and medical consequences of this chronic increase in adipose tissue mass. Pathophysiological mechanisms underlying the complications of obesity include the psychological and behavioral responses to the image projected in a society in

TABLE 20–3 Syndromes that cause human obesity.

Name/OMIM	Clinical Features	Prevalence	Genetics
Prader-Willi OMIM#176270	Diminished fetal activity, obesity, muscular hypotonia, mental retardation, short stature, hypogonadotropic hypogonadism, small hands, and feet	1/25,000	Imprinting + Deletion 15q12

MC4R	2.5% of severely obese patients	Dominant	Severe, variable onset	None

which obesity is considered cosmetically unattractive, the mechanical effects of increased adipose mass on weight-bearing joints as well as other organs, and the metabolic consequences of increased circulating free fatty acids (FFAs).

It is also now clear that the adipose cell is not simply dedicated to inertly storing energy as triglycerides and releasing free fatty acids and glycerol during periods of increased energy needs. In addition to leptin, described earlier, which informs the brain of the level of energy stores, adipose cells secrete a number of factors, known as adipokines, which can play a role in the pathophysiology of obesity and its complications (Figure 20–2). For example, adiponectin is an abundant plasma protein, structurally related to the complement 1q family, which is secreted exclusively from adipose tissue. Adiponectin circulates in serum as a range of multimers from low-molecular-weight trimers to high-molecular-weight (HMW) dodecamers. Circulating levels of adiponectin are negatively correlated with fat mass and are reduced in obesity. Adiponectin improves whole-body insulin sensitivity through its receptor-mediated actions on the muscle and the liver. Specifically, adiponectin stimulates fatty acid oxidation and glucose uptake in skeletal muscle and suppresses glucose output in the liver.

In addition, a number of factors secreted by adipose tissue, particularly in the context of obesity, are proinflammatory cytokines. It is now generally accepted that obesity is a state of chronic, low-grade inflammation. These inflammatory molecules exert their effects through both paracrine and endocrine pathways. Initially thought to be secreted by adipocytes, most of these factors are actually produced by other cells such as macrophages, which infiltrate the adipose tissue in obesity. Tumor necrosis factor-α (TNF-α) was the first adipose-derived factor suggested to represent a link between adiposity and the insulin resistance associated with type 2 diabetes. Released by activated macrophages, which infiltrate expanding adipose tissue in obesity, this cytokine has been strongly implicated in the pathogenesis of insulin resistance, directly impairing insulin signaling in hepatocytes and adipocytes. Other adipokines involved in obesity-associated inflammation include interleukin 6 (IL-6), monocyte-chemoattractant protein-1 (MCP-1), plasminogen-activated inhibitor (PAI-1), and colony-stimulating factor (CSF).

Metabolic Complications of Obesity: Insulin Resistance and Type 2 Diabetes

Hyperinsulinemia is characteristically associated with obesity. This hyperinsulinemia is linked to insulin resistance (ie, the decrease in insulin-stimulated glucose utilization, which increases proportionally with fat mass). One of the major consequences of this obesity-associated insulin resistance is the requirement for increased insulin secretion. While the majority of obese individuals can secrete sufficient insulin to accommodate the insulin-resistant state, this increased burden on the insulin-producing pancreatic beta cells increases the susceptibility to failure, resulting in type 2 diabetes (T2DM) in genetically predisposed individuals. Indeed, over 80% of T2DM patients are obese. In comparison with a normal-weight individual, BMI greater than 40 (obesity class 3) in a person under 55 years of age increases the risk of T2DM by 18.1-fold in men and 12.9-fold in women. Classification as overweight (BMI 25-30) increases the prevalence of T2DM three- to fourfold in both men and women under 55 years of age, and BMI greater than or equal to 25 kg/m^2 has been the recommended criterion for diabetes screening. However, in 2015 the American Diabetes Association revised this criterion for diabetes screening in Asians to be BMI greater than or equal to 23 kg/m^2, based on several studies showing higher diabetes risk at lower BMI in most Asian groups. The relative risks associated with excess body weight

are weaker in older individuals but are still present (eg, about twofold for overweight and three- to sixfold for obesity class 3).

The increased rate of T2DM is the most worrisome public health issue linked to the increased rates of obesity. The anticipated health outcomes such as premature heart disease, peripheral vascular disease, renal failure, blindness, are deeply concerning and place this among our highest contemporary public health priorities. Some recent studies have estimated that the current generation of American youth will be the first to exhibit shorter lifespans than their parents, because of the impact of obesity on T2DM.

Dyslipidemia

Obesity is associated with dyslipidemia characterized by increased levels of very low density lipoprotein (VLDL) cholesterol, triglycerides, and total cholesterol as well as a decrease in HDL cholesterol and an increase in small dense LDL particles. The difference in serum triglyceride concentrations between individuals with BMI less than 21 and those with BMI greater than 30 is about 65 mg/dL (in women) and 62 to 118 mg/dL (in men, depending on age). For HDL cholesterol, each 1-unit BMI change is associated with an HDL-cholesterol decrease of 1.1 mg/dL for young men and 0.7 mg/dL for young women. All of the components of this obesity-associated dyslipidemia have been shown to be atherogenic and play a major role in the development of atherosclerosis and cardiovascular disease in obese individuals.

Weight loss and exercise, even if they do not result in normalization of body weight, can improve this dyslipidemia and thus reduce CVD risk. In addition, obese individuals should be targeted for intense lipid-lowering therapy, when necessary.

The Metabolic Syndrome

The concept of the **metabolic syndrome** was first introduced in 1923 by Kylin who described the clustering of hypertension, hyperglycemia, and gout as a syndrome. Reaven and others redefined this concept as the insulin resistance syndrome, a clustering of glucose intolerance, high triglycerides, low HDL cholesterol, and hypertension. The two most consistent characteristics of persons with the syndrome are insulin resistance and central abdominal obesity. There is strong epidemiologic and pathophysiologic evidence linking visceral adiposity with insulin resistance and diabetes, with dyslipidemia, hyperinsulinemia, and decreased fibrinolysis as possible mediators of the relationship between visceral fat and type 2 diabetes and cardiovascular disease risk.

The earliest attempt to create a definition for this constellation of metabolic disorders was by the WHO wherein an individual with glucose intolerance or insulin resistance was required to have two or more criteria (elevated triglycerides, low HDL cholesterol, high BMI or waist-hip ratio, hypertension, or microalbuminuria) in order to be categorized as having metabolic syndrome. The next attempt at a clinical definition was by the National Cholesterol Education Program (NCEP)-Adult Treatment Panel III in 2001 that required three or more of the following criteria for the metabolic syndrome definition: high fasting glucose, high triglycerides, low HDL, high blood pressure, or waist circumference.

The International Diabetes Federation (IDF) proposed further refined criteria that require central abdominal obesity, and two more criteria as proposed by the NCEP. The IDF criteria were the first ones to account for the heterogeneity of body size among different ethnic groups, and the committee recommended different waist circumference cut-points based on ethnicity with a revised definition for South Asians, Chinese, and Japanese. They recommended similar waist circumference cut-points in men (≥90 cm) and in women (≥80 cm) among these various ethnic groups, compared to the European cut-points of greater than or equal to 94 cm in men and greater than or equal to 80 cm in women. More recently, the utility of the metabolic syndrome has been questioned, given that there are no treatment options available, and rather each cardiometabolic risk factor (eg, blood pressure control) is treated individually.

Cardiovascular Complications

Higher cardiovascular disease risk has been linked to visceral and hepatic adiposity with several distinct mechanisms including inflammation, thrombosis, hyperglycemia, atherogenic dyslipidemia, and adipocytokines (hormones and proteins exclusively secreted by adipose tissue). Obesity has been implicated as one of the major risk factors for hypertension, heart failure, and coronary heart disease. Other cardiovascular conditions associated with obesity include peripheral arterial disease and atrial fibrillation.

Altered hemodynamics of obesity due to increases in total blood volume, systemic arterial pressure, and cardiac output increase the workload of the heart and can lead to adverse effects on cardiovascular structure and function. Overweight individuals develop left ventricular dilation and hypertrophy and left atrial enlargement. These structural abnormalities increase the risk of heart failure and of atrial fibrillation. In the Framingham Heart Study, every 1-unit increase in BMI increased the risk of heart failure by 5% in men and 7% in women. However, several recent studies have also found an obesity-cardiovascular disease paradox where overweight and obese individuals with existing heart failure or heart disease have a lower risk of mortality than those who are underweight or normal weight. These findings suggest that obese individuals may have the metabolic reserve to withstand high catabolic needs as exist in heart failure.

Pulmonary Complications

Obesity can cause alveolar hypoventilation, increased pulmonary blood volume, and mechanical effects on the respiratory system. Obstructive sleep apnea (OSA) is associated with obesity and other features of the metabolic syndrome, with the most closely correlated factor being hypertension. Intermittent upper airway obstruction results in hypoxia, sympathetic nervous system surges, and airway inflammation. Patients with sleep apnea have higher risk of systemic and pulmonary hypertension, heart failure, dysrhythmias, myocardial infarction, and overall mortality. Mechanisms that have been implicated in the development of cardiovascular disease in OSA include increased oxidative stress and inflammation that cause endothelial dysfunction. While significant weight loss can improve OSA and associated metabolic

features, mechanical therapies used to treat sleep apnea with constant positive airway pressure have not been found to improve hypertension or other metabolic features.

Gastrointestinal Complications

Nonalcoholic fatty liver disease (NAFLD) is commonly seen with insulin resistance or obesity and includes a spectrum of liver disease from steatosis to nonalcoholic steatohepatitis, advanced fibrosis, and rarely, cirrhosis. Fat accumulates within the liver with recruitment of inflammatory cells and fibrosis. The prevalence of NAFLD in obesity is 50% to 85%. Risk factors associated with NAFLD besides obesity include advancing age, visceral adiposity, atherogenic dyslipidemia, and hypertension. NAFLD is the leading cause of chronic liver disease in the United States, and given the high rates of obesity, approximately one-third of U.S. adults are estimated to have NAFLD.

NAFLD has been observed in overweight children and adolescents with prevalence estimated at 6% to 23% in population-based U.S. samples. In children, there seems to be a clear male predominance for NAFLD which suggests distinct pathophysiologic mechanisms for NAFLD between adults and children. Histologic criteria have been proposed to distinguish adult (type 1) and pediatric (type 2) NAFLD. In a large study of German children, the three main factors that contributed to NAFLD by principal components analysis included an insulin resistance/visceral adiposity factor, a body fat distribution/CRP factor, and lastly a sex steroid hormone factor.

Other GI complications of abdominal obesity include gastroesophageal reflux disease and hiatal hernia. Both of these conditions can cause erosive mucosal changes in the lower esophagus leading to higher risk of Barrett esophagus.

Reproduction and Gynecologic Complications

Obesity has been associated with both female and male infertility. In women, polycystic ovarian syndrome (PCOS) is the main cause of female infertility associated with obesity. Women with PCOS have ovulatory dysfunction and hyperandrogenemia. PCOS is reviewed in more detail in Chapter 13. In men, obesity can cause reduced sperm counts and motility. Hormonal changes with obesity and associated metabolic disorders may lead to poor sperm production. Obesity is also associated with erectile dysfunction through proinflammatory mechanisms and decreased testosterone levels.

Cancer

Several cancers have been linked to obesity, including breast, endometrial, colorectal, prostate, and renal cell carcinomas. Putative mechanisms for breast and endometrial cancer include higher circulating levels of unopposed estrogen and ovarian hyperandrogenism, causing higher levels of testosterone and lower levels of luteinizing hormone. The relationship between obesity and colon cancer is stronger in men than women.

MANAGEMENT OF THE OBESE PATIENT

Screening and Prevention of Complications

Periodic health screening with a measurement of both height and weight to calculate BMI is recommended by many organizations including the National Heart, Lung, and Blood Institute (NHLBI), the U.S. Preventive Services Task Force, and the WHO. Furthermore, the NHLBI also recommends waist circumference measurement routinely to find persons at risk of metabolic complications of overweight. Patients who are found to be in the overweight or obese categories of BMI are recommended to have other risk factors checked as well, including blood pressure, fasting glucose, and lipoprotein levels.

Therapeutic Approaches for Weight Loss

Several behavioral, pharmacologic, and surgical therapies for weight loss have been studied in randomized controlled trials. In general, behavioral interventions with lifestyle change including diet and exercise and pharmacologic therapies work to achieve modest amounts of weight loss while patients adhere to the intervention. Based on these studies, in 2012 the U.S. Preventive Services Task Force recommended that adults with BMI greater than or equal to 30 kg/m^2 be offered or referred for counseling and behavioral interventions to promote weight loss. Recommended for more severe levels of obesity, bariatric surgery does lead to larger amounts of weight loss, but requires lifelong medical supervision and management of the side effects associated with the surgery.

A. Behavior, diet, and exercise therapies   While many believe that long-term weight loss with lifestyle change is not achievable by most patients, longitudinal studies have found that 20% of overweight individuals are successful at weight loss defined as losing at least 10% of initial body weight and maintaining the loss for at least 1 year. Individuals enrolled in the National Weight Control Registry have lost an average of 33 kg and maintained the loss for more than 5 years. Behaviors that have been most effective for long-term weight loss include high levels of physical activity (~1 hour/d), self-monitoring weight, eating a low-calorie, low-fat diet, eating breakfast regularly, and maintaining a consistent eating pattern throughout the week. Wearable activity trackers and smart phone applications are useful aids for self-monitoring physical activity and dietary intake.

Dietary interventions   Several commercial, fad, and therapeutic dietary interventions exist for weight loss. Recent dietary trends have focused on relative changes in macronutrient composition of the diet to achieve weight loss, such as low-fat or low-carbohydrate diets. Few have been rigorously tested, and no trials have long-term outcome data (defined as the occurrence of comorbidities or mortality). A recent randomized trial comparing four popular diets (Atkins, Zone, Weight Watchers, and Ornish diet) found that weight change did not significantly differ between

participants assigned to any of the four diets, and better dietary adherence predicted higher amount of weight loss. The most difficult diets for participants to adhere to were the very low-fat diet (Ornish) and the low-carbohydrate diet (Atkins). In a recent meta-analysis of five dietary trials for weight loss, low-carbohydrate non–energy-restricted diets were found to be as effective as low-fat, energy-restricted diets for weight loss up to 1 year. In a meta-analysis of 48 randomized controlled trials testing a variety of named diets to no diet for weight loss, there was no difference in weight loss from the low carbohydrate diet trials compared to the low fat diet studies (both types of diet had mean −7.3 kg of weight loss at 12 months vs no diet).

Physical activity interventions   The Institute of Medicine recommends physical activity of 60 min/d for most days of the week for weight loss and/or control of weight. The recommendations for heart disease prevention are 30 min/d of moderate-intensity physical activity on most days per week, or at least 150 min/wk.

In a systematic review of 21 weight loss trials of diet with or without an exercise component, there was moderate quality evidence that both diet and exercise together was most effective for obesity management. Head-to-head trials testing the efficacy of weight loss with diet alone versus exercise alone have found that diet is associated with greater weight loss (−2.9 kg on average) than exercise alone. Isolated aerobic exercise for weight loss was associated with an average of 1.6 kg of weight loss in another meta-analysis.

Exercise has been shown to be important for the maintenance of weight loss. In a randomized controlled trial of 140 postmenopausal women who had lost 25 lbs with a very low calorie diet, all measures of energy expenditure declined after weight loss, but the groups randomized to either aerobic or resistance training had increases in total energy expenditure and non-exercise associated thermogenesis compared to a group that did not exercise.

Pharmacologic intervention/CAM   Weight loss medications have had mixed results with most delivering modest amounts of short-term weight loss, often associated with many undesirable side effects. Currently there are six main categories of weight loss medications approved by the FDA: adrenergic agents, serotonergic agents, combination of both adrenergic/serotonergic agents, lipase inhibitors, GABA-receptor antagonists, and GLP-1 receptor agonists. A majority of available obesity treatments work by suppressing appetite centrally. One approved medication, orlistat, prevents digestion and absorption of dietary fat by inhibiting the gut enzyme lipase.

Table 20–5 shows specific medications in each category, the amount of weight loss reported in trials compared to placebo from a recent review and meta-analysis, and the common side effects of each agent. Lorcaserin, an agonist that targets serotonin 2C receptors within the hypothalamus, promotes the release of melanotropin-α, which stimulates melanocortin receptor-4, resulting in appetite satiety. A phentermine/topiramate combination medication targets multiple pathways that regulate energy homeostasis and appears to be the most effective obesity medication available, although long-term studies are needed. The mechanism of action of naltrexone/bupropion is not completely understood but includes the hypothalamic melanocortin system and mesolimbic reward system. Liraglutide, a glucagon-like peptide (GLP)-1 agent, works peripherally by decreasing gastric emptying and in the caudal brainstem to improve satiety.

Complementary and alternative medications such as herbs, vitamins, nutritional supplements, and meal replacement therapies are commonly used by the general public for weight loss. However, the efficacy and safety of these herbal remedies have not been well studied. A recent meta-analysis of trials found that compounds containing ephedra, *Cissus quadrangularis*, ginseng, bitter melon, and zingiber had some short-term efficacy with weight loss with mostly mild adverse effects. However, longer-term randomized controlled trials are needed to prove efficacy and safety.

TABLE 20–5 Medications for treatment of obesity.

Drug	Category	Recommended Dose	Mean Weight Loss vs Placebo	Side Effects
Phentermine	Adrenergic agent	15-37.5 mg daily	3.6 kg (0.6-6.0 kg) greater weight loss than placebo	Dry mouth, headache, insomnia, irritability, tachycardia, ↑BP
Orlistat	Lipase inhibitor	60-120 mg 3 times daily	-5.8 kg vs -3.0 kg for placebo	Diarrhea, flatulence, fecal urgency and incontinence, abdominal pain, dyspepsia
Lorcaserin	Selective serotonin 2c receptor agonist	10 mg daily or twice daily	-4.5% to -5.8% vs -1.5% to -2.5% for placebo	Headache, nausea, dizziness, fatigue, dry mouth, hypoglycemia
Phentermine/topiramate	Adrenergic agent/GABA receptor antagonist	7.5/46 mg daily	-10.9% vs -1.6% for placebo	Paresthesias, dry mouth, constipation, insomnia, nausea, depression
Naltrexone/bupropion SR	Opioid receptor antagonist/Adrenergic agent	90 mg/8 mg to max dose of 360 mg/32 mg	-5.0% to -9.3% vs -1.2% to -5.1% in placebo	Nausea, headache, constipation, dizziness, insomnia, dry mouth
Liraglutide	GLP-1 receptor agonist	0.6 mg SC/day, to max dose 3 mg/day	-6.2% to -8.0% vs -0.2% to -2.6% in placebo	Nausea, vomiting, diarrhea, constipation, hypoglycemia, upper respiratory tract infection

B. Bariatric surgery   Surgical treatment for weight loss has been performed for the past 50 years, and these procedures are increasing in popularity. Approximately 20,000 weight-loss surgeries were performed in 1995 and over 179,000 were done in 2013, a ninefold increase. There are three main types of bariatric surgeries: restrictive, malabsorptive, and those that have both a restrictive and a malabsorptive component. Purely restrictive surgeries include horizontal gastroplasty, vertical banded gastroplasty, silastic ring vertical gastroplasty, and adjustable gastric banding. Purely malabsorptive surgeries include the oldest of all bariatric procedures, the jejunoileal bypass, biliopancreatic diversion, duodenal switch, and long limb gastric bypass. The combination of restrictive and malabsorptive surgical procedure is the most commonly used bariatric surgery worldwide, the Roux-en-Y gastric bypass procedure (RYGB), which involved stapling the upper stomach into a small 30-mL pouch and attaching it to the jejunum bypassing the lower stomach and duodenum. This procedure can be done with an open surgical approach, or now more commonly with a laparoscopic approach.

Several studies have examined the effects of different types of bariatric surgeries on various outcomes including weight loss, comorbid disease, complication rates, and mortality. There are very few randomized controlled trials comparing different surgical procedures, so most of the outcomes data come from case series, prospective cohort analyses, or nonrandomized trials. The largest and longest double cohort study to date is the Swedish Obese Subjects (SOS) study in which obese adults who voluntarily underwent bariatric surgery were matched to a control group of medically treated patients. After 10 years of follow-up of 1703 participants, those treated with surgery had a 16% weight loss compared to 2% in the controls ($p < 0.001$). They compared the different types of bariatric surgery approaches in this study and found that those who had gastric bypass lost more weight than those who received banding procedures or the vertical banded gastroplasty.

An earlier meta-analysis determined the effect of bariatric surgery on weight loss, mortality, and four comorbid diseases including diabetes, hyperlipidemia, hypertension, and sleep apnea. The mean excess weight loss was 61.2% (58.1%-64.4%), highest in those who had the biliopancreatic diversion or duodenal switch (70.1%) and lowest in those who underwent gastric banding (47.5%). Operative mortality within 30 days of the surgery was 0.1% for purely restrictive procedures and 0.5% for gastric bypass, and 1.1% for biliopancreatic diversion or duodenal switch procedures. Type 2 diabetes resolved in approximately 77% of patients after surgery, hyperlipidemia improved in 70%, hypertension resolved in 62%, and OSA resolved in 86%.

Much attention has focused on determining the mechanisms involved in the dramatic weight loss associated with bariatric surgery. Previous hypotheses that restrictive procedures reduce the quantity of food ingested at any one time, malabsorptive procedures cause wasting of fat calories, with RYGB employing a combination of both mechanisms, have not been supported by studies. More recent thinking attributes weight loss after bariatric procedures to a substantial decline in hunger and increase in satiety that is regulated through neuroendocrine mechanisms and gut hormones such as ghrelin and PYY. The effect of RYGB surgery on ghrelin levels is controversial since some studies have found increased levels, no change, or decreased levels after surgery. These inconsistent results may be explained by the timing of ghrelin sampling after surgery. After purely restrictive surgeries, ghrelin levels increase, which may help explain the more dramatic weight loss observed following RYGB versus purely restrictive surgeries. PYY levels rise to those of a nonobese person following vertical banded gastroplasty. However, with RYGB, there is an early exaggerated response in PYY secretion, approximately two- to fourfold greater than that observed in lean, obese, or gastric banded patients, which may contribute to the sustained weight loss seen with this type of procedure.

Defining appropriate patient criteria to minimize risks and maximize the benefits from bariatric surgery have been debated. Some studies have concluded that surgical intervention is more effective for weight loss and control of comorbid diseases than nonsurgical treatments in patients with a BMI greater than or equal to 40 kg/m^2. In 2004, with extensive scientific input, the National Coverage Advisory Committee panel concluded that bariatric surgery could be offered to Medicare beneficiaries with BMI greater than or equal to 35 kg/m^2 who have at least one comorbid disease associated with obesity and have been unsuccessful previously with medical treatment of obesity. Other criteria for patient selection proposed by leading associations include adequate patient commitment with medical follow-up and use of dietary supplements, no other reversible endocrine disorders causing obesity, no current substance abuse, and no severe psychiatric illness.

C. Interventions with efficacy in children   Several studies have investigated behavioral and lifestyle intervention programs for pediatric weight loss. Most randomized controlled trials of overweight children and adolescents have found positive, but small-to-moderate effects, of combined lifestyle interventions on BMI. Family-based behavioral weight loss programs have produced larger effects that persist for several months of follow-up. Less is known about the long-term safety and efficacy of pharmacologic agents for treatment of pediatric obesity.

Humoral Manifestations of Malignancy

Dolores M. Shoback, MD and Janet L. Funk, MD

ACTH	Adrenocorticotropic hormone		**IL**	Interleukin
ANP	Atrial natriuretic peptide		**LH**	Luteinizing hormone
APUD	Amine precursor uptake and decarboxylation (cell)		**MEPE**	Matrix extracellular phosphoglycoprotein
CRH	Corticotropin-releasing hormone		**MRI**	Magnetic resonance imaging
CT	Computed tomography		**NET**	Neuroendocrine tumor
FDG-PET	Fluorodeoxyglucose positron emission tomography		**PACAP**	Pituitary adenylate cyclase activating peptide
FGF	Fibroblast growth factor		**PHEX**	Phosphate-regulating gene with homologies to endopeptidases on the X chromosome
FSH	Follicle-stimulating hormone			
GH	Growth hormone		**POMC**	Proopiomelanocortin
GHRH	Growth hormone–releasing hormone		**PTH**	Parathyroid hormone
hCG	Human chorionic gonadotropin		**PTHrP**	Parathyroid hormone-related protein
HTLV-1	Human T cell leukemia virus-1		**SIADH**	Syndrome of inappropriate antidiuretic hormone (secretion)
IGF	Insulin-like growth factor		**TNF**	Tumor necrosis factor
IGF-BP3	Insulin-like growth factor binding protein-3		**VIP**	Vasoactive intestinal peptide

ECTOPIC HORMONE AND RECEPTOR SYNDROMES

Some of the most challenging endocrine problems occur in patients with malignancies of diverse cell types, because both endocrine and nonendocrine tumors secrete polypeptide hormones. As it became recognized that a polypeptide hormone could be produced by tumor cells derived from a tissue that normally did not secrete the hormone, the notion of ectopic hormone production developed. Most tumors associated with ectopic hormone syndromes are derived from cells that are normally capable of producing peptide hormones. Initially, it was thought that ectopic hormone production by tumor cells was a rare event. Interestingly, both the frequency and the original conception of this syndrome have been redefined over the last few decades. It has come to be appreciated—through the use of biochemical and molecular biologic techniques—that the synthesis of peptide hormones and the transcription of their genes by tumor cells are in fact quite common occurrences. Tumor cells may differ from normal cells in their ability or inability to process precursor molecules, which may account for the presence or absence of hormone excess states and for the profile of peptide hormone forms and fragments present in the circulation and in tumor cell extracts. However, tumor production of hormone fragments or precursors is much more common than the clinical syndromes of hormone excess.

The classic criteria used to confirm that a tumor is the source of a hormone excess state include the following: (1) evidence of an endocrinopathy in a patient with a tumor; (2) remission of the endocrinopathy after tumor resection; (3) detection of an arteriovenous gradient across the tumor; and (4) confirmation of protein and messenger RNA encoding the hormone produced by tumor tissue.

In addition to classic hormone excess states resulting from the ectopic or inappropriate secretion of a hormone by an endocrine or nonendocrine tumor, endocrinopathies can result from the ectopic expression of a hormone's receptor. This is well illustrated, for example, by the occurrence of Cushing syndrome in pregnancy or in relation to meals, due to the ectopic expression of luteinizing hormone (LH) or gastric inhibitory polypeptide (GIP) receptors in adrenal tissue, respectively. Several other examples of ectopic receptor syndromes have been documented. Some of these will be discussed later, particularly as a cause for unusual forms of adreno-corticotropic hormone (ACTH)-independent Cushing syndrome.

A variety of peptides are produced by both benign and malignant tumors as listed in Table 21–1. The biochemical pathways and machinery leading to the synthesis, processing, and secretion into the circulation of a peptide hormone are present in all cells. In contrast, the multiple enzymatic steps that lead to the production of a highly active steroid hormone (eg, cortisol or 1,25-dihydroxyvitamin D [1,25-(OH)$_2$ D]) are restricted, with rare exceptions, to steroid-producing cells or their precursor cells. Hence, the occurrence of 1,25-(OH)$_2$ D excess caused by a tumor is distinctly unusual, being observed infrequently in hematologic malignancies and only in those with the ability to 1-hydroxylate 25-OH D, the immediate precursor of 1,25-(OH)$_2$ D. Ectopic hormone syndromes—the most common of the paraneoplastic syndromes—thus predominantly reflect peptide hormone excess states. The most common ectopic peptide hormone syndromes are described in greater detail in subsequent sections of this chapter.

TABLE 21–1 Polypeptide hormones produced ectopically by benign and malignant tumors and their associated endocrinopathies.

Hormone	Syndrome
Parathyroid hormone-related protein (PTHrP)	Hypercalcemia
Parathyroid hormone (rare)	Hypercalcemia
Adrenocorticotropin (ACTH)	Cushing syndrome
Corticotropin-releasing hormone (CRH)	Cushing syndrome
Antidiuretic hormone (ADH)	Hyponatremia
Insulin and insulin-like growth factors (IGF)	Hypoglycemia
Growth hormone–releasing hormone (GHRH)	Acromegaly
Calcitonin	*No specific syndrome*
Human chorionic gonadotropin (hCG)	Children: precocious puberty Men: erectile dynsfunction, gynecomastia Women: dysfunctional uterine bleeding
Fibroblast growth factor (FGF) 23	Oncogenic osteomalacia
Vasoactive intestinal peptide (VIP)	Diarrhea

APUD Concept of Neuroendocrine Cell Tumors

Over the years since the initial recognition that nonendocrine tumors were the source of the ectopic hormones produced in these endocrine syndromes, the notion developed that the hormones originated from highly specialized neuroendocrine cells in tumors. These cells were thought to derive from the neural crest and were postulated to be able to synthesize and store biogenic amines and were thus designated as amine precursor uptake and decarboxylation (APUD) cells. Neuroendocrine cells, like calcitonin-secreting C cells and adrenal chromaffin cells, clearly had these properties, and tissues giving rise to ectopic hormone syndromes (eg, lung and gastrointestinal tract) also had APUD cells scattered throughout them. It was originally thought that the tumor cells producing excessive amounts of polypeptide hormones were derived exclusively from APUD cells in the tissue of origin (eg, ACTH-producing cells of the lung).

Newer insights into tumor cell biology have led to a better understanding of the pathogenesis and etiology of the ectopic hormone production states. Studies have shown that not all APUD cells are derived from the neural crest. Some of these cells are of endodermal origin. Furthermore, with careful examination of tumors, it has become clear that peptide hormones are often produced by non-APUD cells. It has, however, been appreciated that the clinically evident hormone hypersecretion states are typically caused by tumors that are in fact derived from APUD cells. These cells are the ones with full capacity to produce and store peptide hormones efficiently in dense secretory granules and then release biologically significant quantities of active hormones into the circulation.

HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia is the most common paraneoplastic endocrine syndrome, occurring in approximately 20% of patients with cancer. In the great majority of patients (98%), the identity of the tumor is apparent at the time of presentation, and the prognosis is poor, as most patients with hypercalcemia of malignancy do not survive beyond 6 months. As discussed more fully in Chapter 8, signs and symptoms of hypercalcemia include nausea, vomiting, severe dehydration (exacerbated by hypercalcemia-induced nephrogenic diabetes insipidus) and a change in mental status.

Pathogenesis

Elevated serum calcium levels primarily result from excessive osteoclast-mediated bone resorption. Tumor-driven osteolysis occurs via two distinct mechanisms: (1) humoral effects of systemically elevated tumor-derived factors and/or (2) localized osteolysis adjacent to malignant cells within the bone marrow (Figure 21–1). When the syndrome of hypercalcemia of malignancy was first appreciated, direct invasion of bone by osteolytic tumors was thought to be causative. However, in the 1980s, a humoral basis was identified as the most frequent cause (>80%), even in settings where focal lytic bone metastases were present.
FIGURE 21–1 Schematic representation of causes and tumor types associated with hypercalcemia of malignancy.

Decreased renal calcium excretion may also contribute to pathogenesis, either because of the hypocalciuric effects of certain humoral mediators of hypercalcemia, such as parathyroid hormone (PTH)-related protein (PTHrP) (discussed later), or because of the decreased glomerular filtration that occurs with hypercalcemia-induced nephrogenic diabetes insipidus.

Humoral Mediators

A humoral cause of hypercalcemia of malignancy was first proposed by Fuller Albright in the 1940s when describing a case occurring in the absence of significant bone metastases. It would take another 50 years for this humoral factor to be identified. It was appreciated early on that the basic biochemical parameters of this syndrome (high serum calcium, low serum phosphorus, elevated nephrogenous cyclic adenosine monophosphate or cAMP) were suggestive of ectopic PTH production. However, PTH was not the culprit, as serum PTH levels in these cases were actually (and appropriately) suppressed. Ultimately, and unlike most other paraneoplastic endocrine syndromes that are caused by well-described hormones of known function, a novel peptide, PTH-related protein (PTHrP), was identified as the humoral mediator of this syndrome in a majority of cases (see Figure 21–1).

PTHrP, initially so named because of its shared biochemical/metabolic effects with PTH, has much in common with PTH. The amino terminal portion of PTHrP bears strong homology to PTH, such that the two peptides bind with similar affinity to a common receptor (now known as the PTH/PTHrP type 1 receptor [PTHR1]) in bone and kidney. Therefore, the biochemical markers of PTHrP-mediated hypercalcemia *in vivo*, when unregulated production by tumors causes elevated circulating PTHrP levels, are similar to those of hyperparathyroidism. Some unexplained differences, however, are seen in PTHrP-mediated

hypercalcemia of malignancy (vs primary hyperparathyroidism), including normal or suppressed 1,25-(OH)$_2$ D levels and an uncoupling of bone resorption and formation that results in severe bone loss. The reasons for these differences are not understood but are speculated to include: (1) the ability of profound hypercalcemia per se to suppress 1,25-(OH)$_2$ D levels; (2) the contributions of additional tumor-derived cytokines, such as interleukin (IL)-1α or IL-6, to the process of bone resorption; and (3) the ability of PTH and PTHrP to interact with the PTHR1 and activate signal transduction pathways differently.

Subsequent study of this previously unknown peptide demonstrated that PTHrP and PTH arose from ancient duplication of a common gene and diverged in their normal functions in many critical ways. Each hormone evolved separately such that in higher vertebrates, PTH regulates calcium homeostasis in an endocrine manner, while PTHrP has critical developmental roles, acting locally in a paracrine or autocrine fashion via binding to PTHR1-expressing cells, to mediate endochondral bone growth, tooth eruption, and the development of the mammary gland and cardiovascular system. As with other developmentally regulated proteins, PTHrP plays less of a role in adult homeostasis, but can be reexpressed in response to specific changes in gene programming, including pregnancy (calcium regulation by the lactating mammary gland and placenta), injury and inflammation (regulation of vascular tone in ischemia, sepsis, and inflammation-associated bone resorption), and/or tumorigenesis (hypercalcemia of malignancy).

When tumor expression of PTHrP results in inappropriately high PTHrP levels that reach bone cells via the circulation or local synthesis in the bone microenvironment, a vicious cycle can ensue. PTHrP stimulates osteoblast or stromal cell expression of RANKL (receptor activator of nuclear factor kappa B ligand), the primary gatekeeper modulating bone resorption in health and disease. RANKL binds to its receptor, RANK, on osteoclasts and

their precursors, stimulating osteoclast differentiation and function. Increased numbers of bone-resorbing osteoclasts are generated both by the local release of PTHrP in the case of bone metastases or by high systemic levels of tumor-derived PTHrP. Both mechanisms cause enhanced bone resorption. In the case of bone metastases, sequestered growth factors, such as transforming growth factor (TGF)-beta, released locally from the bone matrix during resorption, are thought to further enhance tumor cell secretion of PTHrP.

Although PTHrP is by far the most common humoral mediator of hypercalcemia of malignancy (see Figure 21–1), other calciotropic hormones can also cause the syndrome (<1% of cases). Elevated circulating 1,25-(OH)$_2$ D levels, which enhance intestinal calcium absorption and stimulate osteoclast differentiation, can cause hypercalcemia in lymphoma due to increased 1α-hydroxylase activity in tumor-associated macrophages and possibly the lymphoproliferative cells themselves. Ectopic production of PTH is extremely rare, but has occasionally been reported for neuroendocrine tumors (NETs) and other solid tumors.

Solid Tumors Associated with Hypercalcemia of Malignancy

The majority of cases of hypercalcemia occurring with solid tumors (80%) are associated with two common tumor types, squamous cell lung carcinoma and breast carcinoma, and are primarily due to humoral effects of PTHrP (see Figure 21–1). PTHrP-induced hypercalcemia is also frequently seen in renal cell carcinoma. Indeed, PTHrP was first isolated and identified by independent research groups using each of these three tumor types. In contrast, hypercalcemia is rarely seen in other commonly occurring cancers (eg, colon, gastric, thyroid, and small cell lung carcinomas), including tumors that are frequently metastatic to bone (eg, prostate cancer).

A. Squamous cell carcinomas   Squamous cell carcinomas account for more than one-third of all cases of hypercalcemia of malignancy. Humoral effects of tumor-derived PTHrP account for most cases of hypercalcemia in this setting, even when bone metastases are present. Twenty-five percent of patients with squamous cell lung carcinomas develop PTHrP-mediated hypercalcemia, and other sites of squamous cell carcinoma (head, neck, esophagus, cervix, vulva, and skin) are similarly associated with a high incidence of hypercalcemia.

B. Breast carcinoma   While osteolytic bone metastases are a hallmark of advanced breast cancer, occurring in 70% of cases, the majority of these women do not have hypercalcemia. However, when hypercalcemia does occur (30% of advanced-stage breast cancer), it is rarely seen in the absence of bone metastases. Most breast cancer bone metastases (>92%) express PTHrP; thus a local increase in PTHrP is thought to be a key driver of osteolysis-induced hypercalcemia (see Figure 21–1). In addition, humoral effects of PTHrP, as evidenced by elevated circulating levels of PTHrP associated with increased nephrogenous cAMP, have been

documented in two-thirds of hypercalcemia cases occurring with bone metastases as well as in the majority of cases occurring in the absence of bone metastases. Hypercalcemia seen in late stages of breast cancer is usually unremitting and associated with a survival time of weeks to months. Despite this close association of PTHrP with advanced disease, the prognostic significance and pathophysiologic role of PTHrP in primary breast carcinomas, two-thirds of which have been reported to express PTHrP, remain unclear.

C. Renal cell carcinoma   Renal cell carcinoma, while less common than squamous cell or breast carcinoma, is frequently associated with hypercalcemia in advanced cases. While bone metastases are common in advanced disease, hypercalcemia appears to be due primarily to humoral effects of PTHrP. In some series, 100% of renal cell tumors have been reported to stain positively for immunoreactive PTHrP. However, hypercalcemia is reported in less than 20% of cases.

D. Other solid tumors   Hypercalcemia is also associated with other solid tumors, although less frequently. In most of these cases, humoral effects of PTHrP are causative. Bladder carcinoma, large cell and adenocarcinoma of the lung, and endocrine tumors (including islet cell tumors, pheochromocytoma, and carcinoid tumors) have also been reported to secrete PTHrP. PTHrP-mediated hypercalcemia has also been reported for ovarian carcinomas. There are also rare case reports of ectopic PTH production by various neoplasms (eg, ovarian carcinoma, gastric carcinoma, lung cancer [small and squamous]).

Hematologic Malignancies Associated with Hypercalcemia of Malignancy

A. Multiple myeloma   Hypercalcemia (present in 10%-30% at diagnosis) and lytic bone lesions (present in up to 70% at diagnosis) are among the diagnostic criteria for multiple myeloma (MM), which is one of the most common hematologic malignancies. Focal oseolysis, the cause of hypercalcemia in MM (see Figure 21–1), occurs adjacent to malignant plasma cells, which infiltrate the bone marrow and secrete multiple factors capable of stimulating osteoclast differentiation and activity. A major effect of these factors, of which macrophage inflammatory peptide-1 is a key example, is to induce RANKL expression in cells of the osteoblastic lineage. Evidence of RANKL expression by plasma cells also exists. Locally increased RANKL causes bone lysis by binding to its cognate receptor RANK on osteoclast lineage cells, stimulating their differentiation and activity. Defects in bone formation, due to suppression of the Wnt signaling pathway by other tumor factors (eg, Dickkopf-1), also accompany lytic bone disease in MM. In 30% of cases, bone lysis leads to hypercalcemia. Because renal disease occurs frequently in MM due to the filtration of Bence Jones proteins (light chain fragments of IgG), it is hypothesized that patients with renal impairment may be particularly predisposed to development of hypercalcemia in this setting of increased bone resorption.

B. Lymphoma and leukemia Hypercalcemia has been reported in up to 15% of patients with lymphoma; is seen primarily in patients with bone involvement; and can occur with a variety of cell types. In most cases, the etiology is evenly divided between: (1) local lytic effects of tumor-derived factors within the marrow, analogous to the mechanisms discussed for MM, or (2) humoral effects of tumor-derived 1,25-$(OH)_2$ D (see Figure 21–1). 1,25-$(OH)_2$ D-mediated hypercalcemia of malignancy is nearly unique to lymphoma. Its underlying pathology is analogous to that seen in hypercalcemia in granulomatous disorders; in both settings, 1α-hydroxylase activity in infiltrating macrophages is thought to result in unregulated conversion of 25-(OH) D to active 1,25-$(OH)_2$ D. Increased intestinal calcium absorption and increased bone resorption contribute to hypercalcemia in this setting. In addition, there are numerous case reports of humoral effects of tumor-derived PTHrP as a cause of hypercalcemia in non-Hodgkin lymphomas (particularly B cell), acute lymphoblastic leukemia, and blast crises in chronic myeloid leukemia. Patients diagnosed with adult T cell leukemia/lymphoma induced by HTLV-1 (human T cell lymphotrophic virus-1), the first identified human retrovirus, must be considered separately when evaluating possible causes of hypercalcemia. In these patients, hypercalcemia occurs in two-thirds of cases, responds poorly to treatment, and is due to the humoral effects of tumor-derived PTHrP. Tax1, a transcription factor encoded by the HTLV-1 genome, transforms T cells in these cases by altering the regulation of hundreds of host genes, including transactivation of PTHrP. Thus, the clinician confronting lymphoma-induced hypercalcemia must be cognizant of the multiple etiologies driving hypercalcemia in that setting.

Diagnosis

The diagnosis of hypercalcemia is discussed in detail in Chapter 8. Primary hyperparathyroidism, the most common cause of hypercalcemia in outpatients, must still always be considered as a potential cause of hypercalcemia in patients with malignancy, where it can be causal in approximately 10% of patients and is simply screened for by assaying PTH levels. In the setting of hypercalcemia of malignancy with normal renal function, PTH levels are appropriately suppressed. Further evaluation can be guided, in part, by the tumor type, which is usually known prior to presentation with hypercalcemia. Elevated PTHrP is detected in a majority of cases of hypercalcemia of malignancy associated with solid tumors, including breast carcinoma with or without bone metastases, and in HTLV-1–induced T cell lymphomas. Measurement of 1,25-$(OH)_2$ D should be considered in all cases of lymphoma-associated hypercalcemia. Lytic bone lesions are usually identified during tumor staging.

Treatment

The treatment of hypercalcemia is discussed in detail in Chapter 8. In addition to an important role for saline rehydration to promote calciuresis, because bone resorption is central to all causes of hypercalcemia of malignancy, osteoclast-targeted bisphosphonates are a mainstay of therapy. Calcitonin is sometimes also used in the acute setting as its effect is more rapid, albeit of limited magnitude and duration. Denosumab, a monoclonal antibody targeting RANKL that prevents osteoclast differentiation, survival, and resorptive function, has recently been approved for use in the United States in cases of bisphosphonate-refractory hypercalcemia. Glucocorticoids may be efficacious in the treatment of hypercalcemia due either to the local lytic effects of neoplastic plasma cells in MM or to the increased production of 1,25-$(OH)_2$ D in lymphoma. Both bisphosphonates and denosumab are becoming mainstays of palliative care for patients with hypercalcemia; both have demonstrated ability to decrease skeletal-related events (metastases and pathologic fractures) and ameliorate bone pain in these patients. Possible use of these agents for the primary prevention of bone metastases (not yet established) in breast and other cancers is currently an active area of clinical research.

ECTOPIC CUSHING SYNDROME

Many malignant tumors produce the ACTH precursor proopiomelanocortin (POMC) but lack the enzymes necessary to process this precursor to biologically active ACTH. Therefore, only a fraction of such tumors release sufficient ACTH to cause Cushing syndrome. Initially, the tumors recognized to cause this syndrome were of nonpituitary but endocrine origin, such as islet cell carcinomas and pheochromocytomas. Subsequently, a wide variety of different tumor cell types, both endocrine and nonendocrine, have been associated with the ectopic ACTH syndrome.

The classic description of the ectopic ACTH syndrome was made by Grant Liddle and coworkers in the early 1960s and was based on a series of patients who mostly had highly malignant tumors (eg, small cell carcinoma of the lung). More recently, the ectopic ACTH syndrome has been recognized with increasing frequency with benign tumors, specifically carcinoids. Benign lesions typically present in a more subtle clinical manner, often over months to years, before the tumor is identified. The more gradual development of the clinical syndrome plus the more subtle biochemistry have led to considerable challenges in distinguishing this form of the ectopic ACTH syndrome from pituitary tumors causing Cushing disease. This subtle variant of tumor-induced ACTH excess has been dubbed the *occult* ectopic ACTH syndrome, especially when the tumor is not evident by the best diagnostic imaging modalities. Tumors can also cause an ectopic ACTH-like syndrome through production of corticotropin-releasing hormone (CRH), albeit rarely. Indeed, some of the tumors that make the latter cosecrete ACTH as well. Ectopic CRH production has been seen in bronchial carcinoids, medullary thyroid carcinoma, and metastatic prostatic cancer.

Differential Diagnosis

Cushing syndrome—signs and symptoms resulting from unregulated production of glucocorticoids—is caused by a number of underlying disturbances. These must be differentiated to ensure successful treatment. Causes include pituitary ACTH-dependent

Cushing disease, adrenal tumors or ACTH-independent Cushing syndrome, and the ectopic ACTH syndrome. In several large series, 50% to 80% of patients with Cushing syndrome have a pituitary cause. Adrenal adenomas (and very rarely carcinomas) account for 5% to 30% of cases of Cushing syndrome. The ectopic ACTH syndrome comprises approximately 10% to 20% of cases of Cushing syndrome.

A wide variety of tumors cause ectopic ACTH syndrome (Table 21–2). In the classic and initial descriptions of this syndrome, there was a preponderance of malignant tumors, particularly small cell carcinomas of the lung. It is now clear that most cases of ectopic ACTH syndrome are due to benign tumors. Most recently, microscopic carcinoid *tumorlets*, particularly in the lung, have been recognized to cause occult ectopic ACTH syndrome. These tumors may be exceptionally difficult to diagnose by standard techniques.

The diagnosis of Cushing syndrome requires a rigorous approach. Cushing syndrome should be suspected first on solid clinical grounds and then established biochemically. This is accomplished by demonstrating the presence of hypercortisolism—a frankly elevated 24-hour urinary free cortisol level, lack of suppression of plasma cortisol levels after a 1-mg overnight dexamethasone suppression test, or elevated late night salivary cortisol levels (see Chapter 9). In Cushing syndrome due to any cause and often in ectopic ACTH syndrome, random cortisol levels are elevated. Once hypercortisolism is established, plasma ACTH levels are measured. These levels are markedly elevated in classic forms of the ectopic ACTH syndrome, typically secondary to malignant lung neoplasms. There is, however, considerable overlap between the milder cases of the ectopic ACTH syndrome, caused by benign and slowly growing tumors, and Cushing disease due to a pituitary tumor. In the former case, the tumors are often small and clinically silent—hence the descriptor *occult* ectopic ACTH syndrome. For these reasons, rigorous biochemical criteria must be applied in appropriate clinical situations to make certain that the correct diagnosis is made. Plasma ACTH levels in patients with clinically evident tumors are often strikingly elevated (390-2300 pg/mL [87-511 pmol/L] by radioimmunoassay). Individuals with ectopic ACTH syndrome due to occult tumors have ACTH levels that overlap with pituitary-dependent Cushing disease (42-428 pg/mL [9.3-95 pmol/L]). It is said that patients with plasma ACTH levels greater than 200 pg/mL (44.4 pmol/L) typically have the ectopic ACTH syndrome, although further testing is required to prove this and to localize the tumor.

After hypercortisolism and ACTH excess are established, the degree of suppressibility of ACTH with exogenous glucocorticoid is determined. In classic Cushing disease due to a pituitary tumor, supraphysiologic doses of dexamethasone usually suppress the elevated plasma cortisol levels. Tumors responsible for the ectopic ACTH syndrome are classically unresponsive to these same doses of dexamethasone. High-dose dexamethasone suppression testing, as this diagnostic maneuver is called, is accomplished by (1) administering 2 mg of dexamethasone every 6 hours for 2 days and measuring urinary free cortisol or plasma cortisol on the second day, or (2) administering 8 mg of dexamethasone the night before obtaining an 8 AM plasma cortisol level. In both tests, the expected suppression of baseline urinary free cortisol and plasma cortisol should be 50% or greater if the Cushing syndrome is due to a pituitary adenoma (ie, Cushing disease). However, between 15% and 33% of patients with ectopic ACTH syndrome also meet these suppression criteria (false positives), mimicking Cushing disease. In addition, 10% to 25% of patients with Cushing disease fail to suppress with high-dose dexamethasone (false negatives). The overnight test probably has greater sensitivity and accuracy than the classic 2-day test, but neither test is considered useful any longer (see Chapter 9).

Additional provocative tests have been developed to improve the diagnostic discrimination between Cushing disease and ectopic ACTH syndrome using ovine CRH. Pituitary corticotrophs are normally responsive to CRH in Cushing disease and unresponsive when ectopic ACTH production or an adrenal lesion is responsible for the cortisol excess. A positive response to CRH is defined as a 50% or greater increase in plasma ACTH and a 20%

TABLE 21–2 Tumors responsible for the ectopic ACTH syndrome in two large contemporary series.

Tumor Type	Number of Patients (% of total) NIH Series (USA) (1983-2004)[a]	Number of Patients (% of total) St. Bartholomew's Hospital (UK) Cushing Disease Database (1969-2001)[b]
Carcinoid		
Thymic	5/90 (5.5%)	2/40 (5%)
Pulmonary	35/90 (39%)	12/40 (30%)
Appendiceal	1/90 (1%)	–

[b]Data from Isidori AM, Kaltsas GA, Pozza C. Extensive clinical experience: the ectopic adrenocorticotropin syndrome: clinical features, diagnosis, management, and long-term follow-up. *J Clin Endocrinol Metab*. 2006;91:371.

or greater increase in the plasma cortisol concentrations in the periphery. An increase in ACTH of 100% and in cortisol of more than 50% greatly reduces the likelihood of ectopic ACTH syndrome; however, false-positive and false-negative tests (up to 10%) have been reported. Moreover, in the rare instance of ectopic production of CRH (without concomitant ACTH) by a tumor, a false-positive result may be seen, leading to the erroneous diagnosis of pituitary-dependent Cushing disease.

For these reasons, most centers prefer inferior petrosal sinus sampling for ACTH before and after CRH administration, and this test is now the gold standard. The inferior petrosal sinuses drain the pituitary gland. Concomitant peripheral and petrosal sinus samples are obtained, and the central: peripheral ACTH ratio is calculated. In Cushing disease, the ratio should be greater than or equal to 2.0 in the basal state. After CRH administration, this ratio should be greater than or equal to 3.0 in pituitary-dependent Cushing disease. In the ectopic ACTH syndrome, the basal ratio is typically less than 2 and does not rise after the CRH. In rare instances of ectopic CRH syndrome, the basal ratio may be 2.0. The stimulation by CRH gives close to 100% discrimination between ectopic ACTH production and a pituitary tumor secreting ACTH. Generally, a combination of tests is performed to reach a biochemical diagnosis before extensive radiologic studies are undertaken.

The majority of patients (70% or more) with ectopic ACTH syndrome also cosecrete other hormones or tumor marker peptides, among them are carcinoembryonic antigen, somatostatin, calcitonin, gastrin, glucagon, vasoactive intestinal peptide (VIP), bombesin, pancreatic polypeptide, alpha-fetoprotein, and many others. The presence and secretion of these other hormones (in addition to ACTH) suggests that the source of ACTH is nonpituitary in these patients. Given the variety of peptides and the expense inherent in any screening paradigm, measuring these hormones in patients suspected of ectopic ACTH syndrome is not recommended.

The path to localize the tumor responsible for ectopic ACTH production generally starts with chest and abdominal imaging as most tumors are located there. Small cell carcinomas of the lung are usually visible on chest radiograph, whereas bronchial carcinoids are often difficult to detect on plain radiographs. In some situations, these tumors may require a long period (as many as 4 or 5 years) of close follow-up before the tumors are detected. Chest computed tomography (CT) scanning should be employed in all subjects with ectopic ACTH to rule out a lung or mediastinal lesion (such as a thymic carcinoid). Abdominal CT scanning is also performed in these patients to confirm the presence of bilateral adrenal enlargement, a sine qua non of the ectopic ACTH syndrome, and to screen for other possible abdominal tumors responsible for the syndrome (eg, pheochromocytoma, islet cell tumor). In the radiologic evaluation of Cushing syndrome, it is always important to bear in mind that the presence of a pituitary microadenoma on magnetic resonance imaging (MRI) does very little to support the diagnosis of pituitary-dependent Cushing disease—as opposed to an ectopic tumor producing ACTH—because of the great numbers (10%-20%) of

normal individuals with incidental pituitary microadenomas (see Chapter 4). An exception is the pituitary tumor greater than 6 mm. If a lesion of that size is seen, then a pituitary etiology can be strongly considered, if the remainder of the diagnostic testing supports a central etiology.

Octreotide scanning, another important diagnostic technique, can successfully localize tumors responsible for ectopic ACTH production because up to 80% of such tumors express somatostatin receptors. Iodinated or, more recently, indium-111(^{111}In)-labeled octreotide scanning has demonstrated medullary carcinomas of the thyroid, small cell lung cancers, islet cell tumors, pheochromocytomas, and other tumors.

The ideal imaging algorithm for occult tumors causing ectopic ACTH syndrome is controversial. Functional imaging with higher than standard doses of the somatostatin analog [^{111}In]-diethylene triamine pentaacetate-D-Phe-pentetreotide (OctreoScan) or with [^{18}F]-fluorodeoxyglucose positron emission tomography (FDG-PET) was prospectively evaluated in 17 patients with the ectopic ACTH syndrome (based on inferior petrosal sinus sampling) in whom standard imaging studies were inconclusive. Nieman and colleagues found that FDG-PET did not uncover tumors that were not seen on CT or MRI scans. These investigators, however, found OctreoScans to be useful (enhanced sensitivity) in combination with CT/MRI imaging and advocated this diagnostic approach. The somatostatin receptor PET tracer ^{68}Ga-DOTA-NOC (^{68}Ga-labeled [1,4,7,10-tetraazacyclododecane acid]-1-Nal3-octreotide) PET/CT scanning has also been compared to contrast-enhanced CT for localizing tumors in ectopic ACTH, and while sensitivity may be lower, false-positive rates are very low.

Clinical Features

Cushing syndrome causes truncal obesity, violaceous striae, hypertension, fatigue, glucose intolerance, osteopenia, muscle weakness, moon facies, easy bruisability, buffalo hump, depression, hirsutism, and edema. Patients with ectopic ACTH syndrome may show some, all, or none of these features depending on the underlying tumor. It has been appreciated from the initial descriptions of this syndrome that these patients typically present with myopathy, weight loss, and electrolyte and metabolic disturbances more commonly than with the classic features of slowly developing Cushing disease. Hyperpigmentation is also recognized as more common in the ectopic ACTH syndrome than in Cushing disease. Cortisol excess in older men, especially those at risk for lung tumors, is most commonly due to ectopic ACTH production, whereas ACTH-producing pituitary tumors predominate in young and middle-aged women. Glucose intolerance or frank diabetes and hypokalemic alkalosis are typical metabolic disturbances of the ectopic ACTH syndrome. Because of the extreme elevation in plasma cortisol levels in many of these patients, they are at considerable risk for and often succumb to overwhelming opportunistic infections, often with fungal pathogens.

A critical caveat to remember in the clinical evaluation of patients with ACTH-dependent Cushing disease is that slowly

growing and occult tumors producing ACTH may present in exactly the same way as classic Cushing disease due to a pituitary tumor. Therefore, both the clinical findings and the laboratory studies summarized earlier show considerable overlap and may engender confusion in distinguishing these occult tumors from a pituitary lesion.

A small number of patients who have classic features of Cushing syndrome have been shown to have abnormal expression of receptors in their adrenal glands as the cause of their hypercortisolism. The pathophysiology of this form of Cushing syndrome is ACTH-independent, because other hormones are driving the glucocorticoid hypersecretion. This has been likened by Lacroix and colleagues to a *gain of function* mutation causing constitutive activation of a G protein–coupled receptor. Ectopic expression of receptors for gastric inhibitory peptide (GIP), vasopressin (V_2 and V_3), serotonin (5-HT_7), and beta adrenergic agonists have been reported. Altered activity or greater expression of eutopic receptors for serotonin (5-HT_4), LH, and vasopressin (V_1) in adrenal tissue can also cause cortisol excess. In the case of GIP, food-stimulated cortisol hypersecretion has been described. In a case report of excessive LH receptor expression in the adrenals associated with macronodular adrenal hyperplasia, the patient had mild Cushingoid features with pregnancy and the gradual development of full-blown Cushing syndrome with menopause. It is noteworthy that many patients with ectopic or eutopic receptor-mediated Cushing syndrome have macronodular adrenal hyperplasia.

Treatment

Because of the morbidity and mortality of untreated and often severe hypercortisolism (especially due to ectopic ACTH syndrome), therapy is often rapidly instituted to reduce complications. Surgical excision and debulking of the tumor, along with chemotherapy and/or radiation, offer the chance for immediate relief, if the resection is complete. If the tumor cannot be removed, then medical therapy with adrenal steroidogenesis blockers, either alone or in combination, may be instituted including metyrapone, ketoconazole, and mitotane. Limited success is reported with dopamine agonist therapy with cabergoline or with somatostatin receptor-based therapy with octreotide. The glucocorticoid, progesterone, and androgen receptor antagonist mifepristone has also been tested in patients with ectopic ACTH syndrome. The agent may work quickly to block glucocorticoid action and is approved for control of hyperglycemia in patients with hypercortisolism secondary to endogenous Cushing syndrome who have failed surgery or are not candidates for it. The anesthetic agent etomidate can be used to turn off steroidogenesis rapidly in the acutely ill patient deteriorating rapidly from consequences of severe hypercortisolism. All medical therapies require careful dosing and close monitoring for toxicity and for complete adrenal blockade with the emergence of adrenal insufficiency. To gain definitive control of hypercortisolism, bilateral adrenalectomy is an additional option. Expert care by an experienced team of endocrinologists, oncologists, and radiologists is essential for successfully treating these complex and ill patients.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

The syndrome of inappropriate antidiuretic hormone (SIADH) secretion is characterized by inappropriate retention of water such that hypertonic or inappropriately concentrated urine is excreted in the presence of euvolemic hyponatremia. There are many well-recognized causes of this syndrome (Table 21–3).

Etiology and Pathogenesis

Tumors are a common cause of SIADH (see Table 21–3). Bronchogenic carcinoma, particularly small cell carcinoma, has been associated with this syndrome since its initial description in 1957 by Schwartz and Bartter. Small cell carcinoma accounts for 80% of lung tumors associated with SIADH, but only 3% to 15% of patients with this tumor have SIADH. Most of these tumors, even from patients without the clinical syndrome, contain ADH by immunostaining. Other tumors that cause the syndrome include breast, pancreatic, and thymic carcinomas in addition to those listed in Table 21–3. Other causes of excessive ADH release and

TABLE 21–3 Causes of SIADH.

Tumors
    Small cell carcinoma of lung
    Squamous cell carcinoma of lung
    Cancers of the head and neck
    Carcinoma of the duodenum, pancreas, ureter, prostate, uterus, and nasopharynx
    Mesothelioma
    Thymoma
    Hodgkin lymphoma
    Leukemia

Central nervous system disorders
    Brain tumors (primary and metastatic)
    Brain abscess
    Subdural hematoma, subarachnoid hemorrhage
    Meningitis, encephalitis
    Systemic lupus erythematosus
    Demyelinating disorders
    Head trauma
    Acute intermittent porphyria
    Guillian-Barré syndrome
    Spinal cord lesions
    Pituitary stalk lesion
    Transsphenoidal adenectomy
    Hydrocephalus

Drugs
    Nicotine, phenothiazines, tricyclic antidepressants, nonsteroidal anti-inflammatory agents, cyclophosphamide, vincristine, chlorpropamide, colchicine, selective serotonin reuptake inhibitors (sertraline, fluoxetine), azithromycin, thiazide diuretics

Pulmonary disorders
    Tuberculosis
    Fungal, bacterial, viral, mycoplasmal pneumonia
    Empyema, lung abscess
    Chronic obstructive pulmonary disease

Nephrogenic syndrome of inappropriate antidiuresis

Data from Verbalis JG. Disorders of body water homeostasis. *Best Pract Res Clin Endocrinol Metab.* 2003 Dec;17(4):471-503.

of hyponatremia in patients with cancer such as anticancer therapy, other drug treatments, pain, nausea, and vomiting should be considered in this setting.

Excessive production of ADH by tumors leads to an inability to excrete free water. This is due to the fact that tumors release ADH independent of serum osmolality. In addition to the production of ADH, many tumors also contain the mRNA for the hormone atrial natriuretic peptide (ANP), which likely causes no clinical symptoms.

Clinical and Laboratory Features

SIADH is the most common cause of hyponatremia in hospitalized patients. It may present with symptoms due to water intoxication and hyponatremia. Although many patients are asymptomatic, depending on the magnitude and chronicity of their hyponatremia, symptomatic individuals usually have fatigue, headache, nausea, and anorexia initially, which can progress to altered mental status, gait instability and falls, seizures, coma, and even death. Most patients experience weight gain due to water retention but do not have edema. Significant clinical symptoms usually do not develop unless the serum sodium is 125 mEq/L or less, and there is usually a correlation between the level of symptomatology in these patients and their serum sodium values.

Patients with SIADH exhibit hyponatremia, serum hypo-osmolality, less than maximally dilute urine, and the presence of sodium in the urine. Clinically, the diagnosis of SIADH cannot be made unless there is euvolemia with intact renal, adrenal, and thyroid function. Cirrhosis with ascites, nephrosis, congestive heart failure, and recent diuretic use must be excluded. Urinary sodium levels are usually high (>30 mmol/L), and serum urea nitrogen levels are typically low, as are serum uric acid levels. Rarely is it necessary or even helpful to measure ADH levels to make this diagnosis. Although these determinations are available, they are even sometimes misleading. Recent studies support the possibility that copeptin, the C-terminal part of ADH molecule, may be a more stable surrogate marker for ADH and may prove useful ultimately for diagnosis. Once the diagnosis of SIADH is made, all possible causes should be considered (see Table 21–3).

Water restriction and demeclocycline are the traditional therapies. Studies support the efficacy of selective vasopressin antagonists (vaptans) in the treatment of SIADH, and this approach may be considered in cases refractory to the above measures and/or before the use of demeclocycline. In acutely symptomatic patients or when the serum sodium is dangerously low and symptoms of hyponatremia are present, infusion of hypertonic saline and administration of loop diuretics (eg, furosemide) are the treatments of choice. Many patients with SIADH due to neoplasms improve and even remit with effective therapy for their underlying cancer.

NON-ISLET CELL TUMOR-INDUCED HYPOGLYCEMIA

Tumor-induced hypoglycemia is rare and most commonly caused by eutopic insulin production by pancreatic islet cell tumors (insulinomas). The remainder of cases (20%) are primarily due to tumor-derived insulin-like growth factor-2 (IGF-2). Ectopic insulin secretion by tumors has only rarely been reported, and other tumoral mechanisms inducing endogenous insulin are also rare (tumor production of GLP-1 or antibodies against insulin or its receptor).

The most common sources of ectopic IGF-2 driving non-islet cell tumor-induced hypoglycemia are either: (1) large (>2 kg), slow-growing and well-differentiated solitary fibrous tumors of mesenchymal origin (22%) that primarily arise in the pleura but also occur at other sites (bladder, uterus); or (2) hepatocellular carcinomas (17%). Other less commonly reported tumors associated with IGF-2-induced hypoglycemia include adenocarcinomas, gastrointestinal stromal tumors, sarcomas, adrenocortical carcinoma, phyllodes breast tumors, and renal cell carcinomas. Subtle signs of fasting hypoglycemia may be the presenting symptom in these cases, or hypoglycemia may be detected during the course of tumor treatment. As discussed fully in Chapter 18, signs and symptoms of fasting hypoglycemia include sweating, intense hunger, anxiety, altered consciousness, and visual and behavioral changes.

Non-islet cell tumor, IGF-induced hypoglycemia, first described in 1930 by Doege, was identified in a patient with of hypoglycemia associated with a pleural mesenchymal tumor (now specifically known as the Doege-Potter syndrome). This was originally attributed to glucose utilization by these large tumors. However, hypoglycemia is only seen in 5% of such tumors. The actual pathogenesis for non-islet cell tumor-induced hypoglycemia by these and other tumors was elucidated in the last few decades in parallel with our increased understanding of IGF biology. *IGF-2* gene expression is increased in these tumors; however, posttranslational processing is disrupted such that the majority of circulating IGF-2 is a precursor pro-IGF-2 protein (big IGF-2). Big IGF-2 is less likely to form normal ternary complexes with IGF-binding protein 3 (IGF-BP 3) and an acid labile subunit, and therefore is more bioavailable. In addition, it is postulated that big IGF-2 may displace normal IGF-1 and IGF-2 from IGF-BP, as free levels of these hormones are also increased in some patients. In addition, big IGF-2 is thought to feedback inhibit growth hormone (GH) secretion, thus resulting in even lower levels of IGF-BP. This vicious cycle enhances the bioavailability of free IGF peptides whose affinity for the insulin receptor is only tenfold lower than that of insulin itself. The typical hormonal profile of patients with this syndrome includes suppressed levels of insulin, C-peptide, and total IGF-1; and normal or only slightly elevated levels of total IGF-2, while levels of free IGF-2 are markedly (20-fold) increased.

Stimulated glucose disposal in skeletal muscle by IGF binding to the insulin receptor is thought to be a major contributor to hypoglycemia in this syndrome. Diminished hepatic glucose production due to hepatic insulin receptor–mediated IGF-2 effects may also contribute. While GH levels are suppressed, some acromegalic features, thought to be secondary to IGF-2 binding to the type 1 IGF receptor, can also be present (skin tags, rhinophyma).

Treatment of this paraneoplastic syndrome usually involves curative resection or debulking of the tumor. Preoperatively, patients often require continuous glucose infusions to control

their symptoms, and glucagon can be used acutely to raise blood glucose levels. If the lesion is benign, surgery usually brings relief of the hypoglycemia or even definitive cure. In the absence of a surgical cure, additional palliative measures to control hypoglycemic symptoms have been used with some success, including (1) glucocorticoid treatment to suppress tumor production of IGF-1 and induce hepatic gluconeogenesis, and/or (2) GH treatment to increase serum levels of IGF-BP, as well as to induce hepatic gluconeogenesis.

OTHER HORMONES SECRETED BY TUMORS

1. GROWTH HORMONE–RELEASING HORMONE AND GROWTH HORMONE

Acromegaly is primarily due to eutopic production of GH by pituitary adenomas. The remainder of cases (<2%) are due to ectopic production of growth hormone releasing hormone (GHRH) by well-differentiated NETs, the majority of which are bronchial carcinoids or pancreatic endocrine tumors. Ectopic GH overproduction is extremely rare and primarily due to tumors in the sphenoid sinus which may either be pituitary remnants in the embryological pathway of Rathke's pouch invagination and/or inferior protrusions of pituitary tumors due to sellar defects.

Ectopic secretion of GHRH was first described in 1974. Indeed, this hypothalamic hormone was first isolated a decade later from patients with pancreatic GHRH-producing tumors. Excessive peripheral production of GHRH causes hyperplasia of somatotrophs in the pituitary. Resultant elevated levels of circulating GH and IGF-1, lack of suppression of GH by an oral glucose load, and clinical features of acromegaly in this setting are indistinguishable from those caused by GH-secreting pituitary adenomas (see Chapter 4), which can lead to misdiagnosis and unnecessary transsphenoidal surgery. Ectopic GHRH as a cause of acromegaly can be simply and specifically diagnosed by documentation of elevated circulating GHRH levels. However, because ectopic GHRH is rarely a cause of acromegaly, this assay is best reserved for atypical presentations associated with additional signs and symptoms specific to those tumors that are the most frequent source of ectopic GHRH (carcinoid and pancreatic tumors). It should also be noted that in rare instances, hypothalamic GHRH-secreting tumors (hamartomas, gliomas, and gangliocytomas) can also produce excessive GHRH and acromegaly. Because the site of GHRH production is within the hypothalamus, these cases do not represent ectopic GHRH secretion. Moreover, from a diagnostic standpoint, circulating GHRH levels in these cases are not elevated.

Carcinoid tumors, primarily in the lung, but occasionally at other sites (gastrointestinal tract or thymus) are the most frequent peripheral source of GHRH (>50%), followed by pancreatic islet cell tumors (30%). Other NETs associated with GHRH-induced acromegaly include pheochromocytoma, small cell lung cancer, adrenal adenoma, medullary thyroid carcinoma, endometrial cancer, and breast cancer. Interestingly, while 50% of carcinoid

tumors and 25% of endocrine tumors are immunoreactive for GHRH, a minority of these tumors is associated with elevated circulating levels of bioactive GHRH. Slow-growing GHRH-producing carcinoid tumors, the majority of which are bronchial in origin, are responsible for an insidious presentation of acromegaly that is often associated with additional symptoms specific to the tumor (eg, wheezing). While these tumors can be easily detected by routine imaging, octreotide scanning may also be helpful as somatostatin receptors are often present in GHRH-secreting tumors. While 50% of GHRH-secreting tumors have metastasized at time of diagnosis, long-term survival is high, consistent with the indolent nature of many NETs. In addition to surgical resection, somatostatin analogs, particularly those binding to multiple somatostatin receptor subtypes, can be useful in the management of ectopic GHRH-induced acromegaly.

2. CALCITONIN

Circulating levels of calcitonin, formed normally by cleavage of procalcitonin within the C cells of the thyroid in response to hypercalcemia, are elevated when overproduced eutopically by medullary thyroid cancer (see Chapters 7 and 24). NETs of the foregut (primarily pancreas and lung) are the primary source of ectopic calcitonin secretion. Consistent with our lack of knowledge regarding the precise physiologic role of calcitonin, there is often no clinical syndrome associated with its ectopic production. However, after an initial diagnosis, calcitonin levels have been used as a tumor marker to follow responses to treatment. While the incidence of calcitonin hypersecretion appears to be higher in lung (53%) versus pancreatic NETs (11%), pancreatic NETs appear to be the most common source of ectopic calcitonin due to their higher prevalence in reported series. In almost all reported cases of calcitonin-secreting NETs, liver or bone metastases are present. Calcitonin hypersecretion by NETs (or medullary thyroid carcinoma) is often associated with diarrhea (30% of cases) that is poorly responsive to somatostatin, and is likely attributable to calcitonin and/or other gut derived peptides frequently cosecreted by NETs. In the absence of renal failure, which is also associated with elevated calcitonin levels, or evidence of a thyroid tumor, high serum calcitonin levels should suggest a possible foregut NET source. It should be noted that while circulating procalcitonin levels are markedly increased in response to certain inflammatory stimuli, such as bacteremia, calcitonin levels are normal or only moderately elevated in these settings.

3. GONADOTROPINS

The gonadotropins, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and human chorionic gonadotropin (hCG), are structurally related heterodimeric ($\alpha\beta$) glycoproteins that share a common alpha subunit. While hCG is primarily known for its role as a placenta hormone, being produced by trophoblastic cells during pregnancy, all three are in fact produced by the normal pituitary. While LH and FSH are rarely produced ectopically, hCG overproduction by a variety of tumors is common. Ectopic hCG production must be distinguished from eutopic secretion

by trophoblastic tumors (hydatidiform mole, choriocarcinoma). Trophoblastic tumors frequently secrete intact hetrodimers of hCG that are either normally or heavily (hyper-) glycosylated, with the later moiety being particularly associated with choriocarcinoma and normal pregnancy implantation (extravillous invasion of cytotrophoplasts). Germ cell tumors of the testes or ovary also secrete intact hCG (or beta subunits); indeed, serum levels of intact hCG, which are secreted by 20% to 50% of testicular germ cell tumors, are used for diagnosis and monitoring. In contrast, non-trophoblastic, non-germ cell tumors primarily secrete the free beta subunit of hCG (hCGβ), which has been demonstrated to promote tumor growth by inhibiting apoptosis. While hCG binds to a common receptor with LH (the LH/CG receptor), due to the high homology of their beta subunits, which arose from a gene duplication event, the means by which hCGβ exerts its biological effects is not well understood. High circulating levels of hCGβ occur commonly with a large number of tumor types, including: genitourinary tumors (10%-75% of bladder cancers, 25% of renal cancers), non-trophoblastic gynecologic cancers (20%-75% of endometrical cancers), gastrointestinal cancers (40%-60% of biliary, pancreatic and gastric cancers; 15%-20% of liver and colorectal cancers), and lung cancers (13% of small cell cancers, 6% of all cancers). In all cases, increased serum concentrations of hCG are associated with poorer prognosis. Increases in serum immunoreactive hCG, while mild, have frequently been reported in breast cancer (10%-50%) but are of unclear significance, in part due to their possible attribution to the normal increase in pituitary hCG secretion that occurs with age and menopausal status. Given the frequent adverse association between tumor hCG production and prognosis, hCG has been a target of interest for cancer therapeutics. Depending on the hCG isoform produced (intact heterodimer vs beta subunit) and the age and gender of the patient, the clinical signs and symptoms of hCG excess are variable (precocious puberty in children, uterine bleeding in women, hypogonadism in men) and may be absent.

ONCOGENIC OSTEOMALACIA

Etiology and Clinical Features

Oncogenic osteomalacia is a syndrome associated with unusual mesenchymal tumors and rarely with prostate cancer and multiple myeloma. Patients with the syndrome have hypophosphatemia, renal phosphate wasting, and typically low or inappropriately normal serum levels of 1,25-(OH)$_2$ D. Alkaline phosphatase activity, reflecting bone turnover, is often elevated. Levels of calcium are typically normal, although in some cases PTH levels are elevated and calcium levels low. Hypophosphatemia is due to reduced renal phosphate reabsorption. Clinical symptoms include bone pain, proximal muscle weakness, fractures, back pain, waddling gait, and progressive debility. The syndrome often poses a significant diagnostic dilemma to clinicians, because the tumors responsible for it may be very small, obscurely situated, and difficult to identify. Phosphate depletion and low 1,25-(OH)$_2$ D levels lead to poor bone mineralization and osteomalacia. Typically, the diagnosis of osteomalacia is not suspected for years despite the presence of classic symptoms. The humoral basis for the syndrome is supported by the observation that the biochemical abnormalities remit and the osteomalacia heals when the tumor responsible for it is removed.

Pathology and Pathogenesis

Tumors responsible for oncogenic osteomalacia are usually small and grow slowly. The histology is described as phosphaturic mesenchymal tumor mixed connective tissue variant. Because of the unusual histology and often unanticipated locations for these tumors, the syndrome has been dubbed "strange tumors in strange places" by Weiss and colleagues. The range of locations for these tumors includes the lower extremities (45%), head and neck (27%), and upper extremities (17%). In a review of head and neck tumors that cause oncogenic osteomalacia, Gonzalez-Compta and coworkers noted that in 57% and 20% of cases, respectively, tumors were in the sinonasal and mandibular areas. These tumors are generally solitary lesions and benign, although multifocal lesions have been reported as well as malignant phenotypes.

The histologic spectrum of tumors includes hemangiomas, hemangiopericytomas, angiosarcomas, chondrosarcomas, prostate cancer (particularly castrate-resistant), schwannomas, neuroendocrine lesions, mesenchymal tumors, and uncommonly MM. Many of these tumors, classified pathologically as mixed connective tissue tumors, are located in bone. Osteoclast-like giant cells and stromal cells as well as highly vascular features characterize these tumors. Delays in diagnosis of as long as 19 years have been reported, thereby supporting the hypothesis of slow growth of these tumors.

Most of the tumors responsible for this syndrome overexpress fibroblast growth factor (FGF) 23, a protein important in normal phosphate homeostasis (see Chapter 8). FGF23 overexpression appears to be responsible for key aspects of oncogenic osteomalacia, and levels of FGF23 are often dramatically elevated. These levels fall in response to tumor resection, and the biochemical changes and osteomalacia typically resolve after surgery. In addition to FGF23, other genes have been implicated in the pathogenesis of oncogenic osteomalacia including FGF7, the matrix extracellular phosphoglycoprotein (MEPE), and frizzled related protein 4 (FRP4).

Depending on the series, approximately 40% to 60% of FGF23-producing tumors express a fibronectin-FGF-receptor 1 (FN1-FGFR1) fusion gene and some even an FN1-FGF1 fusion gene at a lower prevalence. These findings may be of pathogenetic significance in that FN signaling can increase FGF23 production through an autocrine/paracrine mechanism. Therapies targeting the FGFR1 are being developed as medical therapies for unresectable and metastatic lesions in patients with oncogenic osteomalacia along with antibodies directed against FGF23 itself.

Localization

Tumors causing oncogenic osteomalacia are often small and difficult to find. Thorough cranial, chest, abdominal, pelvic, and extremity imaging are essential for anatomic localization toward

the goal of surgical cure. Somatostatin receptor-based scintigraphy is often an early diagnostic step using 111-Indium octreotide SPECT/CT. 68-Gallium DOTA-TATE PET/CT has also been successful in finding these tumors, which should then be definitively localized by MRI scanning. For tumors that resist localization by these means, selective venous sampling for intact FGF23 has been successfully employed.

Comparison with Other Disorders of FGF23 Overproduction

Tumor-induced osteomalacia and X-linked hypophosphatemic rickets share many features. These features include rickets in growing children and osteomalacia in adults along with hypophosphatemia, low or inappropriately normal $1,25\text{-}(OH)_2$ D, and elevated FGF23 levels. Despite these similarities, there are several unresolved differences between the two syndromes. One is that levels of $1,25\text{-}(OH)_2$ D are inappropriately normal in patients with X-linked hypophosphatemic rickets and frankly low in oncogenic osteomalacia. In addition, patients with X-linked hypophosphatemic rickets demonstrate osteosclerosis and enthesopathy (calcification of tendons and ligaments), which are not seen in oncogenic osteomalacia.

X-linked hypophosphatemic rickets is due to defective functioning of the *PHEX* gene product (PHEX), a protein that is homologous to neutral, membrane-bound endopeptidases. PHEX is thought to activate or inactivate a circulating factor involved in phosphate metabolism, termed phosphatonin. It has long been proposed that the normal function of phosphatonin was to block renal phosphate reabsorption. FGF23 has been shown to inhibit phosphate uptake in kidney cells. PHEX, the endopeptidase product of the *PHEX* gene, can degrade FGF23, but FGF23 is not thought to be a substrate *in vivo* for PHEX. There remain several crucial details to establish regarding the pathogenesis and manifestations of oncogenic osteomalacia and X-linked hypophosphatemic rickets.

GUT HORMONES

Gut hormones, including VIP, somatostatin, gastrin-releasing hormone, and pancreatic polypeptide can be produced ectopically, particularly by NETs (carcinoid, pancreatic islet, and small cell lung cancer). Of these, only ectopic VIP secretion produces a clinical syndrome of voluminous secretory diarrhea, achlorhydria, and hypokalemia. This constellation of symptoms (Verner-Morrison syndrome) has been termed pancreatic cholera when caused by a pancreatic VIP-secreting islet cell tumor. A variety of nonendocrine and neuroendocrine tumors can express and release VIP, including small cell carcinomas of the lung, carcinoids, pheochromocytoma, medullary carcinomas of the thyroid, and some colonic adenocarcinomas. VIP and its closely related hormone PACAP (pituitary adenylate cyclase activating peptide) both have effects on the growth and angiogenesis of the tumors that produce them. These peptides and their receptors are being targeted for the development of new therapies including radioanalogues that may prove useful for molecular localization of the tumors and their metastatic deposits.

Multiple Endocrine Neoplasia

David G. Gardner, MD, MS

ACTH	Adrenocorticotropic hormone	**MEN**	Multiple endocrine neoplasia
CT	Computed tomography	**MRI**	Magnetic resonance imaging
GDNF	Glial cell line-derived neurotrophic factor	**PCR**	Polymerase chain reaction
GDNFR	Glial cell line-derived neurotrophic factor receptor	**PTH**	Parathyroid hormone
		RET	Rearranged during transfection proto-oncogene
GNAS	Gene encoding the alpha subunit of a stimulatory G protein	**VIP**	Vasoactive intestinal peptide
HLXB9	Homeobox protein HB9	**ZES**	Zollinger-Ellison syndrome
MCT	Medullary carcinoma of thyroid		

A group of heritable syndromes characterized by aberrant growth of benign or malignant tumors in a subset of endocrine tissues have been given the collective term multiple endocrine neoplasia (MEN). The tumors may be functional (ie, capable of elaborating hormonal products that result in specific clinical findings characteristic of the hormone excess state) or nonfunctional. There are three major syndromes: MEN1 is characterized by tumors involving the parathyroid glands, the endocrine pancreas, and the pituitary; MEN 2A includes medullary carcinoma of the thyroid (MCT), pheochromocytoma, and hyperparathyroidism; and MEN 2B, like MEN 2A, includes MCT and pheochromocytoma, but hyperparathyroidism is typically absent.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

MEN1, also known as Wermer syndrome, is inherited as an autosomal dominant trait with an estimated prevalence of 2 to 20 per 100,000 in the general population. Approximately 10% of MEN1 mutations arise *de novo*. The term **sporadic MEN1** has been applied to this group. MEN1 has a number of unusual clinical manifestations (Table 22–1) that occur with variable frequency among individuals within affected kindreds. Manifestations of MEN1 have been reported prior to 5 years of age; penetrance is maximal by the fifth decade of life. The diagnosis of MEN1 can

be made based one of three criteria. First, it can be based on the occurrence of 2 or more primary MEN1-associated tumors (discussed later) in a single individual. Second, it can be made in a first degree relative of a clinically diagnosed MEN1 patient if they present with a single MEN1-associated tumor. Third, it can be diagnosed based on identification of a germline MEN1 mutation.

Hyperparathyroidism is the most common feature of MEN1, with an estimated penetrance of 90% or greater over the lifetime of an individual harboring the *MEN1* gene. The diagnosis of hyperparathyroidism is usually made through a combination of clinical and laboratory criteria similar to those used in the identification of sporadic disease (see Chapter 8). It is typically the first clinical manifestation of MEN1, although this varies as a function of the patient population being examined. Hyperparathyroidism in MEN1 is due to hyperplasia of all four parathyroid glands (or more, if supernumerary glands are present). However, involved glands may undergo metachronous enlargement, and selective resection of these glands often results in sustained clinical remissions. MEN1 is a rare cause of hyperparathyroidism, accounting for only 2% to 4% of cases in the general population.

Enteropancreatic tumors in MEN1 (~50% of all MEN1 patients) can be either functional (ie, capable of producing a secreted product with biologic activity) or nonfunctional. Gastrinomas, frequently associated with Zollinger-Ellison syndrome (ZES),

TABLE 22–1 Clinical manifestations of MEN1.

Manifestation	(%)
Hyperparathyroidism	90
Enteropancreatic tumors	30-70
Gastrinoma	40
Insulinoma	10
Non-functioning and PPoma	20-55
Glucagonoma	<1
VIPoma	<1
Pituitary adenomas	30-40
Prolactinoma	20
Somatotropinoma	10
Corticotropinoma	<5
Non-functional	<5
Carcinoid tumors	10-20
Adrenal adenomas	25-40
Subcutaneous lipomas	30
Facial angiofibromas	85
Meningioma	8
Collagenomas	70

Abbreviations: PP, pancreatic polypeptide; VIP, vasoactive intestinal polypeptide.

represent approximately 40% to 60% of the enteropancreatic tumors associated with this syndrome. Of equal importance, roughly 25% of patients with ZES are found in MEN1 kindreds. Insulinomas constitute approximately 20% of the islet cell tumors, and the remainder represent a collection of functional (eg, glucagon- or vasoactive intestinal peptide [VIP]-producing tumors) and nonfunctional tumors. It is noteworthy that the gastrinomas of MEN1 are often small, multicentric, and ectopically located outside the pancreatic bed, most often in the duodenal submucosa. This latter feature can have a major impact on the therapeutic approach to these patients (discussed later). Gastrinomas in MEN1 are frequently malignant, as are their sporadic counterparts; however, for reasons that are only poorly understood, the biologic behavior of these tumors is less aggressive than those found in sporadic disease.

The diagnosis of gastrinomas is based on demonstration of hypergastrinemia in the presence of gastric acid hypersecretion. This latter criterion excludes other more common causes of hypergastrinemia (eg, achlorhydria). When the diagnosis is in question, the secretin stimulation test, which stimulates gastrin secretion from gastrinomas but not from normal tissue, may be employed. *Note*: The availability of secretin for parenteral administration is now quite limited. Histamine receptor blockers and proton pump inhibitors reflexively increase serum gastrin levels and should be discontinued 30 hours and 7 days, respectively, prior to testing to exclude gastrinoma. Others have advocated measurements of multiple gastrointestinal hormones following a standardized mixed meal as the most efficient means of detecting the presence of neuroendocrine tumors in MEN1.

Because of their small size, gastrinomas can be difficult to localize in MEN1. Computed tomography (CT) and magnetic resonance imaging (MRI) may be useful in identifying larger lesions but are typically not helpful in identifying smaller ones. These imaging procedures are useful, however, in demonstrating hepatic metastases when present. The most promising localization techniques studied to date include endoscopic and intraoperative ultrasound, selective arterial secretin injection (followed by hepatic vein sampling for gastrin), and radiolabeled octreotide scanning. Each of these has been employed successfully to identify tumors in studies involving small groups of patients. It is important to recognize, however, that almost half of gastrinomas are not found with preoperative localization studies.

Insulinomas in MEN1 are detected using conventional biochemical testing (see Chapter 18). They can also be difficult to localize given their potential for multicentricity. Endoscopic ultrasound and selective arterial infusions of calcium with hepatic vein sampling (for insulin) have been used successfully to identify lesions in small groups of patients. Metastases are present in up to 50% of patients with MEN1-associated insulinoma, compared with 10% of their sporadic counterparts.

Glucagonomas, VIPomas, and somatostatinomas are diagnosed based on twofold or greater elevations in plasma glucagons, VIP, or somatostatin levels, respectively, in the presence of one or more pancreatic nodules. Nonfunctional tumors are typically diagnosed following imaging studies. Plasma glucagon, chromogranin A or pancreatic peptide levels lack the sensitivity to assist detection of nonfunctional tumors.

Pituitary adenomas occur in approximately 30-40% of patients harboring *MEN-1* gene mutations. The majority of such tumors secrete prolactin, with or without secretion of excess growth hormone, followed by those secreting growth hormone alone, nonfunctional tumors, and those secreting excessive amounts of adrenocorticotropic hormone (ACTH) (Cushing disease). In considering patients with growth hormone excess, it is important to recall that ~75% of reported growth hormone releasing hormone (GRH)-producing pancreatic neuroendocrine tumors have developed in MEN1 patients. A prolactinoma variant of MEN1 has been described (Burin variant). This variant is characterized by an increased frequency of prolactinomas, carcinoids, and hyperparathyroidism and infrequent appearance of gastrinomas in affected kindreds. It does not appear to be associated with a specific mutation of the *MEN1* gene. In one instance it has been linked to a germline mutation in the gene encoding the cyclin-dependent kinase inhibitor p27^{Kip1}, but this has not been confirmed in other patients. Pituitary tumors in MEN1 are rarely malignant. Recent studies suggest that they may be larger and more aggressive than their sporadic counterparts, although this is controversial. There is a high incidence of macroadenoma, they display a propensity for making more than a single pituitary hormone, and there is a suggestion that these tumors do not respond as well to medical therapy as do their sporadic counterparts. Diagnosis and management are similar to that of their sporadic counterparts (see Chapter 4).

Adrenal adenomas, including cortisol-producing adenomas, are seen in MEN1, theoretically making the differential diagnosis of Cushing syndrome in this setting complex (ie, adrenal adenoma

vs basophilic adenoma of the pituitary gland vs ectopic ACTH secretion from a carcinoid tumor, which is also commonly associated with this syndrome). Empirically, most hypercortisolemia in this setting is due to pituitary disease. Pheochromocytomas harboring an MEN1 rather than an MEN2 mutation have been described in seven patients. Thyroid disease has been said to be more common in MEN1; however, with the possible exception of thyroid adenomas, this link remains obscure. Subcutaneous lipomas, skin collagenomas, and multiple facial angiofibromas (particularly on the upper lip and vermillion border of the lip) are seen in 30% to 90% of family members in affected kindreds. Although clinically of little importance, when present, they may prove useful in identifying affected individuals within a kindred and lead to more effective screening (discussed later). Carcinoid tumors are seen with increased frequency in MEN1. They are almost exclusively foregut carcinoids and may be found in the thymus, in the lung (bronchial carcinoids), or in the gastric mucosa. It is likely that chronic hypergastrinemia (eg, that resulting from coexistent ZES and proton pump inhibitor therapy) contributes to the increased incidence of gastric carcinoids in MEN1. For unclear reasons, thymic carcinoids appear more commonly in males, bronchial carcinoids in females. They occasionally secrete hormonal products (eg, ectopic ACTH), are often malignant, and may behave aggressively. Leiomyomas, meningiomas, and ependymomas have been described in MEN1. Disease-specific mortality is due to pancreatic islet carcinoma and malignant thymic carcinoid.

Pathogenesis

MEN1 is inherited as an autosomal dominant trait. Traditional linkage studies localized the defective gene to the long arm of chromosome 11q13. Parallel analyses of DNA from endocrine tumors taken from MEN1 patients demonstrated allelic loss in this area, frequently resulting from large DNA deletions. This raised the possibility that the defective gene was a tumor suppressor gene involved in the control of cellular growth. In this paradigm (Figure 22–1), the inherited defective allele is silent in the presence of a normal, functioning allele on the second chromosome. A subsequent somatic mutation (often a deletion that removes the normal allele) results in a null genotype in which the suppressor gene locus is either absent or defective on both alleles. The high frequency with which such deletions occur is thought to account for the dominant nature of this particular genetic defect. Noteworthy, some of the neuroendocrine tumors seen in MEN1 have failed to demonstrate loss of heterozygosity suggesting that other events might be involved in suppressing the second (ie, normal) allele. Release of the tumor suppressor gene's growth regulatory activity results in a hyperplastic growth response in cells harboring the somatic mutation. This promitogenic state likely provides the substrate for subsequent somatic mutations that result in acquisition of a more aggressive, and at times malignant, phenotype, as occurs in gastrinomas associated with ZES. Recent studies have succeeded in identifying the gene (*MEN1*),
FIGURE 22–1 An example of allelic loss in *Men1* involving large deletion of genetic material. Afflicted patient's germ cells (shown on left) harbor both a normal and defective gene at the *Men1* locus. Each of these is detected using selective restriction enzyme digestion and Southern blot analysis of the genomic DNA. Affected somatic cells (eg, parathyroid chief cells) undergo a second mutation, typically a deletion of the normal allele, resulting in detection of only the mutant allele by Southern analysis. Sporadic disease is thought to follow sequential mutation or deletion of each *Men1* allele in the somatic cell. Solid bar (light purple) with asterisk represents radiolabeled probe used in Southern analysis; arrows indicate points of restriction enzyme digestion.
FIGURE 22–2 Some of the more common germline menin mutations from 56 MEN1 kindreds and somatic mutations from 24 endocrine tumors. Mutations above the bar cause protein truncations through stop codons or frameshifts leading to premature stop codons; two cause splice errors. Mutations below the bar cause missense or single-amino-acid codon changes. (Reproduced with permission from Marx S, et al. Multiple endocrine neoplasia type 1: clinical and genetic topics. *Ann Intern Med*. 1998 Sep 15;129(6):484-494.)

encoding the protein menin, which appears to be responsible for MEN1 (Figure 22–2). Mutations have been identified throughout the entire 610-amino-acid length of the *menin* coding sequence and include nonsense mutations, missense mutations, and deletions. Over 1300 independent mutations have been described in MEN1 kindreds to date. Nevertheless, 5% to 10% of presumed *MEN1* mutations are not detectable using available methodology. Menin is a ubiquitously expressed tumor suppressor gene product which has been shown to interact with several components of the trithorax family histone methyltransferase complex, including the mixed lineage leukemia (MLL) proteins. Menin, through this complex, controls expression of the cyclin-dependent kinase inhibitors p27^{Kip1} and p18^{Ink4c}. This complex also methylates the lysine 4 residue of histone 3 (H3K4), a modification which has been linked to transcriptional activation. Loss of function of *menin* (eg, through those mutations associated with MEN1) results in downregulation of p27^{Kip1} and p18^{Ink4c} and deregulated cell growth. Menin also suppresses expression of the developmentally programmed transcription factor, HLXB9, which may also lead to increased growth in menin-deficient cells. Mice heterozygous for deletion of the *menin* gene locus (*Men1-/-*) develop parathyroid dysplasia, adenomas, and carcinomas; pancreatic islet tumors, anterior pituitary tumors, and adrenal cortical tumors, all of which display loss of heterozygosity at the *Men1* locus.

Mutation of a second gene, *CDKN1B*, encoding the cyclin dependent kinase inhibitor p27^{KIP1} (discussed earlier) has been reported in patients who lacked menin mutations but did have the MEN1-associated tumors, particularly parathyroid and pituitary adenomas and, much less commonly, neuroendocrine tumors of the pancreas. This condition has recently been referred to as MEN4 and it accounts for ~1.5%-3% of patients with the MEN1 phenotype. Germline mutations in other cyclin dependent kinase inhibitors, including p15^{INK}, p18^{INK}, and p21 may account for 1%, 0.5%, and 0.5% of MEN1 patients, respectively.

The *MEN1* gene is also the gene most frequently mutated in a variety of sporadic endocrine tumors. Parathyroid adenomas (20%), gastrinomas (40%), insulinomas (15%), VIP-secreting tumors (60%), nonfunctioning pancreatic tumors (15%), glucagonomas (60%), adrenal cortical tumors (<5%), angiofibromas (10%), lipomas (30%), bronchial carcinoids (35%), and pituitary tumors (<5%) often harbor somatic mutations at the *MEN1* locus. It is important to note that screening for germline mutations at the *MEN1* locus fails to detect mutations 5% to 10% of the time despite evidence for loss of heterozygosity at 11q13. Some of these may represent alternate gene targets (discussed MEN4 earlier). In other cases, it may be that the relevant mutations are in regulatory regions surrounding the *MEN1* gene. Haplotype testing or genetic linkage analysis can be useful in these cases to identify relevant *MEN1* carriers. Unlike MEN2 (discussed later), there is no clear

association between specific *MEN1* gene mutations and the nature or extent of endocrine gland involvement, although nonsense mutations at Tyr[312] and Arg[460] have been shown to be more common with the Burin variant.

Treatment

Treatment of MEN1-associated tumors is more complicated than that of its sporadic counterparts. First, MEN1-associated tumors are usually multiple, making surgical cure difficult, if not impossible. Second, occult metastases are more common in MEN1-associated tumors. Third, MEN1-associated tumors are often larger, clinically aggressive and more resistant to therapy than their sporadic counterparts. Therapy of hyperparathyroidism in MEN1 is directed toward surgical extirpation of hyperplastic parathyroid tissue, typically with resection of three and one-half glands. This leaves one-half gland in situ in an attempt to preserve residual parathyroid function and avoid hypoparathyroidism. Alternatively, patients may be subjected to total parathyroidectomy with transplantation of the most normal appearing tissue to the nondominant forearm. There have been no head-to-head comparisons made between these approaches. Total parathyroidectomy (with transplant) is associated with a higher frequency of hypoparathyroidism, whereas subtotal parathyroidectomy has a higher rate of recurrence. Prophylactic near-total thymectomy is often performed at the time of the initial neck exploration to remove potential intrathymic parathyroid glands as well as thymic carcinoid tumors.

Both persistence and recurrence of hyperparathyroidism occur more frequently in MEN1 than in sporadic disease. Persistence of hyperparathyroidism, defined as a failure to normalize serum calcium and parathyroid hormone (PTH) levels following the initial surgery, with removal of 3 to 3.5 parathyroid glands, occurs in 12% of cases of MEN1. Recurrent disease, defined as reappearance of hyperparathyroidism following at least 3 months of normocalcemia, is seen in as many as 44% of these cases 8 to 12 years following surgery. The high frequency of persistent hyperparathyroidism in MEN1 probably reflects the high frequency of supernumerary glands (prevalence as high as 30%) and ectopically located parathyroid tissue in patients carrying the *Men1* gene. The increased frequency of recurrent disease is thought to result from the continued presence of the underlying mitogenic stimulus that drives parathyroid gland growth in this syndrome. Reoperation for recurrent disease in the neck is successful about 90% of the time, whereas autograft removal is successful in about 60% of patients.

Therapy of gastrinomas in MEN1 remains controversial. Suppression of gastric acid production with proton pump inhibitors (eg, omeprazole) remains a mainstay of therapy. Conservative medical management of these tumors has been predicated on their assumed low-grade malignant behavior, the dominance of complications related to gastric acid hypersecretion in contributing to morbidity and mortality, and the failure of most attempts at surgical resection to alter the natural course of the disease. More recently, recognition of the potential for more aggressive behavior in some of these tumors—in a recent study, 14% of these tumors demonstrated aggressive growth—and the fact that many of these

tumors are ectopically located in duodenal submucosa and peripancreatic lymph nodes rather than the pancreatic bed has renewed interest in the possibility of surgical cure. A number of small studies have reported encouraging results when measures to both localize and remove gastrinoma tissue in the pancreas, duodenum, and regional lymph nodes have been used. Although the nature of the underlying genetic lesion and the multicentricity of these tumors may place limits on the prospects for cure of this disease in most patients, the slow growth characteristics of these tumors permit long periods of symptom-free survival following reduction of the tumor burden. For patients with liver or other metastatic disease, symptoms related to hypergastrinemia may be controlled with the proton pump antagonists, as described earlier. More conventional cancer therapy (eg, systemic chemotherapy, radiation therapy, or selective chemoembolization of hepatic metastases) is palliative and reserved for advanced stages of the disease. Islet tumors more than 3 cm carry an increased risk of malignancy and are usually resected regardless of functional status.

It is important to remember that calcium stimulates gastric acid secretion. This may occur through gastrin-dependent and gastrin-independent pathways. In MEN1 patients with both hyperparathyroidism and ZES, correction of the hyperparathyroidism and attendant hypercalcemia frequently results in a reduction in both basal and maximal acid output and a decline in serum gastrin levels. Secretin stimulation tests often normalize following parathyroidectomy. More importantly, there is a reduction in the dose of medication (eg, proton pump inhibitor) required to control symptoms of ZES following parathyroid surgery in approximately 60% of patients.

Unlike gastrinomas, insulinomas are rarely localized outside the pancreatic bed. Therefore, a more aggressive approach can be directed toward the pancreas in planning surgical resection. Enucleation of the identifiable lesions in the pancreatic head and blind resection of the pancreatic body and tail are often successful in correcting hyperinsulinemia. Resection of glucagonomas and VIPomas, regardless of size, has also been recommended for symptom control. Nonsurgical candidates (eg, those with serious coexisting disease or those in whom candidate tumors cannot be identified) can be managed with conventional medical therapy (eg, diazoxide or verapamil) (see Chapter 18).

Nonfunctional tumors may be the most common pancreatoduodenal neuroendocrine tumors in MEN1. They are managed somewhat differently than the functional tumors. Surgical efforts to minimize spread of metastases are weighed against the need to avoid incurring surgical complications, including mortality, with little clinical benefit. In general, surgery is not recommended for tumors less than 2 cm in diameter. Life expectancy of MEN1 patients with nonfunctional tumors (~43 years) is similar to that of those with gastrinomas and considerably shorter than those with other types of functional tumors (~61 years).

Screening

MEN1 gene testing should be offered to all index cases and their first-degree relatives. Guidelines suggest that this should be done

at the earliest opportunity since clinical manifestations can appear before the age of 5. MEN1 accounts for less than 1% of all pituitary tumors, 2% to 4% of cases of primary hyperparathyroidism, 20% of all thymic neuroendocrine tumors, and about 25% of all gastrinomas. Thus, although routine screening for *Men1* gene mutations is not indicated for sporadic cases of hyperparathyroidism or patients with pituitary tumors, screening of all cases of ZES and thymic neuroendocrine tumors is likely to be cost-effective in identifying carriers. The frequency of germline mutations in the *Men1* gene in patients with tumors thought to be sporadic based on family analysis is about 5% for gastrinomas and 1% to 2% for other manifestations (eg, hyperparathyroidism, prolactinomas). Excluding those patients with ZES or thymic neuroendocrine tumors, screening for MEN1 outside affected MEN1 kindreds should be limited to those individuals for whom the index of suspicion for the syndrome is high (eg, familial history of endocrine tumors or hypersecretory states; history of multiple endocrine tumors, including pancreatic neuroendocrine tumors, or parathyroid hyperplasia at age <30 in the index case). Identification of the carrier state should be performed with the intent of acquiring information that allows the clinician to focus screening on the relevant patient population (eg, members of affected kindred who do not share the *Men1* gene mutation need not be subjected to follow-up screening). Unlike the situation in MEN2 (discussed later), carrier analysis should not be used to support a major therapeutic intervention. Such interventions (eg, pancreatic exploration) may be associated with significant morbidity, and there is no evidence that they prolong patient survival. Genetic screening is available commercially at a number of locations (see www.genetests.org).

Although most clinicians agree that screening for MEN1-associated neoplasia in high-risk groups (eg patients with MEN1 and relatives harboring a mutant MEN1 allele) is worthwhile, details of the individual screening protocols vary considerably—from more focused, cost-effective approaches to broad-based screening designed to detect occult disease. One example is presented in Figure 22–3. A complete examination and full family history should be obtained on all patients. In individuals within affected kindreds, ionized (or albumin-corrected) calcium and PTH levels should be checked at yearly intervals beginning around age 8. Fasting serum gastrin levels (with documentation of gastric hyperacidity) should also be determined annually beginning at age 20—or more frequently if ZES is a prominent component of the phenotype in the affected kindred. In kindreds in whom the disease is particularly aggressive, the secretin stimulation test (if available) can lend additional diagnostic sensitivity. Insulinoma screening with determination of fasting glucose, insulin, and proinsulin levels may prove useful, particularly if symptoms of hypoglycemia are present. This screening should begin around age 5. Pancreatic polypeptide measurements may identify an unsuspected pancreatic neuroendocrine tumor. Levels of chromogranin A, a secretory product of parathyroid glands and other neuroendocrine tissues, can also be helpful in assessing hypersecretory states, although elevations are not specific for MEN1-associated endocrinopathies. Routine screening for other functional islet cell tumors (eg, glucagonomas and VIPomas) is justified if clinical findings (eg, watery diarrhea, hypokalemia, necrolytic migratory erythema) are present. As noted earlier, pancreatic neuroendocrine lesions are typically multifocal and may be very small, which make detection difficult even with sophisticated imaging studies. The same holds true for the pituitary lesions. In the absence of obvious clinical findings (eg, evidence of a hyper- or hyposecretory state or symptoms referable to a mass lesion in the sella turcica), routine screening should be confined to periodic measurements of serum prolactin and perhaps insulin-like growth factor-I. The former has been found to be useful in identifying pituitary disease in females harboring the *Men1* gene defect. Imaging studies (eg, CT or MRI of the pituitary, anterior mediastinum and abdomen) should be performed at presentation and repeated at 1-3-year intervals, based on perceived clinical risk for developing neoplastic lesions. A thorough family history that excludes pituitary disease in the kindred may mitigate the need for pituitary imaging studies over the long term.

Penetrance of MEN1 is greater than 95% by age 45. Screening should be continued at periodic intervals at least to age 45. If there is no evidence of typical endocrine organ involvement by that age, screening frequency might be reduced. It is important to note, however, that the risk is not reduced to zero at age 45. A minority of patients presents with their first manifestation of the syndrome well after age 45. Surgical resection of diseased tissue (eg, parathyroidectomy) should be followed with continued screening looking both for recurrent disease and involvement of other organ systems.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

MEN2 is an autosomal dominant disorder with an estimated prevalence of 1 to 10 per 100,000 in the general population. It can be subdivided into two independent syndromes: MEN 2A (Sipple syndrome) and MEN 2B. Manifestations of MEN 2A include MCT, pheochromocytoma, and hyperparathyroidism. MEN 2B includes MCT, pheochromocytoma, and a number of somatic manifestations (Table 22–2; Figure 22–4), but hyperparathyroidism is rare.

Medullary carcinoma of the thyroid is the most common manifestation of MEN2 and often represents the first clinical presentation in individuals with multiorgan involvement. It also dominates the clinical course of patients affected with the disease. From 80% to 100% of individuals at risk develop MCT at some point during their lifetime. The classic thyroid lesion of MEN2 is hyperplasia of the calcitonin-producing parafollicular cells, which typically serves as the precursor of MCT. These tumors in MEN2 patients tend to be multicentric and concentrated in the upper third of the thyroid gland, reflecting the normal distribution of parafollicular cells.

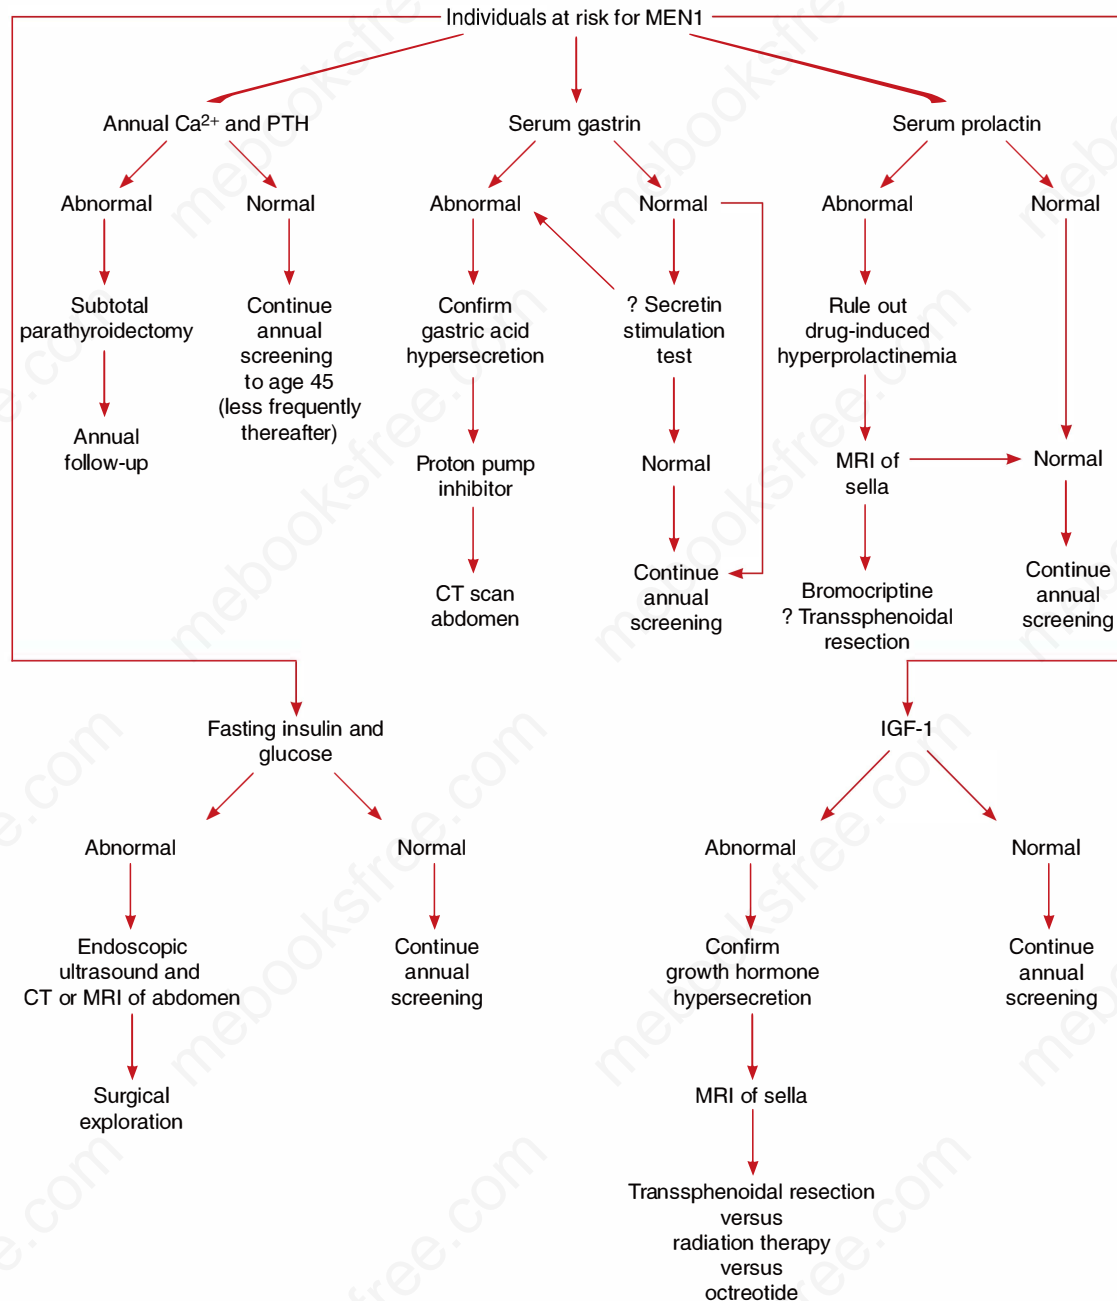
As much as one-fourth of all MCT is genetic in origin. Roughly 80% of the heritable fraction is attributable to *MEN 2A*; 15% occurs as an isolated entity (isolated familial MCT), and 5% is found in *MEN 2B* kindreds. Isolated familial MCT is defined as MCT presenting as the only clinical manifestation in more than


FIGURE 22–3 Screening for MEN1-associated neoplasia. Testing is targeted to individuals who either harbor the *MEN1* gene or have a high probability of harboring the *MEN1* gene (eg, first-degree relatives of affected kindred members). If genetic testing is available and the specific mutation has been confirmed, screening for endocrine neoplasia would be limited to those individuals harboring the defective gene. Screening for other pancreatic (eg, insulinomas) or pituitary tumors (eg, somatotroph adenomas) is based on the prevalence of the specific lesion in the affected kindred or the presence of signs or symptoms suggesting a particular lesion (IGF, insulin-like growth factor).

10 carriers in a kindred and multiple carriers or affected members over the age of 50 with adequate history and laboratory support to rule out the presence of pheochromocytoma or hyperparathyroidism. The disease tends to behave more aggressively in MEN 2B than with either MEN 2A or familial MCT, with earlier presentation (often before age 5) and more rapid progression.

Biochemical diagnosis depends heavily on the calcitonin-producing properties of the hyperplastic parafollicular cells or MCT. These lesions respond to pentagastrin or calcium infusions with significant increments in plasma calcitonin levels (see Chapter 8). Occasionally, immunohistochemical staining of poorly differentiated thyroid tumors for calcitonin reveals the identity of the malignancy. The presence of extracellular amyloid is also one of the identifying features of these tumors. This material reacts with anticalcitonin antisera, suggesting that it includes aggregated hormone released from neighboring tumor cells. MCT spreads

TABLE 22–2 Clinical manifestations of MEN2.

Manifestation	(%)
MEN 2A	
Medullary carcinoma of thyroid	80-100
Pheochromocytoma	40
Hyperparathyroidism	25
MEN 2B	
Medullary carcinoma of thyroid	100
Pheochromocytoma	50
Marfanoid habitus	75
Mucosal neuromas	100
Ganglioneuromatosis of bowel	>40

initially within the thyroid bed and to regional lymph nodes. Distant metastases to liver, lung, and bone occur late in the course of the disease.

Pheochromocytomas develop in approximately 50% of individuals harboring the *MEN2* gene. Pheochromocytoma is diagnosed after MCT in 50% of cases, concurrently in 40% of cases and before MTC in 10% of cases. They are usually located in the adrenal bed, often are bilateral, and are rarely malignant. Diagnosis is based on standard clinical criteria (eg, hypertension, presence of headaches, palpitations, diaphoresis), elevations in plasma or urine catecholamines or catecholamine metabolites (eg, urinary or plasma metanephrine or normetanephrine), and demonstration of an adrenal mass on conventional abdominal CT scanning or MR imaging. As noted earlier for MCT, pheochromocytomas in MEN2 are preceded by a hyperplastic phase (adrenal medullary

FIGURE 22–4 Patient with MEN 2B syndrome. Note the multiple neuromas on the lips and tongue and the marfanoid facies.

hyperplasia), although, unlike parafollicular cell hyperplasia, the adrenal precursor lesion can be difficult to detect with conventional biochemical testing. As in MEN1, hyperparathyroidism in MEN2 is due to hyperplasia of the parathyroid glands. It is seen in about 25% of patients harboring the *MEN 2A* gene and is reported, but rarely seen, as part of MEN 2B. The disease is usually less aggressive than its counterpart in MEN1 and approximates more closely the behavior of sporadic disease. It responds well to surgical management.

A number of other phenotypic features are associated with the MEN2 syndromes. Cutaneous lichen amyloidosis is a pruritic erythematous skin lesion that is seen coincident with or often preceding the development of MCT in MEN2. Amyloid in these lesions is composed of keratin rather than calcitonin, as seen in MCT. Cutaneous lichen amyloidosis is thought to result from an abnormality in cutaneous innervation that leads to hyperesthesia and pruritis. Repeated scratching of the pruritic area results in epidermal thickening and increased pigmentation. It has been noted more frequently in association with specific mutations of the *MEN2* gene (specifically Cys[634] and less commonly Val[804]). It can be present before the onset of clinically evident MCT. In a second variant, MEN 2A or familial MCT is associated with Hirschsprung disease (congenital megacolon). This is most frequently found with *RET* gene mutations involving Cys[609] (15%), Cys[611] (5%), Cys[618] (30%), and Cys[620] (50%) (see later). The intestinal ganglioneuromatosis, pes cavus, pectus excavatum, mucosal neuromas, marfanoid habitus, and medullated corneal nerves seen in MEN 2B appear to be related to the underlying genetic defect. The intestinal lesions can disrupt gut motility, resulting in periods of severe constipation or diarrhea.

Pathogenesis

The pathogenesis of the MEN2 syndromes has been worked out in elegant detail. Traditional genetic linkage studies localized the defective genes in *MEN 2A*, *MEN 2B*, and familial *MCT* to the pericentromeric region of chromosome 10. Subsequent refinement in these analyses indicated that the defective gene was either closely linked to or identical with the *ret* proto-oncogene. RET is a single transmembrane domain, tyrosine kinase-linked protein that forms part of the receptor for the glial cell line–derived neurotrophic factor (GDNF) (Figure 22–5). This receptor, GDNFR (glial cell line–derived neurotrophic factor receptor), is a glycosyl phosphatidyl inositol-linked cell-surface protein. Additional ligands, neurturin, persephin, and artemin have been shown to associate with and activate RET through their cognate receptors GDNFR$_{\alpha1-4}$. As depicted schematically in Figure 22–6, its most striking structural feature is a series of cysteine residues clustered just outside the membrane-spanning segment. These cysteine residues are thought to exert a tonic inhibitory control on RET activity in the normal cell. RET also has a cadherin-like domain in that portion of the molecule projecting into the extracellular space and a tyrosine kinase-like domain in the intracellular portion of the molecule. RET is expressed endogenously in a variety of cells of neural crest origin,
FIGURE 22–5 Structure of GDNFR-α/RET receptor complex. GDNF identifies the ligand, glial cell line–derived neurotrophic factor, and GDNFR-α, the GDNF receptor (TKD, tyrosine kinase domain).
FIGURE 22–6 Structural schematic of wild-type RET, including amino acids that have been shown to be mutated in different disease states. MEN 2A is associated with mutations of Cys^{609}, Cys^{611}, Cys^{618}, Cys^{620}, Cys^{630}, Cys^{634}, and, rarely, Leu^{790} and Tyr^{791}. Familial MCT of the thyroid is frequently associated with mutations at the same Cys residues with the exception of Cys^{634}, as well as mutations at Glu^{768}, Leu^{790}, Tyr^{791}, Val^{804}, and Ser^{891}. MEN 2B mutations typically involve Met^{918} or, more rarely, Ala^{883}, Ser^{922}, or Val^{804}/Ser^{904}. Hirschsprung disease is associated with multiple mutations or deletions extending over the full length of the RET molecule.

and it appears to play an important role in development. Knockout of the *RET* gene locus in mice results in the absence of myenteric ganglia in the submucosa of the small and large intestine and a variety of genitourinary anomalies, implying an important role in renal development. Approximately 95% of MEN 2A and 2B patients and 88% of familial MCT have identifiable *RET* mutations. From 1% to 7% of sporadic MCT have somatic mutations in the *RET* gene.

Characterization of the *RET* gene in patients with MEN 2A demonstrated a number of mutations in affected kindred members that were not present in their normal counterparts. The mutations were clustered in the cysteines located in RET's extracellular, juxtamembrane domain (see Figure 22–6). Structurally, these cysteines are encoded by nucleotides in exons 10 and 11 of the *RET* gene. A number of these mutations were simple missense mutations, whereas others involved deletion or insertion of small segments of DNA, but in each case one of the aforementioned cysteines proved to be involved. Selective mutation of one of these six cysteines has now been shown to account for more than 97% of all *RET* mutations associated with MEN 2A. The most frequently mutated residue is Cys^{634}. This amino acid is mutated to arginine (Arg), phenylalanine (Phe), serine (Ser), glycine (Gly), tyrosine (Tyr), or tryptophan (Trp) in approximately 84% of affected MEN 2A kindreds. It should be noted that the Cys-to-Arg mutation at position 634 is also the most common mutation at this position, accounting for about 64% of all codon changes at this location. Interestingly, a rare but unique mutation involving a four-amino-acid insertion between Cys^{634} and Arg^{635} has been described that results in MCT and a high incidence of hyperparathyroidism but not pheochromocytoma.

Ironically, patients with familial MCT display many of the same cysteine mutations identified in MEN 2A. This implies the existence of independent modulatory genomic or epigenetic factors that restrict the effects of the *RET* mutation to the parafollicular cells of the thyroid in familial MCT. The exception is the mutation of Cys^{634} to Arg^{634}, which is almost uniformly associated with MEN 2A. Several additional mutations have been identified that may be more specific for familial MCT (see Figure 22–6). The observation that mutations of Cys^{634} have higher transforming potential than mutations at these other residues has led to the suggestion that MEN 2A represents the more severe phenotype (vs familial MCT) along a spectrum of disease resulting from RET activation. In fact, the noncysteine mutations, which are more common in familial MCT (as high as 60% of familial MCT in one series), are associated with delayed onset of parafollicular C cell disease, but other clinical features (tumor size, bilaterality, the presence of nodal metastases) are not different in patients harboring cysteine versus noncysteine mutations.

Interestingly, patients with MEN 2B do not harbor mutations in the cysteine residues affected in MEN 2A and familial MCT. Instead, the majority possess a single-point mutation involving conversion of Met^{918} to Thr^{918}. This mutation is found in more than 95% of cases of MEN 2B. A minority of patients have been shown to harbor an independent mutation of Ala^{883} to Phe^{883},

Ser^{922} to Tyr^{922}, or a mono-allelic combination of Val^{804} to Met^{804} plus Ser^{904} to Cys^{904} or Asp^{805} to Lys^{805}. MEN 2B arises from spontaneous *de novo* mutations in as many as 50% of affected individuals. For unknown reasons, these mutations are found almost exclusively on the paternal allele.

A number of the germline mutations identified in MEN 2A and familial MCT and the Met^{918} mutation in MEN 2B have been demonstrated as somatic mutations in sporadic MCT (~30%-40%) and pheochromocytoma (<10%). Sporadic parathyroid disease due to these mutations is not known to occur. The presence of the Met^{918} mutation, in particular, is associated with a less favorable clinical outcome in sporadic MCT.

Independent studies have shown a close linkage between the *RET* gene locus and Hirschsprung disease, a disorder characterized by failure of myenteric ganglia to develop normally in the hindgut of affected individuals. This leads to impaired gut motility and, in severe cases, megacolon (a phenotype similar to that reported for the *RET* knockout mice). Examination of *RET* coding sequence in Hirschsprung kindreds revealed a variety of mutations in both the intracellular and extracellular domains, some of which (eg, deletions) would be predicted to eliminate normal expression of the *RET* gene. This, together with findings from the *RET*, *GDNF*, and *GDNFRa-1* knockout mice, suggests that Hirschsprung disease represents the null phenotype for the *RET* locus. Interestingly, several patients have been described who possess features of both MEN2 and Hirschsprung disease. The *RET* mutations in these cases have involved conversion of Cys^{609}, Cys^{611}, Cys^{618}, or Cys^{620} to Arg. These mutations, while promoting dimerization and increasing tyrosine kinase activity in the RET protein (discussed later), also appear to have difficulty trafficking to and accumulating in the plasma membrane. It is likely that predominance of one or the other of these mechanisms in different cell types could result in a phenotype characterized by both activation (eg, MEN2) and suppression due to haploinsufficiency (eg, Hirschsprung disease) of RET activity in the same individual.

By inference, the defect in RET function in MEN2 or familial MCT arises from increased or altered activity of the RET tyrosine kinase. In the case of RET$_{MEN 2A}$, the increase in activity appears to arise from interference with the tonic inhibition of RET tyrosine kinase activity by the clustered cysteine residues in the extracellular domain. This leads to increased dimer formation, autophosphorylation, and tyrosine kinase activity in the mutant RET molecules. In the case of RET$_{MEN 2B}$, there appears to be a constituitive increase in tyrosine kinase activity as well as a change in substrate specificity of the tyrosine kinase that contributes to the phenotype. The activity of RET$_{MEN 2B}$—rather than being restricted to conventional RET substrates (RET substrates are similar to those recognized by the epidermal growth factor receptor)—is capable of phosphorylating substrates normally recognized by members of the Src and Abl families of cytoplasmic tyrosine kinases, signaling pathways which are closely identified with the regulation of cell growth. Thus, it appears that RET$_{MEN 2B}$ has acquired the capacity for activation of a potent mitogenic pathway in the expressing endocrine cells merely by altering its selection of substrates for phosphorylation. RET$_{MEN 2B}$ also potentiates phosphorylation of Tyr^{1062} more effectively than RET$_{MEN 2A}$. This tyrosine serves as a docking site for multiple effector proteins, including Shc and phosphatidyl inositol 3′-kinase, implying that RET$_{MEN 2B}$ may be more effective in triggering downstream signaling pathways.

Treatment

Treatment of heritable MCT should include total thyroidectomy with at least central lymph node dissection. Given the multicentric nature of the disease, subtotal thyroidectomy predictably results in recurrent disease. Basal or stimulated calcitonin levels are used in the postoperative setting to evaluate the presence of residual disease. Postoperative measurement of serum thyroglobulin levels provide an estimate of residual thyroid tissue and, inferentially, tissue at risk for developing MCT. The precise timing of surgery in patients with subclinical disease (ie, positive by genetic testing but without clinical or laboratory abnormalities) is controversial (discussed later), but most clinicians would agree that in kindreds with MEN 2B or clinically aggressive MCT, patients should undergo surgery as soon as the genetic defect is demonstrated. Typically, this is before age 6 months in MEN 2B (eg, mutation at Ala^{883} or Met^{918}) and before age 5 years in MEN 2A (eg, mutation at Cys^{611}, Cys^{618}, Cys^{620}, or Cys^{634}), although some would argue that Cys^{634} should be operated in the first year of life. Foci of microscopic MCT are common, and metastatic disease has been described in the first year of life in patients with MEN 2B. The presence of a thyroid nodule or lymph node metastases at the time of diagnosis is strongly associated with persistent or recurrent disease and low rate of cure. Mutations associated with familial MCT (eg, Cys^{609}, Glu^{768}, Leu^{790}, Tyr^{791}, Val^{804}, or Ser^{891}) tend to be associated with more indolent disease. Some have suggested that surgery in these patients can be deferred until plasma calcitonin levels (basal or stimulated) are elevated. Patients should always be screened for the presence of pheochromocytoma before undergoing neck exploration. Surgery for metastatic disease is palliative and targeted at reducing tumor burden rather than cure. Localization techniques (eg, MRI or selective venous sampling for calcitonin) can be helpful in identifying foci of malignant tissue. Recent randomized, double blind, phase 3 clinical trials involving the tyrosine kinase inhibitors vandetanib and cabozantinib have shown significant improvement in progression-free survival in patients treated with these agents. Each has now been approved for treatment of patients with advanced MCT. These agents (vandetanib and cabozantinib) provide objective response rates of 45% and 28%, respectively, when compared with placebo. Radiation and chemotherapy are of limited utility in MCT and are largely confined to later stages of the disease.

Treatment of pheochromocytomas in MEN2 is similar to that for sporadic pheochromocytomas (see Chapter 11). Alpha- and (occasionally) beta-adrenergic blockade is used to control blood pressure and associated hyperadrenergic symptoms and to restore normal intravascular volume in preparation for surgical resection of the tumor. Given the propensity for bilaterality of pheochromocytomas in this disorder, some have favored bilateral adrenalectomy at the time of initial surgery. However, because the incidence

of bilaterality is well under 100% and because these tumors are rarely malignant, the most prudent strategy in the face of unilateral adrenal enlargement would appear to be unilateral adrenalectomy at the initial surgery with careful attention at follow-up, looking for the presence of disease in the contralateral adrenal gland. This vigilant approach has the advantage of minimizing morbidity from recurrent pheochromocytoma while sparing the patient the risks associated with lifelong adrenal insufficiency.

Screening

Genetic screening for MEN 2A, MEN 2B, or familial MCT is routinely carried out using polymerase chain reaction (PCR)-based tests designed to identify specific mutations in the *RET* coding sequence (Figure 22–7; see www.genetests.org for laboratories performing these tests). Known *RET* mutations account for more than 95% of all instances of MEN2, and selected mutations (eg, Cys^{634} to Arg^{634} in MEN 2A) account for a disproportionate number of affected individuals. Individuals lacking any of the known *RET* mutations can be tested using conventional haplotype analysis if informative genetic markers and affected family members are available. Biochemical testing using basal or stimulated plasma calcitonin levels has been largely supplanted by genetic screens. The biochemical tests remain useful, however, in identifying residual disease after thyroidectomy.

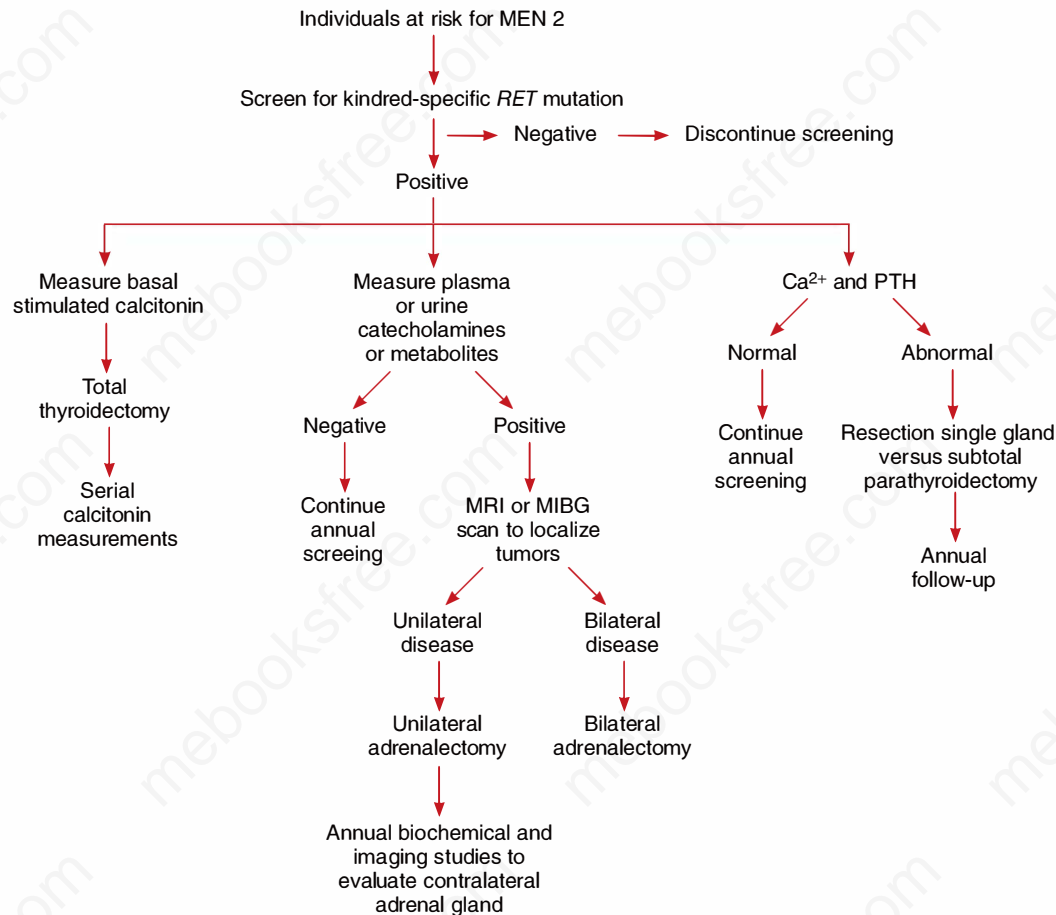
In view of the fact that a high proportion of cases of MCT are familial to begin with and as much as 3% to 7% of patients with apparently sporadic MCT harbor germline *RET* mutations, genetic testing for *RET* germline mutations is probably indicated for all patients presenting with MCT. Controversy persists, however, in terms of what should be done for patients once the mutation has been identified. Some investigators citing incomplete clinical penetrance (according to published data, 40% of gene carriers do not present symptomatically prior to age 70) have argued that employing solely genetic criteria in making the decision for operative intervention subjects a small minority of patients to premature thyroidectomy. They argue that genetic testing should be used to identify those patients who require close clinical and biochemical surveillance to assist with the timing of surgery. Ideally, such biochemical testing (eg, pentagastrin stimulation)


FIGURE 22–7 Screening for neoplasia in MEN 2. Genetic screening has largely supplanted biochemical testing in identifying individuals at risk. Details of decisions regarding treatment are discussed in the text. Preoperative plasma calcitonin levels are potentially useful for follow-up but should not supplant genetic testing in assessing the need for surgery (MIBG, metaiodobenzylguanidine; *RET*, rearranged during transfection proto-oncogene).

should be performed on an annual basis. Exceptions to this general approach might include patients with MEN 2B or a particularly aggressive form of familial MCT where the potential for significant morbidity and mortality would justify operation in any patient harboring the genetic defect regardless of the physical or biochemical manifestations of the disease. Genetic considerations for patients presenting with seemingly sporadic pheochromocytoma are discussed in Chapter 11. *RET* gene mutations in sporadic hyperparathyroidism are very rare, arguing against routine screening for mutations in this group.

Most investigators in the field believe that the true penetrance of MCT—combined clinical and preclinical disease—in MEN 2A is close to 100%. This, when coupled with the high degree of sensitivity and specificity of the PCR-based genetic screens, difficulties encountered in obtaining adequate long-term patient follow-up and biochemical screening, and the potential for false positive and false negative biochemical screening tests (ie, basal or stimulated calcitonin levels)—even within MEN2 kindreds—has led to the recommendation that total thyroidectomy should be performed in most individuals harboring an MEN2–associated *RET* mutation. This argument has now been supported by several clinical studies in which parafollicular cell hyperplasia as well as early MCT have been identified in operative specimens taken from genetically affected individuals despite normal pentagastrin stimulation tests. False-positive biochemical tests are also a concern. There are several reports in the literature of patients in affected kindreds who have undergone total thyroidectomy following positive pentagastrin stimulation tests but did not, in fact, harbor the *MEN2* gene mutation. Histologic examination of

excised tissues revealed parafollicular cell hyperplasia, presumably unrelated to MEN2, but no MCT. Collectively, these findings point out the relative deficiencies of biochemical versus genetic testing and offer a compelling argument for early operation as a means of reliably eradicating the disease.

Several groups have published recommendations regarding the appropriate age to initiate screening and the timing of surgery for MCT in individuals with confirmed *RET* mutations. These are generally segregated based on the nature of the specific *RET* mutations and the relationship of these mutations to the development of aggressive MCT. One set of recommendations is presented in Table 22–3. As noted, prophylactic surgery is recommended for all MEN 2B patients (eg, M918T or A883F). Patients at the next level (ie, C634R/F/S/W/Y) should be screened in the first years of life and operated before age 5. Patients at the third level (basically MEN 2A patients other than the C634 mutations—ie, C609, C611, C620, C630) should be screened early and operated prior to age 5, but more flexibility is available if selected criteria are met (eg, normal calcitonin levels, normal ultrasound, less aggressive MCT in other family members and family preference). The final group, which is associated with a less aggressive clinical course, includes all those mutations associated with familial, isolated MCT. Screening for MCT in this group, as well as consideration for thyroidectomy, can often be deferred beyond age 5 if the criteria above are satisfied. Routine screening for pheochromocytoma and hyperparathyroidism in individuals at risk can typically be initiated later, but all patients undergoing thyroidectomy should have pheochromocytoma ruled out first. Screening should continue at 1-3 year intervals at least until age 50.

TABLE 22–3 Recommendations for timing of prophylactic thyroidectomy and screening for pheochromocytoma and hyperparathyroidism in MEN 2 based on genotype.

ATA Risk Level	RET Mutation(s)	Recommended Age	Pheo Screening	hPTH Screening Thyroidectomy
A (low)	Glu 786	May delay beyond age 5 if calcitonin levels nl, U/S nl and family history of indolent disease	Age 20	Age 20
	Leu 790			
	Val 804			
	Arg 833			
B	Cys 609	Before age 5 (may consider delay based on same criteria used for Risk Level A)	Age 8 for Cys 630	Age 8 for Cys 630
	Cys 611		Age 20 for all others	Age 20 for all others
	Cys 618			
	Cys 620			
	Cys 630			
C	Cys 634	Before age 5	Age 8	Age 8
D (high)	A 833	Early year 1	Age 8	N/A
	M 918			

Mutations described for Risk Level A are representative but do not include all mutations described for this group. Data from Moline J, Eng C. Multiple endocrine neoplasia type 2: an overview. *Genet Med*. 2011 Sep;13(9):755-764.

OTHER DISORDERS CHARACTERIZED BY MULTIPLE ENDOCRINE ORGAN INVOLVEMENT

Carney Complex

Carney complex is an autosomal dominant disorder characterized by cardiac, endocrine, cutaneous, and neural tumors. Myxomas of the heart, breast, and skin are seen frequently in this disorder, as is spotty pigmentation of the skin (lentiginosis) and ear canal trichofolliculo-epitheliomas. Additional rare manifestations include psammomatous melanotic schwannoma, breast ductal adenoma, and osteochondromyxoma. Endocrine tumors include primary pigmented micronodular adrenocortical hyperplasia (an ACTH-independent form of Cushing syndrome), follicular thyroid carcinomas, adrenocortical carcinoma, somatotroph (growth hormone–secreting) adenomas of the pituitary gland, large-cell calcifying Sertoli cell tumors of the testes, and ovarian cysts. Pancreatic neoplasms occur in ~2.5% of patients but may be aggressive. They are the major cause of cancer death in Carney Complex patients. In approximately two-thirds of the known Carney complex kindreds, the genetic lesion maps to 17q22-24, a locus that harbors the type 1A regulatory subunit of protein kinase A. This gene functions as a classic tumor suppressor, and loss of heterozygosity at this locus is associated with the Carney phenotype. A second locus, presumably accounting for some fraction of the remaining half of Carney complex kindreds, is located at 2p16. The nature of the genetic lesion at this locus remains unknown at present; however, the phenotype is indistinguishable from that found with the 17q22-24 mutations alluded to above.

McCune-Albright Syndrome

The central findings in McCune-Albright syndrome include bony fibrous dysplasia (either monostotic or polyostotic, café au lait spots, and gonadotropin-independent precocious puberty). However, affected individuals also develop tumors or nodular hyperplasia of a number of endocrine glands with associated hypersecretory syndromes. One may see involvement of the pituitary somatotrophs (acromegaly), thyroid gland (hyperthyroidism), or the adrenal cortex (hypercortisolemia). Patients with McCune-Albright syndrome frequently demonstrate hypophosphatemic rickets. This is thought to result from secretion of fibroblast growth factor-23 that is produced in the mesenchymal cells associated with the dysplastic bone lesions. They also have nonendocrine organ involvement that leads to cardiomyopathy with sudden death and liver function abnormalities. The molecular lesion in McCune-Albright syndrome involves a somatic activating mutation of *GNAS*, encoding the alpha subunit of the Gs protein, at the Arg^{201} position, converting the Arg to either Cys or His (see Chapter 1), that leads to ligand-independent activation of adenylyl cyclase and increased intracellular concentrations of cyclic AMP. This somatic mutation is thought to occur early in development, leading to genetic mosaicism for the mutant allele. The phenotype of an individual patient is determined by the tissue distribution of the mutation-bearing cells and the percentage of cells within a given tissue that harbor the mutation. Interestingly, *GNAS* mutations have been described in a subset of patients harboring intramuscular myxomas (Mazabraud syndrome) with or without associated fibrous dysplasia, a feature that is reminiscent of the Carney complex (discussed earlier), another genetic disease which seems to target the cyclic AMP-signaling pathway.

Neurofibromatosis Type 1

Neurofibromatosis type 1 (von Recklinghausen disease) is an autosomal dominant genetic disorder characterized by a variety of skin manifestations, including café-au-lait spots, subcutaneous neurofibromas, and axillary and inguinal freckles as well as neural gliomas (eg, optic nerve) and hamartomas of the iris (Lisch nodules). In addition, patients may have a number of endocrine neoplasias, including pheochromocytoma, hyperparathyroidism, MCT, and somatostatin-producing carcinoid tumors of the duodenal wall. The genetic lesion in neurofibromatosis type 1 is located at 17q11.2, a locus that harbors the neurofibromin gene. Neurofibromin is a homolog of the p21 Ras-dependent GTPase-activating proteins and is thought to function in a tumor suppressor mode through regulation of Ras-dependent signaling activity.

Von Hippel-Lindau Disease

Von Hippel-Lindau disease is a heritable autosomal dominant disorder characterized by retinal and cerebellar hemangioblastomas, renal cell carcinoma, islet cell tumors, pheochromocytomas, and renal, pancreatic, and epididymal cysts. The presence of pheochromocytomas and most of the islet cell tumors is confined to the type 2 variant of the disease, which accounts for 25% to 35% of affected kindreds. The genetic lesion has been localized to 3p25. The von Hippel-Lindau protein, which is normally encoded by this locus, participates in the formation of a multiprotein complex involved in the regulation of hypoxia-induced gene transcriptional activity, fibronectin matrix assembly, and ubiquitin ligases.

PART I: ENDOCRINE MANAGEMENT OF TRANSGENDER YOUTH

Introduction

Gender nonconforming/transgender youth, in increasing numbers, are seeking medical services to enable the development of physical characteristics consistent with their experienced gender. These services including use of agents to block endogenous puberty at Tanner stage 2 with subsequent use of cross-sex hormones are based on longitudinal studies demonstrating that those individuals who were first identified as gender dysphoric in early or middle childhood and continue to meet the mental health criteria for being transgender at early puberty are likely to be transgender as adults. The goals of **Part I** of this chapter are to review terms and definitions applicable to gender nonconforming youth (and adults), endocrine, genetic and neuroanatomical studies that shed light on the biologic underpinnings of gender identity and to review the natural history of transgenderism, current clinical practice guidelines for transgender youth, and limitations and challenges to optimal care.

Terms and Definitions

"Gender identity" refers to a person's inner sense of self as male or female (and is not always binary). In contrast, a person's "sex" refers to the physical attributes that characterize biologic maleness or femaleness (eg, the genitalia). Most children, at birth, are assigned a "sex of rearing" (some mental health providers prefer the term "gender of rearing") based on genital anatomy. With that assignment comes societal expectations of gender roles, behaviors, and expressions, which are sometimes referred to as a child's "assigned (or natal) gender." In contrast to "sex (or gender) of rearing," "gender identity" can only be assumed, and not, in fact, known until an individual achieves a particular level of psychological development and self-awareness. "Cisgender" refers to an individual for whom gender identity and physical sex characteristics are in alignment.

"Gender nonconforming" is a term sometimes used when gender identity is not consistent with the gender assumed based on birth sex assignment. As defined by the American Psychiatric Association, "transgender" refers to a person who transiently or persistently identifies with a gender different from their "natal gender." The World Professional Association for Transgender Health

(WPATH) Standards of Care (SOC) describes "transgender" (adjective) as "a diverse group of individuals who cross or transcend culturally defined categories of gender" and "transsexual" (adjective) as "individuals who seek to change or have changed their primary and/or secondary sex characteristics through feminizing or masculinizing medical interventions (hormones and/or surgery), typically accompanied by a permanent change in gender role." "Transsexual" has also been used to describe a person who identifies as a member of the gender opposite to that assigned at birth, but who has not necessarily sought medical and/or surgical interventions.

"Transgender," defined more narrowly, refers to an individual whose gender identity is the "opposite" of their "assigned" or "natal gender." A person with a female gender identity and male assigned sex would be referred to as a "transgender girl/woman," "transfemale," or MTF (male to female); a person with a male gender identity and female assigned sex would be referred to as a "transgender boy/man," "transmale," or FTM.

The terms "gender queer," "gender variant," "gender expansive," "gender creative," or "gender independent" are increasingly used to describe individuals who state that their gender identities are neither male nor female. Some of these individuals accept their assigned genders but not the cultural expectations for those genders. "Gender fluid" refers to an individual whose gender identity changes over time or is not a fixed binary. In this context, it is not clear whether core gender identity is, in fact, changing, or whether gender fluidity reflects an ongoing process of self-awareness.

"Gender behavior" is not equivalent to gender identity, and the majority of youth with gender non-conforming behavior will not turn out to have a transgender identity. In the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) 5, "Gender dysphoria" refers to clinically significant distress related to the incongruence between one's "affirmed" or "experienced gender" and one's "assigned (or natal) gender." This term was replaced "Gender Identity Disorder" (GID) found in the earlier DSM IV. The DSM 5 has distinct diagnostic criteria for "gender dysphoria in children" and "gender dysphoria in adolescents and adults" [specifying with or without a disorder of sex development (DSD)]. Replacing "disorder" with "dysphoria" depathologizes the transgender identity, and instead, focuses on dysphoria as the clinical problem. It should be noted that the majority of patients with "gender dysphoria" do not have a DSD. Whether in children or adolescents, a core feature of "gender dysphoria" is "a marked incongruence between one's experienced/expressed gender and assigned gender" of at least 6 months' duration.

"Sexual identity" (or "sexual orientation") is often confused with "gender identity." While the former refers to whom one is sexually attracted, the latter refers to whom one "is" as male, female, or somewhere on the gender continuum. As with cisgender individuals, gender nonconforming/transgender individuals may have a heterosexual, homosexual, or bisexual orientation.

Prevalence of Transgenderism in Youth

While prevalence data for younger transgender adolescents are lacking, multidisciplinary clinics for transgender youth and adolescents in Europe and North America have seen a steadily increasing demand for services in recent years, with a ratio of phenotypic males to females close to 1:1.

Mental Health Concerns and Impact of Family Support

Life-threatening behaviors represent a significant risk for transgender youth and adolescents. A retrospective cohort study of 180 transgender individuals aged 12 to 29 years seen in a Boston clinic between 2002 and 2011 were compared to an equal number of cis-gender, age-matched controls. In comparison to controls, transgender youth/young adults had a two- to threefold increased risk of anxiety, depression, suicidal ideation, suicide attempts, and self-harm without lethal intent. The impact of the degree of parental support on mental health outcomes was reported in a cohort of transgender youth and young adults age 16 to 24 years (n = 84) from Ontario, Canada: Satisfaction with life and self-esteem were significantly greater in transgender youth whose parents were "very supportive" versus those whose parents were "somewhat to not at all supportive." In addition, depression and suicide attempts were significantly decreased in transgender youth whose parents were supportive in comparison to those whose parents were not supportive. Even with supportive parents, transgender youth still have a significant risk for depression, perhaps in part from their experience of transphobia from members of their communities and feelings of rejection and social isolation.

Biologic Underpinnings of Gender Identity

Numerous studies from a variety of biomedical disciplines—endocrine, genetic, and neuroanatomical—have begun to shed light on the biologic underpinnings of gender identity. Results of these studies support the concept that gender identity is not simply a psychosocial construct, but likely reflects a complex interplay of biologic, environmental, and cultural factors.

While the majority of transgender patients do not have a DSD, studies of gender identity outcome within the endocrine discipline have been principally carried out in patients with a variety of DSDs, primarily exploring the role of prenatal and postnatal androgens in gender identity development. For example, studies in 46, XX patients with "classical" congenital adrenal hyperplasia (CAH) caused by mutations in the *CYP21A2* gene resulting in 21-hydroxylase deficiency and varying degrees of genital masculinization, demonstrate a greater than expected number of patients with gender dysphoria, "atypical gender identity," or who were transgender. In a meta-analysis of 250 patients with 46, XX 21-hydroxylase deficiency leading to virilizing CAH and raised female, nearly 95% of patients reported a female gender identity without gender dysphoria, while 5.2% reported either a male gender identity or gender dysphoria. Of note, there was no apparent correlation with the degree of genital masculinization and gender identity outcome. A study of adult women with classical 21-hydroxylase deficiency demonstrated a relationship between severity of disease and gender identity outcome: Of 42 patients

with the salt-wasting form, 3 (7.1%) had either gender dysphoria or had changed gender to male; no gender dysphoria was seen in less severely affected individuals. These and other studies demonstrate that the majority of 46, XX patients with virilizing CAH from 21-hydroylase deficiency appear to have a female gender identity. However, the finding that 5.2% to 11.6% of such patients have gender dysphoria, an "atypical gender identity" or are transgender would appear to be much more common than expected based on the reported prevalence of FTM transsexualism, implying that there is some role for prenatal/postnatal androgens in gender identity outcome. It is noteworthy that in 46, XX individuals with virilizing CAH from 21-hydroylase deficiency, prenatal androgens are more likely to affect gender behavior and sexual orientation than gender identity.

The potential effects of prenatal and postnatal androgen exposure on gender identity outcome and "gender role change" have also been explored in other hormonal and non-hormonal DSDs. For example, in 5α-reductase-2 deficiency (5α-RD-2), among 46 XY individuals raised female, a "gender role change from female to male" (typically after puberty) was reported in 56% to 63% of the patients. Gender role changes from female to male were also reported in 39% to 64% of 46 XY individuals raised female with 17β-hydroxysteroid dehydrogenase-3 deficiency (17β-HSD-3). In the largest series of patients with 5α-RD-2 and 17β-HSD-3 reviewed by Cohen-Kettenis and colleagues, individuals undergoing gender role change from female to male had intact testes, implying a potential role of prenatal as well as postnatal androgen exposure in gender identity outcome.

Gender identity outcome has also been studied in patients with a variety of "non-hormonal" DSDs, including cloacal exstrophy, penile ablation, and penile agenesis. A study of patients with 46 XY cloacal exstrophy reported that the majority (8 of 14) who had undergone neonatal sex reassignment to female (castration) subsequently declared a male gender identity, and that 2 patients raised as males remained male. A literature review of individuals with 46 XY cloacal exstrophy found that of 51 patients assigned female, the majority (65%) were living as female while 14% were living as female but with possible gender dysphoria, and approximately 22% were living as male. In addition, of 16 males with penile agenesis assigned female at birth and of 7 males with penile ablation reassigned to female in infancy or early childhood, the majority were living as female.

These studies of gender identity outcome in hormonal and non-hormonal DSDs, taken together, indicate that gender identity is not solely dependent on prenatal and postnatal androgen exposure; however, the occurrence of gender identity change (in comparison to the "natal gender") at a rate significantly higher than would be expected in the general population supports some role of prenatal and possibly postnatal androgens in gender identity development. Potential limitations of all these survey/questionnaire-based studies to assess gender identity include a person's degree of self-awareness and one's willingness to disclose this information in the study context.

While the above-noted studies support some role of androgens in male gender identity, a case report in a 46, XY individual with complete androgen insensitivity syndrome (CAIS) challenges the concept that androgen receptor (AR) signaling is required for male gender identity development. Individuals with CAIS typically have unambiguous female genitalia and a female gender identity; however, an individual with CAIS, associated with an unambiguous female phenotype and an *AR* gene mutation resulting in a premature stop codon, was found to have a male gender identity (26). As acknowledged by the authors of that study, this patient may have had a post-zygotic *de novo AR* gene mutation (the mother's DNA was not available) and could theoretically have brain mosaicism (with a normal AR in the brain).

With respect to genetics and gender identity, heritability of transsexualism has been suggested primarily from studies describing concordance of transsexualism in monozygotic twin pairs. A study of survey responses from parents of twins (96 monozygotic pairs and 61 dizygotic pairs, ages 7-14 years) demonstrated a 2.3% prevalence of clinically significant GID (based on DSM-IV criteria). These authors reported that heritability accounted for 62% of the variance for GID in their twin sample. A more recent study supporting a role for genetic factors in gender identity outcome demonstrated a 39.1% concordance for GID (based on DSM-IV criteria) in 23 monozygotic female and male twin pairs, with no concordance in 21 same-sex dizygotic female and male twin pairs or in 7 opposite-sex twin pairs. However, with respect to specific candidate genes [estrogen receptor α (*ER*α) and β (*ER*β), androgen receptor (*AR*), aromatase, (*CYP19*), progesterone receptor (*PGR*), and the *CYP17* gene], association studies of polymorphisms with transsexualism have been inconsistent and lacking strong statistical significance.

With respect to neuroanatomical considerations and gender identity, it has been known for some time that some brain structures are sexually dimorphic, while one component of the hypothalamus has been reported to be sexual orientation-dimorphic. Numerous studies in transgender adults, carried out prior to any cross-sex hormone treatment, have provided evidence indicating that some sexually dimorphic structures appear to align more closely with a person's gender identity than with their physical sex characteristics. A trend towards similar findings has also been reported in MRI studies of gray matter of gender dysphoric youth.

Transgender Youth: Natural History

Once puberty has begun, the majority of gender dysphoric prepubertal youth will no longer meet the mental health criteria for gender dysphoria. While gender fluidity may be a contributing factor, the lack of persistence of gender dysphoria in the majority of gender dysphoric prepubertal youth likely reflects the heterogeneous nature of this group. Many such individuals will turn out to be homosexual (natal males, in particular) rather than transgender. Investigators have attempted to identify factors that predict gender dysphoria "persisters" versus "desisters." Persisters reported relatively greater degrees of gender dysphoria and were more likely to have experienced social transition (to their affirmed gender) during childhood. In addition, persisters believed they "were" the other sex, while desisters "wished they were" the other sex. The limitations in prediction of persistence, coupled with the

observation that most gender dysphoric children will not become transgender adolescents or adults, have led some investigators and/or practitioners to promote efforts to encourage gender dysphoric children to accept their natal gender. In contrast, a model of care that affirms a child's gender expression is thought to have a more optimal mental health outcome. Long-term outcomes studies are needed to resolve these differences in approach to the care of gender dysphoric prepubertal youth.

Clinical Practice Guidelines for Transgender Youth

Persistence of gender dysphoria following initiation of puberty implies a very high likelihood that such individuals will be transgender as adults; in fact, the emergence or worsening of gender dysphoria with onset of puberty is thought to have significant diagnostic value in the determination of being transgender. With the availability of gender-affirming medical interventions (as detailed later), however, awareness of such treatment options may positively impact and, thus, limit the degree of dysphoria that might otherwise accompany the onset of puberty in a transgender individual. It is therefore essential that gender dysphoric youth undergo a thorough psychological diagnostic evaluation by a qualified mental health provider. An important role of the mental health/gender specialist is not only to determine the presence or absence of gender dysphoria, but also to evaluate for the presence of other mental health concerns. For example, while there is an increased association of gender dysphoria and autism spectrum disorder, the majority of gender dysphoric children and adolescents do not have an underlying severe psychiatric illness.

Management of Early Pubertal Transgender Youth

Pubertal suppression with a gonadotropin releasing hormone (GnRH) agonist (classically used for the treatment of precocious puberty) in early/mid-pubertal gender dysphoric adolescents was first described in studies from the Netherlands. This treatment is fully reversible and allows additional time for gender exploration without the pressure of ongoing pubertal development. The physical changes of puberty, once completed, cannot be reversed (by means other than surgical or, for voice, other than by voice training)—for example, low voice, Adam's apple, and facial features in phenotypic males and breast development in phenotypic females. Preventing pubertal development that does not match a person's gender identity can theoretically lead to decreased distress and can ultimately enable the individual to more easily "blend" in society as an adult. Subsequently, if the individual continues to identify as transgender, cross-sex hormones can be added while continuing GnRH agonist suppression of endogenous puberty, enabling the individual to experience only the physical changes of puberty that match the person's experienced/affirmed gender identity. The Endocrine Society (ES) guidelines and WPATH SOC endorse the use of pubertal blockers (using GnRH agonists) at Tanner 2/3 in individuals experiencing a significant increase in gender dysphoria with onset of puberty. While age-specific

guidelines for subsequent interventions are not delineated in the WPATH SOC, the ES guidelines suggest that cross-sex hormones can be initiated at about the age of 16 years (the legal age for medical decision-making in some countries), while surgical procedures (with the exception of mastectomy) should be deferred until the individual is at least 18 years of age. Delaying cross-sex hormone treatment until age 16 could not only be detrimental to bone health, but, by keeping someone in a prepubertal state until this age, would isolate the individual further from age-matched peers, with potentially negative consequences for emotional well-being. Gender centers at our institution and elsewhere are therefore studying the impact of cross-sex hormone treatment initiation at 14 years of age (which approximates the upper end of the age range for normal pubertal onset in natal males and 1 year beyond the upper end of the age range in natal females). In this group, sex steroids are increased gradually over the course of 2 to 3 years.

The above-noted ES and WPATH recommendations are supported by limited available outcomes data. A prospective follow-up study from the Netherlands assessed 70 gender dysphoric adolescents (33 MTF, 37 FTM), average age 13.65 years (range 11.1-17 years) at initial assessment, who were Tanner Stage 2 to 3, had "life-long gender dysphoria" that increased with puberty, had stable psychological function, and were supported by their families. These adolescents were studied at the initiation of GnRH agonist treatment and approximately 2 years later, just before starting cross-sex hormones. While gender dysphoria persisted, depressive symptoms decreased, general mental health functioning improved, no subjects withdrew from pubertal suppression, and all went on to cross-sex hormone treatment. A subsequent report from this initial cohort in the Netherlands assessed mental health outcomes in 55 transgender adolescents/young adults (22 MTF, 33 FTM) at 3 time points: before the start of GnRH agonist treatment, at initiation of cross-sex hormones (average 16.7 years at start of treatment), and at least 1 year after "gender reassignment surgery" (average age 20.7 years). Despite a decrease in depression and an improvement in general mental health functioning, gender dysphoria persisted during the period of pubertal suppression (as noted in earlier reports); however, following cross-sex hormone treatment and "gender reassignment surgery," gender dysphoria was resolved, and psychological functioning steadily improved. Well-being was found to be similar to or better than that in age-matched young adults from the general population, and none of the study participants regretted treatment. This study represents the first long-term follow-up of patients managed according to currently existing clinical practice guidelines for transgender youth and underscores the benefit of the multidisciplinary approach to care.

The primary risks of pubertal suppression in gender dysphoric youth treated with GnRH agonists include adverse effects on bone mineralization, compromised fertility, and unknown effects on brain development.

Bone mineral density (BMD) studies of the lumbar spine, femoral neck, and total body were initially carried out in a small number of gender dysphoric adolescents during 2 years of GnRH agonist alone and for an additional 2 years of combination treatment with GnRH agonist and cross-sex hormones. BMD (g/cm^2) did not change significantly during

treatment with GnRH agonist alone, though z-scores decreased; during combination therapy with GnRH agonist and cross-sex hormones, absolute BMD increased, as did z-scores.

A 6-year longitudinal, observational study assessed BMD in 34 transgender adolescents (15 MTF, 19 FTM) who had received GnRH agonist beginning at an average age of 14.9 to 15 years (individuals were mid-late pubertal at study onset by testicular volume or breast stage), had initiation of cross-sex hormones at 16.4 to 16.6 years, followed by gonadectomy with discontinuation of GnRH agonist at a minimum age of 18 years. Over the 6-year observation period, areal BMD z-scores decreased significantly in MTF individuals with a trend for a decrease in FTM individuals, suggesting either a delay in attainment of peak bone mass, or an attenuation of peak bone mass, itself. As acknowledged by the authors, potential study limitations included a relatively small number of subjects, the fact that individuals were already late pubertal at the time of GnRH agonist initiation, the possibility that relatively low doses of cross-sex hormones were used during the initial period of that phase of treatment, and that information was not available regarding dietary calcium intake, vitamin D levels, and weight bearing exercise, all of which can influence BMD. It would seem important, particularly during GnRH agonist treatment, to ensure adequate intake of calcium and vitamin D, to encourage weight-bearing exercise, and to monitor levels of 25-OH vitamin D routinely.

Any use of pubertal blockers and cross-sex hormones in transgender youth should include an informed consent process and a discussion about implications for fertility. Transgender adolescents may wish to preserve fertility, which may be otherwise compromised if puberty is suppressed at an early stage and the patient completes phenotypic transition with the use of cross-sex hormones. While full *in vitro* maturation of germ cells has not yet been achieved in humans, promising studies have been carried out in mice.

Regarding potential adverse effects of GnRH agonists (and cross-sex hormones) on the brain, a recent study investigated whether GnRH agonist treatment of gender dysphoric adolescents would impair executive functioning (reasoning, problem solving, etc.), thought to reflect prefrontal brain activation, and to have significant development during puberty. No significant detrimental effects of GnRH agonist treatment on executive functioning were observed.

A report from Vancouver, Canada, assessed potential adverse effects of GnRH agonist treatment in transgender youth. Relatively few adverse effects were observed: Of 27 patients receiving GnRH agonist, one developed a sterile abscess at the injection site, one developed transient leg pains and headaches, and one developed significant weight gain.

Management of Late Pubertal Transgender Youth

It is not unusual for some transgender adolescents to first come to medical attention when they are late pubertal (Tanner 4/5). FTM individuals can be treated with testosterone alone while MTF individuals are optimally treated with estrogen with concurrent use of an agent that blocks testosterone secretion and/or action.

GnRH agonists can be used to suppress the hypothalamic-pituitary-gonadal axis, potentially enabling use of lower doses of cross-sex hormones to induce phenotypic transition to the affirmed gender, thereby decreasing potential toxicities associated with cross-sex hormone treatment. In this older cohort, cross-sex hormone regimens may be increased to full replacement doses over a shorter interval than used for the younger cohort that had been initially treated with pubertal blockers at Tanner 2/3. While GnRH agonists are the preferred option for pubertal suppression in both the early and late pubertal individuals, this treatment is costly and often inaccessible. Options for pubertal suppression and cross-sex hormone treatment are listed in Table 23–1.

TABLE 23–1 Hormonal interventions for transgender adolescents (all currently off-label for gender non-conforming/transgender youth).

A. Inhibitors of gonadal sex steroid secretion or action

1. GnRH analogues: Inhibition of the hypothalamic-pituitary-gonadal (HPG) axis (FTM and MTF)

   a. Leuprolide acetate IM (1- or 3-month preparations) or SC (1-, 3-, 4-, or 6-month preparations) at dose sufficient to suppress pituitary gonadotropins and gonadal sex steroids

   b. Histrelin acetate 50 mg SC implant (once-yearly dosing, though may have longer effectiveness)

   c. Other options: goserelin acetate SC implant (4- or 12-week preparations); nafarelin acetate intranasal (multiple daily doses) also available, but no reported use in this population

2. Alternative approaches

   a. Medroxyprogesterone acetate orally (up to 40 mg/d) or IM (150 mg q 3 months): Inhibition of HPG axis and direct inhibition of gonadal steroidogenesis (FTM and MTF)

   b. Spironolactone (25-50 mg/d with gradual increase to 100-300 mg/d orally, divided into BID dosing): Inhibition of testosterone synthesis and action (MTF)

   c. Cyproterone acetate (gradual increase up to 100 mg/d orally; not available in United States): Inhibition of testosterone synthesis and action (MTF)

   d. Finasteride (2.5-5 mg/d orally): Inhibition of Type II 5α-reductase, blocking conversion of testosterone to 5α-dihydrotestosterone (MTF)

B. Cross-sex hormones

1. MTF: Estrogen: 17 β-estradiol

   a. Transdermal: twice weekly patches [6.25 μg (achieved by cutting a 25 mcg patch) with gradual increase to full adult dose (typically, 100-200 μg patch)] Oral/sublingual: daily (0.25 mg with gradual increase to full adult dose of 2-6 mg/d)

   b. Parenteral IM (synthetic esters of 17 β-estradiol): estradiol valerate (5-20 mg increasing up to 30-40 mg q 2 weeks) or estradiol cypionate (2-10 mg q 1 week)

2. FTM: Testosterone

   a. Parenteral IM or SC (synthetic esters of testosterone): testosterone cypionate or enanthate (12.5 mg q week or 25 mg q 2 weeks, with gradual increase to 50-100 mg q week or 100-200 mg q 2 weeks)

   b. Transdermal (consider once full adult testosterone dose has been achieved parenterally): patch (2-6 mg/d) or 1.62% gel (20.25-81 mg/d)

Abbreviations: MTF, Male-to-Female; FTM, Female-to-Male.

Reproduced with permission from Rosenthal SM. Approach to the patient: transgender youth: endocrine considerations. *J Clin Endocrinol Metab.* 2014 Dec;99(12): 4379-4389.

With respect to estrogen treatment, 17 β-estradiol (transdermal, oral, or parenteral) is preferred to conjugated (eg, premarin) or synthetic estrogens (eg, ethinyl estradiol) given that conjugated and synthetic estrogen levels cannot be monitored in the serum and that ethinyl estradiol (in comparison to 17 β-estradiol) is associated with an increased risk for venous thromboembolic disease and death from cardiovascular causes. MTF individuals treated with estrogen may have impaired insulin sensitivity and hyperprolactinemia. Principal risks associated with testosterone treatment in FTM individuals include cystic acne, polycythemia, hypertension, an atherogenic lipid profile, and possible decreased insulin sensitivity. Table 23–2 summarizes surveillance recommendations for desired as well as adverse effects during treatment with pubertal blockers alone and in combination with cross-sex hormones, adapted from the current ES guidelines.

Some Tanner 4/5-transgender adolescents present for medical services before 16 years of age. As with the group treated with GnRH agonists at early puberty, we and others are studying the consequences of cross-sex hormone treatment at 14 years of age. Some gender dysphoric youth first come to medical attention when they are Tanner 4/5, but less than 14 years of age. These

TABLE 23–2   Monitoring during pubertal suppression and during cross-sex hormone treatment.*

A. Pubertal suppression	
Measure	Frequency
1. Physical examination: height, weight, Tanner Staging	T 0 & q 3 mo
2. Hormonal studies: ultrasensitive LH, FSH, estradiol/testosterone	T 0 & q 3 mo
3. Metabolic: Ca, phos, alk phos, 25-OH Vitamin D (see also ref. 3)	T 0 & q 1 yr
4. Bone mineral density: DXA	T 0 & q 1 yr
5. Bone age	T 0 & q 1 yr
B. Cross-sex hormone treatment in previously suppressed patients or in late pubertal patients not previously suppressed	
Measure	Frequency
1. Physical examination: height, weight, Tanner Staging, BP (for FTM, in particular); monitor for adverse reactions	T 0 & q 3 mo**
2. Hormonal studies: ultrasensitive LH, FSH, estradiol/testosterone	T 0 & q 3 mo**
If MTF: also monitor prolactin	T 0 & q 1 yr
3. Metabolic: Ca, phos, alk phos, 25-OH vitamin D, complete blood count, renal & liver function, fasting lipids, glucose, insulin, glycosylated hemoglobin	T 0 & q 3 mo**
If MTF on spironolactone: serum electrolytes (potassium)	T 0 & q 3 mo**
4. Bone mineral density: DXA (if puberty previously suppressed)	T 0 & q 1 yr***
5. Bone age (if puberty previously suppressed)	T 0 & q 1 yr***

*Modified from Hembree WC et al., 2009; **q 3-12 mo after 1st yr; ***Until puberty is completed.

Abbreviations: MTF, Male-to-Female; FTM, Female-to-Male.

Data from Hembree WC, Cohen-Kettenis P, Delemarre-van de Waal HA, et al. Endocrine treatment of transsexual persons: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2009 Sep;94(9):3132-3154.

individuals would be candidates for pubertal blockers (eg, to stop menses in an FTM adolescent), but without supportive outcomes data, they would not currently be candidates for cross-sex hormone use under most circumstances.

Areas of Uncertainty/Barriers to Care/and Priorities for Research

Areas of uncertainty and barriers to state-of-the art practice limit the ability to provide optimal health care to gender dysphoric/transgender youth. Currently, there are only limited safety and efficacy studies, with virtually no published data on the use of pubertal blockers in gender dysphoric individuals less than 12 years of age or cross-sex hormones in transgender youth less than 16 years of age. In addition, randomized controlled trials for hormonal interventions in gender dysphoric youth have not been considered feasible or ethical. Current clinical practice guidelines are based on best available evidence, with significant reliance on expert opinion. The Institute of Medicine of the National Academies in the United States has endorsed the need for prospective, longitudinal safety, and efficacy studies of medical interventions in gender non-conforming/transgender youth. Challenges to implementation of current clinical practice guidelines in the United States include the fact that pubertal blockers and cross-sex hormone treatments are off-label for gender dysphoric youth, are expensive, and coverage is often denied by insurance companies. In addition, while an increasing number of clinical programs have emerged in recent years, there are many geographic regions in which such services do not exist, limiting access to care and often requiring patients and families to travel long distances. Furthermore, lack of training of providers and prejudice and misunderstanding on the part of family, community, and medical and mental health professionals may limit access to optimal care. A report surveying the memberships of the Pediatric Endocrine Society and the Society for Adolescent Health and Medicine explored providers' clinical experiences, comfort, and confidence with and barriers to providing care to transgender youth. Principal barriers to provision of transgender-related care included lack of the following: training, exposure to transgender patients, available qualified mental health providers, and insurance reimbursement.

Endocrine Management of Transgender Youth: Conclusions

Significant advances in our understanding of gender nonconforming/transgender youth have been achieved, though many gaps in knowledge remain. Compelling studies have demonstrated that gender identity is not simply a psychosocial construct, but likely reflects a complex interplay of biologic, environmental, and cultural factors. The replacement of "disorder" with "dysphoria" in DSM-5 removes the connotation that a transgender identity, itself, is pathologic, and instead, focuses on dysphoria as the clinical concern. A landmark study from the Netherlands indicates that mental health comorbidities in gender-dysphoric youth significantly diminish or resolve when such

individuals are subject to a gender-affirming model of care, optimally delivered in a multidisciplinary clinical setting. Further prospective studies focused on long-term safety and efficacy are necessary to optimize medical and mental health care for transgender youth.

PART II: ENDOCRINE MANAGEMENT OF TRANSGENDER ADULTS

Introduction

The age adulthood begins is variably defined at age 18 to 21 years, at which time persons can independently give informed consent for invasive procedures. Most persons this age who have persistent gender dysphoria are treated with adult protocols. The natural history of gender dysphoria in adults has not been well documented although when most adults present for hormone treatment they describe the occurrence of symptoms beginning during childhood. The goals of **Part II** of this chapter are to review adult presentation of gender dysphoria, endocrine status in adults with gender dysphoria, strategies for sex steroid treatment, potential adverse effects of estradiol and testosterone treatment, genital and breast surgery options, reproductive decisions, the role of voice therapy, and considerations for care of elder transgender individuals.

Adult Presentation of Gender Dysphoria

Adults with gender dysphoria variably present to mental health professionals, to physicians experienced in endocrine treatment, to surgeons, or to clinics with all of these types of providers. Appropriate clinical management may require all of the above. The first step is confirmation of the diagnosis, gender dysphoria, assessment of readiness of the person to begin treatment and evaluation of risk factors for medical treatment (Table 23–3). Rarely, adults with psychological and/or developmental problems may present with gender problems but are not confirmed to exhibit gender dysphoria. The second step is exploration of appropriate hormonal protocols, including the associated risks, benefits, and contraindications. Third, hormone treatment is initiated using varying protocols suitable for transgender women (MTF) or transgender men (FTM) (Table 23–4). Consultation with surgeons who specialize in genital surgery occurs after at least 1 year of cross-sex hormone treatment. Breast and facial surgery are commonly explored.

In clinical practice, persons with gender dysphoria who seek treatment with sex steroids, genital surgery and social transition to a new gender may present at any time during adulthood. Clinical histories usually describe gender-related conflicts with their natal sex, especially during puberty. Many have married, become parents, and lived as a person of their natal sex, a man or a woman. Conflicts between natal sex and gender often occasion presentation to a mental health professional, although the diagnosis of gender dysphoria may not be apparent. Most give a history of incomplete resolution of childhood symptoms despite living in their natal sex as adults. Exploration of the components

TABLE 23–3 Hormone protocols for transgender adults.

A. Male-to-female (MTF) protocols

a. Phase 1: Blocking testosterone production
(May be given initially to reduce testosterone levels or simultaneously with estrogen)

i. Spironolactone	100-200 mg/d
ii. Cyproterone acetate	50-100 mg/d
iii. GnRH analog	3.76 mg/mo
(Gonadotropin Releasing Hormone Agonist)	

b. Phase 2: Estradiol administration

i. Oral estradiol	2.0-5.0 mg daily
ii. Transdermal E2 patch	0.1-0.4 2-3× weekly*
iii. Parenteral E2 valerate or cypionate	2-10 mg/wk

B. Female-to-male (FTM) protocols

a. Phase 1: Blocking ovulation/estradiol production
(Note: Testosterone injections alone at early follicular phase may block ovulation)

i. Medroxyprogesterone acetate	30-40 mg/d
ii. Cyproterone acetate	50-100 mg/d
iii. GnRH analog	3.75-15 mg q 1-3 mo

b. Phase 2: Testosterone administration
(Note: Phase 1 medications may be given before, simultaneously or not at all with testosterone)

i. Transdermal	
1. Testosterone Gel 1%	2.5-10 mg/d
2. Testosterone transdermal patch	2.5-10 mg/q 2-3 d
ii. Parenteral	
1. Testosterone enanthate/cypionate	50-100 mg q 2 wks
	30-60 mg q wk
2. Testosterone undecanoate	1000 mg q 8-12 wks

*Recommended for MTF over 40 years old

**Synthetic estradiol esters not recommended

TABLE 23–4 Transgender medical evaluation.

1. Review gender dysphoria history
   a. If present, review mental health professional recommendation

2. Medical and mental health history
   a. Assess risk factors to sex steroids
      i. Transgender women (MTF)
         1. Thromboembolic disease/history
         2. Hyperprolactinemia
         3. Cerebrovascular disease
         4. Severe migraine headaches
         5. Breast cancer
      ii. Transgender men (FTM)
         1. Erythrocytosis
         2. Severe liver dysfunction
         3. Hypertension
         4. Breast or uterine cancer
   b. Family history
      i. Reproductive tract cancer
      ii. Diagnosis of mental health illness
      iii. Osteoporosis/history of bone fracture

3. Medications and allergies

4. Alcohol use, smoking, addiction history, hospitalizations

5. Physical examination
   a. Breast examination
   b. Reproductive tract examination

of gender change includes discussions of hormone treatment as well as surgical options. New onset of gender dysphoria as an adult is unusual.

Endocrine Considerations and Management

Endocrine evaluation of adults with gender dysphoria usually discovers normal development of the body that reflects natal sex changes as well as, after puberty, body changes produced by appearance of their natal sex hormones. However, amongst some persons with a DSD, CAH, AIS, and 5α-RD, there is more frequent occurrence of gender dysphoria and gender change than in the general population. Studies of the relationship of early exposure to androgens may explain sexual and social behavior, but they do not clarify patient-initiated gender choice. However, circulating levels of testosterone, metabolism to estrogens, and impact upon bone development in natal males are determined, in large part, genetically. This may account for the variability observed in bone responses during sex steroid treatment.

The design of the sex steroid protocols used is based upon, first, the treatment that will most appropriately and completely suppress natal sex steroids, either before or at the same time exogenous sex steroids are given (see Table 23–4). Second, the protocol should utilize the most effective available method by which sex steroids of the person's new gender can be administered. For example, some FTM protocols may use testosterone alone, thereby suppressing ovulation, preventing uterine bleeding, achieving effective virilization, while avoiding adverse effects. On the other hand, MTF protocols using physiologic replacement doses of estradiol alone may not sufficiently suppress endogenous testosterone levels and, thereby, result in insufficient feminization. In such cases, it may be necessary to use additional agents, initially alone or as a combination with estrogens, that will effectively suppress endogenous testosterone levels to those of natal women. Progestins have been used frequently to suppress endogenous sex steroids, as have GnRH analogs. The doses of exogenous sex steroids required to suppress endogenous sex steroids may vary with the individual, the dose used, the method of administration and their natal sex.

The goal of testosterone treatment in transgender men (FTM) with regular menses is to suppress ovulation and, thereby, maintain low estradiol levels. Thus, the time to initiate testosterone treatment in protocols for transgender men (FTM) is important. Treatment should begin during or immediately following menses when estradiol and progesterone levels are lowest, when there is little stimulation of the endometrium and there is no follicular development (estrogen levels are in the male normal range). Levels of free testosterone should be maintained above the mid-range of the adult natal male in order to suppress follicular development and uterine bleeding. Testosterone may be given by intramuscular injection or by transdermal application of testosterone gel. Transdermal patches do not permit easy dose adjustment. Total and free testosterone, total estradiol, and LH/FSH levels should be measured at 3-month intervals initially to ensure ovarian suppression and to avoid adverse effects (Table 23–5).

TABLE 23–5   Monitoring sex steroid treatment in adults male-to-female (MTF).

1. Signs of feminization
   a. Evaluate 3-4 times year 1 and 1-2 times years 2-4
   b. Breast growth
   c. Loss of terminal hair growth
   d. Body fat redistribution
   e. Decrease testicular size
2. Assess hormone levels
   a. Evaluate 3-4 times year 1 and 1-2 times year 2-4
   b. Estradiol: 100-200 pg/dL
   c. Testosterone: <50 ng/dL
   d. Prolactin: Pretreatment, annual
   e. LH/FSH: if testosterone levels >100 ng/dL
3. Spironolactone use
   a. Electrolytes (potassium): Baseline, every 2-3 months × 2 and after increased dose × 2
4. Bone mineral density assessment
   a. Baseline if risk factors present
   b. Age 60 years old
   c. Non-compliant sex steroid use
   d. Cessation of sex steroids
5. Routine breast, colon, and prostate cancer screening

Female-to-male (FTM)
1. Signs of virilization:
   a. Evaluate 3-4 times year 1 and 1-2 times years 2-4
   b. Cessation of menses
   c. Facial/body hair growth
   d. Increase muscle mass
   e. Deepening of voice
   f. Clitoral enlargement
2. Assess hormone levels
   a. Measure testosterone every 3 months until levels remain in physiologic range of natal adult male;
   b. Testosterone enanthate/cypionate: demonstrate peak and trough levels within physiologic range of natal adult male × 2;
   c. Transdermal testosterone: assess after 2 weeks of use, measure more than 2 hours after application;
   d. Testosterone undecanoate: measure testosterone prior to next injection; if <400 ng/dL, increase dose/interval;
3. Obtain weight, CBC, blood pressure, lipids every 3-4 months year 1 and 1-2 times yearly thereafter;
4. Annual PAP if cervix present;
5. If mastectomy, regular examination of periareolar tissue; if no mastectomy, mammograms as recommended by the American Cancer Society.

When transgender men are given high doses of testosterone, the biologically active free testosterone is determined by the clearance rate of testosterone, the binding to SHBG and the aromatization to estradiol. Variation in each of the above will determine the appropriate testosterone dose needed for each person. At the onset of puberty in natal males and during testosterone replacement in hypogonadal men, high aromatase levels may result in high estradiol levels and transient gynecomastia. In adult natal women who are transgender men (FTM), aromatase activity is higher than adult men. Thus, when a full adult male dose of testosterone is given to an FTM, high estradiol levels may result. Little is known about aromatization of testosterone in the endometrium and its potential for causing uterine bleeding, although aromatase inhibitors have been used successfully to treat

endometrial spotting. Published protocols using testosterone alone for transgender men (FTM) report cessation of ovulation and little uterine bleeding. However, initial suppression of ovulation with progestins or GnRH agonist may be necessary. In addition to the effect of changes in aromatase levels, alterations in testosterone clearance and binding by sex hormone binding globulin (SHBG) may alter the testosterone dose required. Monitoring of blood pressure and hemoglobin levels will prevent adverse effects; while estradiol and gonadotropin levels will monitor ovarian suppression (see Table 23–5).

Estradiol treatment of transgender women (MTF) requires suppression of endogenous testosterone levels from 300-1000 ng/dL to less than 50 ng/dL. Oral, transdermal and intramuscular preparations are available. Estradiol levels in natal, ovulatory women average 100-200 pg/mL and should be the goal for transgender women. However, estrogen doses that achieve this range of estradiol in MTF may fail to suppress endogenous testosterone levels to less than 50 ng/dL. Natal women whose testosterone levels exceed 50 ng/dL may exhibit hirsutism or signs of mild virilization, despite good estradiol levels. Thus, optimal suppression of endogenous testosterone by exogenous estradiol usually requires use of a second medication. Compounds with progestin activity (spironolactone, medroxyprogesterone, and cyproterone acetate) are most commonly used. GnRH analogs also effectively reduce testosterone levels to less than 50 ng/dL. Medications with 5α-reductase inhibitory activity may reduce balding in transgender men and women. However, their use in MTF protocols is not advised due to their failure to suppress endogenous testosterone levels in transgender women and their adverse effects.

Protocols that effectively suppress endogenous sex steroids and maintain adult levels of the new exogenous sex steroid should have periodic assessment during the first 1 to 2 years of treatment (see Table 23–5). Variations in transdermal absorption occur over time, as does metabolic clearance, and SHBG levels. Most of these changes occur within the first 6 to 12 months of treatment. Stable sex steroid levels achieve gender-specific body changes that begin within 6 months and stabilize within 2 to 5 years. Effects of estrogen include changes in body fat, muscles and skin, decreases in sexual function, libido, breast growth, minor decreases in testicular size, decreased body hair growth, and slowing of male baldness. Effects of testosterone include acne, body hair growth, scalp hair loss, changes in muscle mass and body fat, voice deepening, genital changes, and clitoral enlargement. Increasing sex steroid doses does not change the time course of these changes in adults.

Surveillance for Potential Adverse Effects of Hormonal Treatment

Transgender men and women should be screened for heart disease, hypertension, metabolic syndrome, lipid disorders, diabetes, and breast and prostate cancer. The frequency of this monitoring varies from 1 to 4 times during the first year to annually after 3 years. Elevated prolactin levels and prolactinomas, as well as excess cases of thrombophlebitis, have been reported in transgender women. Data suggest that ethinyl estradiol increases the risk of vascular disease in transgender women. Breast development is variable in MTF persons, is considered inadequate by most transgender women and is not improved by use of progestins. There is a high request rate for mammoplasty. Low bone mass has been observed in transgender women despite physiologic levels of estradiol. Cardiovascular disease is higher in MTF persons treated with estrogen than in testosterone treated FTM persons, reversing the trend observed in natal men and women. Surveillance of laboratory tests that monitor general health should occur at baseline and be monitored periodically. Normal ranges should be interpreted with caution since studies have shown that the "normal range" for transgender men and women may not be coincident with those of natal men and women.

Surgical Considerations

Transgender men and women may elect to have both major and minor surgical procedures during gender transition. Transgender women select facial treatment over chest and genital procedures whilst transgender men opt for chest/breast procedures. MTF persons, especially those 20 to 30 years old, may plan genital surgery that creates a neovagina. A variety of techniques have been developed, each with advantages and disadvantages. Clitoroplasty is widely used and results in good sexual sensitivity; creation of labia minora and labia majora utilizes a variety of techniques with variable success. Breast development during estradiol treatment occurs during a 1- to 2-year period, and outcomes are variable. Breast augmentation is requested in approximately 50% of transgender women. Standard breast cancer screening is required after 2 years of estrogen treatment. For FTM persons, phalloplasty is available in a greater number of centers, although metoidioplasty is selected more frequently, preserving sensitivity and facilitating urination while standing. Mastectomy in FTM persons may leave residual subareolar breast tissue for cosmetic reasons. Close surveillance for cancer screening is required. It is unlikely that screening for endometrial and ovarian cancer occurs regularly in FTM persons and, thus, hysterectomy/ovariectomy should be considered.

Reproductive Options

Both transgender women and transgender men may elect to have children. A variety of options are available, although the number of transgender persons electing pregnancy is low. The impact of gender transition upon future reproductive options should be discussed with all transgender persons who are seeking hormonal or surgical transition. In transgender women, sperm cryopreservation prior to estrogen treatment is available at modest cost. Although 51% of MTF persons indicated they would elect sperm cryopreservation, published reports of pregnancy using cryopreserved sperm from transgender women are few. Testis morphology in adult men treated with estradiol suggests that residual Leydig cells, Sertoli cells and spermatogonia remain, although no studies have demonstrated recovery of spermatogenesis following cessation of estradiol. Transgender men who have transitioned with testosterone and maintained reproductive organs have successfully elected pregnancy. Oocyte, ovarian, and embryo cryopreservation are available prior to initiation of testosterone treatment in

transgender men, although the chances of achieving live births from these tissues are small. In most states and countries, transgender families may also elect adoption.

Voice Therapy

Increasingly, transgender persons seek advice and treatment from speech language pathologists, although one survey indicates that many felt improperly prepared and that specific training courses are limited. Half of transgender persons surveyed were unaware of available services. Correlation of speech patterns with body movement also aids identity as female. One chart review of 25 persons undergoing feminizing hormone treatment found that 80% successfully present as female 100% of the time. Happiness of MTF with their voice after voice training correlates more so with perceived femininity and quality of life than with achieved pitch. MTF adolescents may also benefit from voice and communication therapy. Surgical techniques are available for MTF transgender persons. However, comparison of the outcomes of speech therapy alone, surgical techniques alone, and surgery followed by speech therapy has not been studied. Of the three approaches for FTM, there are no outcome comparison studies. In contrast to MTF persons, intonation shows little correlation with male identity. Long-term follow-up of androgen effects upon voice in transgender men do not differ from those observed in biological males. Hematocrit and CAG repeat lengths in the androgen receptor (an indication of androgen sensitivity) correlate directly with vocal androgen sensitivity and reflect the extent of voice deepening when treated with testosterone. Difficulties in pitch-lowering occur only in 10% of FTM persons treated long term with testosterone and may be related to decreased androgen sensitivity. Medical providers of transgender persons, especially MTF, should be aware that speech language pathologists indicate that working with transgender persons is within their scope of practice.

Aging and Transgender Care

Increasingly, transgender persons have reached the age of 50 years. Many were referred at a younger age to mental health professionals, providers skilled in sex steroid treatment, and specialized surgeons who provided guidance throughout their gender transition. However, specialized needs for long-term follow-up medical care needed during aging are less well known amongst generalists who serve as primary care physicians for transgender persons. Maintenance of secondary sex characteristics in both MTF and FTM persons is a central concern of most transgender persons. In addition, concerns about cancer risk are prominent. Regular breast and genital examinations, as well as sexually transmitted disease screening, occur infrequently in transgender men whereas these examinations are frequent in transgender women. No data are available for prostate and PSA surveillance in MTF persons.

Considerations for continuing sex steroid treatment (estrogen and testosterone) are similar for transgender men and transgender women to those for natal men and natal women, respectively. In MTF and FTM who had gonadectomy, LH and FSH levels can be used to monitor maintenance of prescribed doses of sex steroids. There are no data that estradiol treatment causes prolactin-secreting pituitary adenomas, although estrogen treatment may increase prolactin levels when adenomas are present. Small increases in prolactin may occur during estradiol treatment in the absence of adenomas, although these increases usually remain within the normal range and are stable during estrogen treatment. Thus, screening of prolactin levels is recommended before starting estrogen treatment and should continue periodically in MTF persons who continue estradiol treatment. Use of transdermal estradiol is preferable in older age, especially for those with heart disease, hypertension, bone disease, and risk of thrombophlebitis. As in older natal women, dose reduction may be considered for risk reduction. Regular prostate examinations are recommended although cases of prostate cancer or hypertrophy are rare. The reverse trend in cardiovascular risk factor surveillance should continue in both MTF and FTM persons.

FTM persons who elect hysterectomy may continue testosterone treatment without concerns about aromatization to estradiol. As suggested above, ovariectomy should be performed when hysterectomy is elected. As in natal men, normal testosterone levels in transgender older men exert no adverse effects upon cardiovascular disease, diabetes, hypertension or metabolic syndrome. Subareolar breast tissue in FTM should be monitored for rare cases of cancer in residual tissue following mastectomy. Bone density in older men is usually maintained by testosterone and the estradiol produced by aromatization of testosterone. Periodic BMD assessments should be done in both transgender men and transgender women, especially when sex steroid treatment is stopped.

Endocrine Management of Transgender Adults: Conclusions

Treatment of adult transgender men and transgender women with physiologic replacement doses of testosterone and estradiol, respectively, facilitates the psychological, metabolic and physical changes that resolve gender dysphoria and enables a successful lifestyle transition to that of their appropriate gender. The principles of effective treatment are to suppress the natal sex steroids and to replace them with sex steroid levels appropriate for the transgender person. Guidelines for safe and effective treatment, noting both risks and benefits, are available to physicians providing care during the transition and during long-term care. Health-care coverage and protection against discrimination increasingly enable life fulfillment for transgender persons.

IL	Interleukin		

Acute or chronic failure of an endocrine gland can occasionally result in catastrophic illness and even death. Thus, it is important to recognize and appropriately manage these endocrine emergencies. This chapter will discuss crises involving the thyroid, anterior pituitary, or adrenal glands; diabetes mellitus; and abnormalities in calcium, sodium, and water balance. Except where indicated, management recommendations are provided for adult patients. Studies in the general area of endocrine emergencies have been limited in size and number. In many instances, recommendations offered in this chapter are based on published expert opinion rather than scientific evidence.

MYXEDEMA COMA

Clinical Setting

Myxedema coma is the end stage of untreated or inadequately treated hypothyroidism. It has an estimated incidence of 0.22 per million per year. The clinical picture is often that of an elderly obese female, presenting in midwinter with increased lethargy, somnolence, and confusion. The presentation is one of severe hypothyroidism, with or without coma (the term myxedema coma may, therefore, be a misnomer). The history from the patient may be inadequate, but the family may report that the patient has had

thyroid surgery or radioiodine treatment in the past or that the patient has previously been receiving thyroid hormone therapy. Myxedema coma is most frequently associated with discontinuation of thyroid hormone therapy. It presents less frequently as the first manifestation of hypothyroidism. It may be precipitated by an illness such as a cerebrovascular accident, myocardial infarction, or an infection such as a urinary tract infection or pneumonia. Other precipitating factors include gastrointestinal hemorrhage; acute trauma; excessive hydration; or administration of a sedative, narcotic, or potent diuretic drug.

Diagnosis

The physical findings are not specific. The patient may be semicomatose or comatose with dry, coarse skin, hoarse voice, thin scalp and eyebrow hair, possibly a scar on the neck, and slow reflex relaxation time. There is marked hypothermia, with body temperature sometimes falling to as low as 24°C (75°F), particularly in the winter months. It is important to be alert to the presence of complicating factors such as pneumonia, urinary tract infection, ileus, anemia, hypoglycemia, or seizures. Fever may be masked by coexistent hypothermia. Often there are pericardial, pleural, or peritoneal effusions. The key laboratory tests are a low free thyroxine (FT$_4$) and elevated thyroid-stimulating hormone (TSH). The TSH elevation may be less than predicted due to the presence of

euthyroid sick syndrome or glucocorticoid or dopamine therapy. TSH may also be low when central hypothyroidism is present—myxedema coma has a pituitary or hypothalamic etiology approximately 5% of the time. Central hypothyroidism is characterized by low FT_4 and low or normal TSH. Pituitary insufficiency can be confirmed with a low serum cortisol, impaired response to the cosyntropin stimulation test, and/or low follicle-stimulating hormone and luteinizing hormone. It is essential to check blood gases, electrolytes, creatinine, and an electrocardiogram in evaluating pulmonary, renal, cardiac, and central nervous system status. Myxedema may cause prolongation of the Q-T interval leading to torsade de pointes. The combination of hypothermia, hyponatremia, and hypercapnia should increase suspicion of myxedema coma. It may be necessary to differentiate myxedema coma from the euthyroid sick syndrome associated with coma due to other causes. These patients may present with a low triiodothyronine (T_3), normal or low TSH, but the FT_4 (by dialysis) is normal.

Myxedema coma is a complex problem involving a number of organ systems. The pathogenesis is presented in Figure 24–1. The decrease in serum T_4 results in a lowering of intracellular T_3. This can directly affect central nervous system function with altered mental status. The decrease in intracellular T_3 causes decreased thermogenesis, resulting in hypothermia, which in turn causes decreased central nervous system sensitivity to hypercapnia and hypoxia. The resulting respiratory insufficiency induces cerebral anoxia and coma. While coma, per se, is the dominant clinical manifestation, disorientation, depression, and psychosis with hallucinations (ie, myxedema madness) are often seen. At the same time, the decreased intracellular T_3 results in decreased cardiac inotropism and chronotropism, decreased sensitivity to adrenergic stimuli, decreased cardiac output, and generalized vasoconstriction. This leads to a low-output state which, if untreated, culminates in decreased blood pressure and eventually shock and death. Finally, there is a change in fluid balance with increased water retention due to impaired renal perfusion and syndrome of inappropriate antidiuretic hormone secretion (SIADH), as well as increased vascular permeability. These changes result in effusions and hyponatremia, which in turn contributes to the coma. There is also an increased risk of bleeding (eg, gastrointestinal bleeding) due to an acquired coagulopathy reflecting deficiency of a number of clotting factors (von Willebrand factor as well as factors V, VII, VIII, IX, and X).

Management

Management of myxedema coma involves much more than simply replacing T_4 (Table 24–1). The patient is severely ill and usually is admitted to the intensive care unit (ICU) for intubation and ventilatory support. Oral medications may be poorly absorbed (due to gastric atony or ileus), and medications should be given intravenously if possible. A loading dose of 300 to 400 μg of L-T_4 intravenously is given initially to saturate T_4 binding sites in plasma-binding proteins. The patient is then maintained on 50 to 100 μg of L-T_4 intravenously daily. In addition, small doses of T_3 (eg, 10 μg intravenously every 6-8 hours) may be given over the first 48 hours, but this is usually not necessary, and it may contribute to untoward cardiovascular events. Its use should be restricted to younger patients without history of ischemic heart disease or cardiac arrhythmias. Water restriction is necessary to correct the hyponatremia, and intravenous glucose counteracts the tendency
FIGURE 24–1 Pathogenesis of myxedema coma (CNS, central nervous system). (See text for details.)

TABLE 24–1 Management of myxedema coma.

(1) Admit to ICU for ventilatory support and for intravenous medications.
(2) Parenteral thyroxine: Give a loading dose of 300-400 μg IV, then 50-100 μg IV daily. (May also give liothyronine sodium, 10 μg IV every 8 h for the first 48 h if necessary.)
(3) Electrolytes: Water restriction for hyponatremia. Avoid fluid overload.
(4) Limit sedation. Appropriate reduction in drug dosage.
(5) Glucocorticoids: Controversial but necessary in hypopituitarism or polyglandular failure. Dosage: Hydrocortisone sodium phosphate or sodium succinate, 50-100 mg every 6 h initially and tapered downward over 1 wk. (If initial serum cortisol was >30 μg/dL, corticosteroids are unnecessary.)
(6) Hypothermia: Do not externally rewarm.

to hypoglycemia. It is essential to treat the precipitating illness (eg, pneumonia or urinary tract infection). The use of hydrocortisone is prudent because patients may have hypopituitarism or autoimmune polyglandular failure. Glucocorticoids are generally given in high doses until baseline cortisol or the results of rapid adrenocorticotropic hormone (ACTH) testing are available. If the initial serum cortisol is more than 30 μg/dL, steroid support is probably unnecessary. However, if serum cortisol is less than 30 μg/dL, hydrocortisone should be given intravenously in a dosage of 50 to 100 mg every 6 hours for the first 48 hours and the dose then tapered over the next 5 to 7 days while the pituitary-adrenal axis undergoes formal testing. Once myxedema coma is suspected in a hypothermic patient, external rewarming should be avoided, because this may cause redistribution of blood flow to subcutaneous tissues and cardiovascular collapse.

Prior to the recognition of the need for intravenous L-T_4 and for respiratory support, the mortality from myxedema coma was about 80%. Currently, the mortality is about 20% and is mostly due to the underlying or precipitating illness. Predictors of acute mortality include level of consciousness, lower Glasgow scores, and higher (acute physiology and chronic health evaluation) APACHE II scores, all indicative of the severity of the illness at presentation. Higher mortality is also associated with increased age, cardiac complications, and high-dose thyroid hormone replacement when this has been used (≥500 μg/d of L-T_4 or ≥75 μg/d of L-T_3). The latter presumably reflects the increased metabolic demand attendant to high dose replacement in the setting of limited physiologic reserve. Persistent hypothermia and bradycardia, despite therapy, are associated with a poor prognosis.

THYROID STORM

Clinical Setting

Thyroid storm, or thyrotoxic crisis, is an acute, life-threatening exacerbation of thyrotoxicosis. It accounts for 1% to 2% of hospital admissions for thyrotoxicosis. It may occur in a patient with a history of Graves disease who has discontinued antithyroid medication or in a patient with previously undiagnosed hyperthyroidism. There are rare reports of "storm" with subacute thyroiditis or

overdose with exogenous L-T_4. The clinical picture is that of an acute onset of hyperpyrexia (with temperature >40°C [104°F]), sweating, marked tachycardia often with atrial fibrillation, nausea, vomiting, diarrhea, agitation, tremulousness, and altered mentation. The presence of jaundice is considered a poor prognostic sign. Occasionally, the presentation is apathetic without the restlessness and agitation, but with symptoms of weakness, confusion, cardiovascular and gastrointestinal dysfunction, and hyperpyrexia. Some of the factors that may precipitate thyroid storm are listed in Table 24–2.

Diagnosis

The diagnosis is largely based in the clinical findings. Serum T_4, free T_4, T_3, and free T_3 are all elevated, and TSH is suppressed. Patients present with hyperthermia, often out of proportion to the magnitude of coincident infection, diaphoresis, tachycardia (often with supraventricular tachyarrhythmias and high output heart failure), and central nervous system dysfunction. The latter most clearly distinguishes thyroid storm from severe, but compensated, hyperthyroidism. It is thought that thyroid storm represents an exacerbation of thyrotoxicosis associated with a shift of T_4 from the bound to the free compartment with an increase in free T_3 and T_4, as well as an exaggerated response to a surge of catecholamines that results from the stress of the precipitating event. The cause of death is usually cardiac arrhythmia and failure. Liver function abnormalities are often seen, as is leukocytosis, even in the absence of infection. Hypercoagulability is related to increased levels of a number of clotting factors (eg, factors II, VIII, and IX).

Management

The management of thyroid storm is summarized in Table 24–3. Patients are typically admitted to an ICU for cardiac monitoring. Initially, it is important to block further synthesis and secretion of thyroid hormone, first with antithyroid drugs and then with iodide. One may give propylthiouracil, 150 mg every 6 hours orally or rectally, or methimazole, 20 mg every 8 hours orally or rectally. A few hours after initiation of antithyroid drug therapy, iodides may be started. Traditionally, saturated solution of potassium iodide, 5 drops twice daily, has been used, but, if available, iopanoic acid in a dose of 0.5 g twice daily orally or intravenously, or iohexol 0.6 g (2 mL of Omnipaque 300) intravenously twice daily is the

TABLE 24–3   Management of thyroid storm.

Supportive care
Fluids
Oxygen
Cooling blanket
Acetaminophen
Multivitamins
If indicated, antibiotics, digoxin
Specific measures
Propranolol, 40-80 mg orally every 6 h
Propylthiouracil, 150 mg every 6 h, or methimazole, 20 mg every 8 h; may be administered per rectum if oral route is unavailable
Saturated solution of potassium iodide, 5 drops (250 mg) orally twice daily; or iopanoic acid, 0.5 g IV or orally twice daily; or iohexol, 0.6 g (2 mL of Omnipaque 300) IV twice daily
Dexamethasone, 2 mg every 6 h
Cholestyramine or colestipol, 20-30 g/d

treatment of choice. These drugs not only inhibit thyroid hormone synthesis but also block the conversion of T_4 to T_3, lowering the thyroid hormone level in the blood. Unfortunately, these agents are not readily available in the United States. In patients who are allergic to iodine, lithium carbonate may be used to block thyroid hormone release. It is administered initially at 300 mg every 6 hours with subsequent monitoring to maintain lithium levels in the therapeutic range (0.8-1.2 mEq/L). Additional specific therapy includes β-adrenergic blockade with propranolol, 40 to 80 mg orally every 6 hours or 0.5 to 1 mg intravenously over 10 minutes every 3 hours, with continuous cardiac monitoring. In patients with asthma, the $β_1$-selective antagonist esmolol can be given as a bolus dose (0.25-0.5 mg/kg over 10 minutes) followed by continuous intravenous infusion (0.05-0.1 mg/kg/min). The half-life of glucocorticoids is markedly reduced in severe thyrotoxicosis, so that adrenal support may be very useful. Dexamethasone also reduces conversion of T_4 to T_3 (as do the beta-blockers, especially propranolol). For this purpose, dexamethasone is given in a dosage of 2 mg every 6 hours for 48 hours, followed by tapering of the dose. Cholestyramine or colestipol binds T_4 in the gut interfering with its enterohepatic circulation and may help bring the circulating level of T_4 down more quickly. Plasmapheresis and plasma exchange have been used to reduce serum FT_4 levels emergently in nonresponders, but the durability of response is limited to 24 to 48 hours, requiring a plan for definitive therapy in the short term. Emergent total thyroidectomy may be considered for those patients who fail to respond to medical therapy in a timely fashion, particularly older patients with cardiorespiratory failure. Supportive therapy includes adequate fluids, oxygen, treatment of the precipitating illness (eg, infection), management of atrial fibrillation or heart failure, if present, parenteral water-soluble vitamins, and a cooling blanket and acetaminophen for hyperpyrexia. Aspirin should be avoided, because it will displace T_4 from thyroid hormone–binding globulin, resulting in an increase in FT_4.

Therapy for thyroid storm has improved markedly, so the mortality has dropped from 100% in the 1920s to about 20% to 30% in recent series.

THYROTOXIC PERIODIC PARALYSIS

Clinical Setting

Thyrotoxic periodic paralysis (TPP) is a rare but frightening thyroid emergency. Incidence in the United States has been estimated at 0.1%-0.2% of thyrotoxic patients. The usual clinical presentation is of an Asian male (male:female ratio approximately 17:1) with symptoms of untreated hyperthyroidism who awakens at night or in the early morning hours with flaccid ascending paralysis. Typically, there is a history of vigorous exercise, alcohol abuse, and/or a large high-carbohydrate meal before retiring. There is usually no family history of periodic paralysis, but there may be a family history of autoimmune thyroid disease. Initially the patient presents with muscle cramps and stiffness. Over time this progresses to mild weakness and, at the extreme, total paralysis. The paralysis initially involves the lower extremities but progresses to the girdle muscles, followed by the upper extremities. Proximal muscle groups, typically beginning in the lower extremities, are affected to a greater extent than distal. Sensory function, facial and respiratory muscles are usually spared. Bowel and bladder function may be compromised in attacks affecting all four extremities. Deep tendon reflexes are depressed or absent. The acute episode may be complicated by cardiac arrhythmias due to the concomitant presence of hypokalemia. The illness has also been reported to occur in Native Americans, African Americans, Polynesians, Nepalese, Lebanese, and Turks and in individuals of Mexican or South American descent, but it is unusual in these latter ethnic groups. Paralysis of specific muscle groups recovers in the reverse order of appearance—usually within 36 and virtually always within 72 hours.

Diagnosis

The differential diagnosis of TPP includes familial periodic paralysis, Guillain-Barré syndrome, and acute intermittent porphyria. The diagnosis is based on the absence of a family history, the characteristic presentation, the presence of hyperthyroidism due either to Graves disease or toxic nodular goiter (other types of hyperthyroidism have been implicated as well), and usually a low serum potassium level.

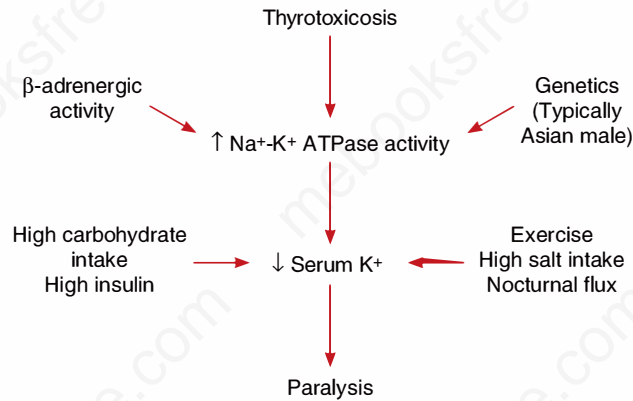
The pathogenesis is summarized in Figure 24–2. Thyrotoxicosis, increased β-adrenergic activity, and an assumed genetic predisposition, perhaps involving a defective inward-rectifying potassium channel Kir2.6, which together with increased Na^+-K^+ ATPase activity leads to increased intracellular potassium concentrations. A high-carbohydrate meal with increased insulin secretion and glycogen deposition, vigorous exercise, high salt intake, and the normal nocturnal potassium flux serve to drive serum potassium levels even lower, resulting in flaccid neuromuscular paralysis. Note that there is no loss of total body potassium, merely a shift from the extracellular to the intracellular space. Consequently, aggressive potassium repletion, particularly through the parenteral route, is discouraged because this frequently results in significant *hyperkalemia* as potassium redistributes across cellular compartments following resolution of the attack. Hypophosphatemia and hypomagnesemia may be present. This is also assumed to reflect


FIGURE 24–2 Pathogenesis of thyrotoxic periodic paralysis. (See text for details.)

intracellular sequestration. The electromyogram, performed while the patient is experiencing weakness, shows myopathic changes with reduced amplitude of compound muscle action potentials. These do not change in amplitude after administration of intra-arterial low-dose epinephrine (distinguishes from familial periodic paralysis). Electrocardiograms show changes associated with hypo-kalemia, tachycardia, increased QRS voltage, first-degree heart block, and, on occasion, serious ventricular arrhythmias.

Management

The management of this problem is presented in Table 24–4. Propranolol in doses of 60 mg every 6 hours blocks the β-adrenergic stimulation of Na$^+$-K$^+$ ATPase. Antithyroid drug therapy should be started immediately, even though it takes time to bring the patient into a euthyroid state. Oral potassium, if indicated, should be administered cautiously. It is particularly important to be cautious if administering intravenous potassium, which may raise total body potassium to toxic levels as the episode resolves. One should also avoid intravenous glucose, which stimulates insulin secretion and worsens hypokalemia, and β-adrenergic agonists such as isoproterenol, which promote movement of potassium into the intracellular compartment and exacerbate the problem. There is no role for potassium supplementation in pre-venting attacks. Acetazolamide, which has been shown to reduce frequency of attacks in familial periodic paralysis, may worsen attacks of TPP and should be avoided. With appropriate treat-ment, recovery is rapid, and once the thyrotoxicosis is controlled, the paralysis will not recur.

TABLE 24–4 Management of thyrotoxic periodic paralysis.

(1) Oral potassium supplement (if needed); monitor serum K$^+$
(2) Oral propranolol (60 mg every 6 h)
(3) Antithyroid drug therapy

Avoid:
IV potassium
IV glucose (ie, crystalloid fluid replacement only)
β-Adrenergic agonists (eg, isoproterenol)

AMIODARONE-INDUCED THYROTOXICOSIS

Clinical Setting

Amiodarone is a benzofuran derivative that is widely used in the treatment of cardiac arrhythmias. It contains two atoms of iodine per molecule, which represents 37.5% iodine by weight. The compound is stored in adipose tissue and has a half-life in the body of 2 to 3 months, with gradual and continuous release of iodide. The usual daily maintenance dose of amiodarone of 200 to 400 mg/d releases 6000 to 12,000 μg of iodine daily, which when compared to the normal daily requirement of about 150 μg of iodine represents an enormous iodine load.

The structure of amiodarone resembles that of T$_3$, and it is thought that part of the cardiac depressant effect of amiodarone may be due to binding to and blocking the thyroid hormone receptor in cardiac muscle. However, the effect of amiodarone on the thyroid gland is different and is due in part to a direct effect of iodine on the thyroid follicular cell—to inhibit or stimulate hor-mone synthesis—and a cytotoxic effect of amiodarone that leads to destruction of the follicular cell and release of stored hormone. Thus, the drug may induce hypothyroidism, which is easily man-aged by thyroxine replacement, or hyperthyroidism, which, because of the underlying heart disease, is much more difficult to manage and may represent a true thyroid emergency. Two mecha-nisms have been suggested to explain the development of hyper-thyroidism: (1) the high iodine level in a multinodular gland, or in the gland of a patient with latent Graves disease, or even in a previ-ously normal gland, can induce hyperthyroidism (see Chapter 7), and (2) the toxic effect of amiodarone itself may cause acute and chronic thyroiditis with release of T$_4$ and T$_3$ into the circulation and severe thyrotoxicosis. Risk factors for amiodarone-induced thyrotoxicosis include the presence of autoimmune thyroiditis and baseline elevation of TSH levels.

The patient with amiodarone-induced thyrotoxicosis may have been on the drug for months. Thyrotoxicosis typically appears 6 to 12 months after the onset of treatment. The underlying heart disease gradually worsens with increasingly frequent episodes of arrhythmia and heart failure. At the same time there may be weight loss, heat intolerance, increased nervousness, and marked muscle weakness. On physical examination, one may find non-tender nodular or diffuse thyroid enlargement, tachycardia with or without atrial fibrillation, tremor, hyperreflexia, and, occasionally, lid lag and stare. Laboratory findings are unique because amioda-rone inhibits the conversion of T$_4$ to T$_3$. Thus, even in the euthy-roid patient taking amiodarone, total T$_4$ may be elevated while TSH is normal. In the hyperthyroid patient, the FT$_4$ is markedly elevated and TSH is less than 0.01 mU/L (below the detection limit of the assay). Radioiodine uptake in the iodide-loaded patient is low. It has been difficult to distinguish thyrotoxicosis due to follicular cell hyperfunction (type 1) from that due to fol-licular cell destruction (type 2). Thyroid ultrasound with color Doppler studies may show increased circulation with hyperfunc-tion and decreased blood flow with thyroiditis. Also, the cytokine interleukin (IL)-6 is low in patients with hyperfunction, whereas

TABLE 24–5 Management of amiodarone-induced hyperthyroidism.

(1) Stop amiodarone if possible
(2) Institute beta-blocker therapy if possible
(3) Antithyroid drugs: Methimazole, 40-60 mg/d
(4) Potassium perchlorate, 200 mg every 6 h
(5) Cholestyramine or colestipol, 20-30 g/d
(6) Prednisone, 40 mg/d, for acute thyroiditis (consider monitoring IL-6 levels)
(7) Thyroidectomy

it is markedly elevated in patients with thyroiditis. A recent study suggests that sestamibi scan of the thyroid may be helpful in separating type 1 versus type 2 disease.

Management

Management of amiodarone-induced hyperthyroidism is difficult (Table 24–5). Ideally, amiodarone should be discontinued, but often it cannot be stopped because of the underlying heart disease, and even if it is discontinued, the iodine load persists for several months. Further synthesis of T_4 should be blocked with methimazole in an initial dosage of 40 to 80 mg/d or propylthiouracil in doses of 400 to 800 mg/d followed by a taper to a maintenance dose. β-Adrenergic blockade, if needed (amiodarone, itself, has some β-blocking activity), should be instituted with propranolol or a comparable drug if cardiac status permits it. Potassium perchlorate, which is no longer available in the United States, in a dosage of 250 mg every 6 hours blocks further iodine uptake and lowers intrathyroidal iodide content. Aplastic anemia has occurred in patients on high-dose or long-term potassium perchlorate therapy, so that use of this medication has usually been limited to 1 month. Iopanoic acid (0.5 g orally twice daily) can be used to decrease T_4 to T_3 conversion. Cholestyramine or colestipol in a dosage of 20 to 30 g/d binds T_4 and T_3 in the gut and brings blood levels down more quickly. If there is reason to suspect thyroiditis (elevated serum IL-6 or decreased blood flow on ultrasound), corticosteroid therapy often yields dramatic results. Prednisone is given in a dosage of 40 mg/d for 1 month, gradually tapering the dose over the following 2 months. In those cases where a mixed etiology is suspected (ie, hyperfunction plus thyroiditis), a combination of steroids, antithyroid drugs, and beta-blockers can be used. If medical therapy is unable to control the disease, thyroidectomy results in a permanent cure and may be used as a last resort. Iopanoic acid (discussed earlier) can be used to prepare the patient for surgery. Perioperative mortality may be as high as 8% to 9% due to the underlying cardiac disease.

ACUTE ADRENAL INSUFFICIENCY

Clinical Setting

Acute adrenal insufficiency usually occurs as an acute illness in a patient with chronic adrenal insufficiency (see Chapter 9). The chronic adrenal insufficiency may be primary, due to

destruction of the adrenal glands associated with autoimmune adrenalitis, adrenal leukodystrophy or, rarely, tuberculosis, fungus, or metastatic malignancy. Chronic secondary adrenal insufficiency can be seen in the setting of pituitary or hypothalamic disease. Acute adrenal insufficiency may also occur with bilateral adrenal hemorrhage in a previously healthy individual during the course of septicemia with disseminated intravascular coagulopathy, in a patient with antiphospholipid antibody syndrome, or in a patient receiving anticoagulant therapy. In the patient with known adrenal insufficiency, an acute crisis may be precipitated by inadvertent omission of steroid medication or by the concurrent development of a precipitating illness such as severe infection, acute myocardial infarction, cerebrovascular hemorrhage or infarction, surgery without adrenal support overly strenuous exercise, or severe acute trauma. Acute adrenal insufficiency may also be precipitated by the sudden withdrawal of steroids in a patient previously on long-term pharmacologic steroid therapy with associated adrenal atrophy (ie, secondary adrenal insufficiency). Finally, administration of drugs impairing adrenal hormone synthesis such as ketoconazole, aminoglutethimide, etomidate, or mitotane—or drugs increasing steroid metabolism such as phenytoin or rifampin—may precipitate an adrenal crisis.

The patient presents with an acute onset of nausea, vomiting, hyperpyrexia, abdominal pain, dehydration, hypotension, and shock. A clue to the diagnosis of primary adrenal insufficiency is the presence of pigmentation in unexposed areas of the skin, particularly in the creases of the palms and in the buccal mucosa. The differential diagnosis includes consideration of other causes of cardiovascular collapse, sepsis, and intra-abdominal abscess. Failure of the hypotension to respond to pressors is suggestive of adrenal insufficiency and is an indication for a trial of glucocorticoid therapy.

Diagnosis

Primary adrenal insufficiency is characterized by hyponatremia and hyperkalemia. However, in situations of adrenal crisis, the hyponatremia may be obscured by dehydration. Random serum cortisol determinations are not helpful unless the levels are very low (<5 µg/dL [138 nmol/L]) during a period of great stress. The key diagnostic test is failure of serum cortisol to rise above 20 µg/dL (552 nmol/L) 30 minutes after intravenous injection of 250 µg synthetic ACTH (cosyntropin) (see Chapter 9 for details). This test functions best in the diagnosis of primary versus secondary adrenal insufficiency. At a specificity of 95%, sensitivities are 97% and 57%, respectively (see Chapter 3). Interpretation of the test, particularly in the evaluation of secondary adrenal insufficiency, is complicated in the presence of hypoalbuminemia, a marker for reduced protein-bound cortisol in plasma. In this setting, serum-free cortisol levels provide a more accurate assessment of adrenal function. Random serum free cortisol of greater than 1.8 µg/dL and a Cortrosyn-stimulated value of greater than 3.1 µg/dL in critically ill patients are considered normal but these cutoffs are likely to be assay dependent. There has been increased interest in using a more

physiologic dose of ACTH to perform this stimulation test (1 μg vs 250 μg); however, a recent comparison suggests no particular advantage in the performance characteristics of the low-dose test. Basal serum ACTH is elevated (>52 pg/mL [>11 pmol/L]) in patients with primary adrenal insufficiency but not in patients with secondary adrenal insufficiency due to pituitary or hypothalamic disease. Computed tomography (CT) or sonography of the abdomen reveals adrenal enlargement in patients with adrenal hemorrhage, active tuberculosis, or metastatic malignancy. Atrophy of the adrenals is associated with chronic adrenal insufficiency.

Management

The management of adrenal crisis is outlined in Table 24–6. Hydrocortisone should be administered in a dosage of 100 mg intravenously followed by 50 to 75 mg every 6 hours thereafter. Fluids and Na$^+$ should be replaced with several liters of 5% glucose in normal saline. After the first 24 hours, the dose of intravenous hydrocortisone can be slowly reduced, but intravenous doses should be given at least every 6 hours because of the short half-life (1 hour) of hydrocortisone in the circulation. When the patient can tolerate oral feedings, hydrocortisone can be given orally, but the first oral dose should overlap the last intravenous dose. Alternatively, hydrocortisone can be administered as a continuous infusion at the rate of 10 mg/h for the first 24 hours, followed by a gradual decrease in the dose. Mineralocorticoid is not necessary during the acute replacement period since enough NaCl and glucocorticoid are being administered to treat the mineralocorticoid deficiency. However, in patients with chronic primary adrenal insufficiency, mineralocorticoid supplementation is necessary when shifting to an oral maintenance program (see Chapter 9). After steroid therapy has been instituted, it is extremely important to evaluate and treat the illness that may have precipitated the acute crisis (eg, infection, myocardial infarction).

Prevention of acute adrenal insufficiency in patients with chronic adrenal insufficiency exposed to mild stress can be addressed merely by doubling the daily steroid dose until the condition resolves followed by rapid titration back to prestress doses. More severe stress (eg, severe infection) requires intravenous hydrocortisone in dosages as outlined above or administration of dexamethasone sodium phosphate, 4 mg intramuscularly every 24 hours for two doses. Dexamethasone would replace glucocorticoids but not

TABLE 24–6 Management of adrenal crisis.

(1) Hydrocortisone sodium phosphate or sodium succinate, 100 mg IV stat and then 50-75 mg IV every 6 h for 24 h. Then taper slowly downward over the next 72 h, giving the drug every 4-6 h IV. When patient is tolerating oral feedings, shift to oral replacement therapy, overlapping the first oral and last intravenous doses.
(2) Replace salt and fluid losses with several liters of 5% glucose in normal saline IV.
(3) Patients with primary adrenal insufficiency may require mineralocorticoid (fludrocortisone) when shifted to oral hydrocortisone maintenance therapy.
(4) Diagnose and treat the illness that precipitated the acute crisis.

mineralocorticoid and would not be adequate in the presence of severe dehydration.

PITUITARY APOPLEXY

Pituitary apoplexy is a rare syndrome of violent headache, visual and cranial nerve disturbances, and mental confusion, resulting from hemorrhage or infarction of pituitary tissue.

Clinical Setting

Pituitary apoplexy usually occurs as a sudden crisis in a patient with a known or, more rarely, previously unrecognized pituitary tumor. However, it may occur in a normal gland during or after parturition. Risk factors include cardiac surgery, dynamic pituitary function testing, head trauma, bleeding disorders, hypertension, or anticoagulation therapy. Apoplexy develops in pituitary adenomas due to bleeding and necrosis as they outgrow their blood supply or through compression of infundibular or superior pituitary vessels against the diaphragma sella. The patient presents with severe headache and visual disturbances, often a bitemporal hemianopia due to compression of the optic chiasm. There may be visual and oculomotor defects, either bilateral or unilateral, due to extension of the hemorrhage into the cavernous sinus(es) where cranial nerves II, III, IV, and VI are located. Often there are meningeal symptoms with stiff neck and mental confusion, so that the differential diagnosis includes subarachnoid hemorrhage and meningitis. Finally, there may be symptoms of acute secondary adrenal insufficiency with nausea, vomiting, hypotension, and collapse. A more subacute/chronic presentation (ie, subclinical hemorrhage followed by partial resolution) may be dominated by symptoms of hypopituitarism.

Diagnosis

The diagnosis of pituitary apoplexy is best approached with computed tomography (CT) and magnetic resonance imaging (MRI) of the cranium with multiple sections through the sella turcica. Pituitary enlargement and signs of hemorrhage are diagnostic. CT is most useful in the acute setting (24-48 hours) while MRI is optimal for identifying blood in the subacute setting (4-30 days). In the acute setting, hormonal studies are of academic interest only since therapy should include glucocorticoid support regardless of the acute findings. After appropriate acute management, evaluation of anterior and posterior pituitary function is indicated to evaluate the possibility of permanent hypopituitarism.

Management

Management involves both hormonal and neurosurgical therapy. High-dose dexamethasone, 4 mg twice daily, provides both glucocorticoid support and relief of cerebral edema. Alternatively, hydrocortisone 50 mg IV every 6 hours can be used. Transsphenoidal pituitary decompression often provides dramatic relief of visual and extraocular motor dysfunction and in the level of consciousness. Pituitary hormone secretion also may improve

particularly in those with normal or elevated prolactin levels. The need for emergent surgery is controversial and should be approached on a case-by-case basis. Conservative medical management in less severely affected patients has been shown to result in recovery of both neurological and endocrine function. After the acute episode has subsided, the patient must be evaluated for the possibility of multiple pituitary hormonal deficiencies (see Chapter 4).

DIABETIC KETOACIDOSIS

Clinical Setting

Diabetic ketoacidosis (DKA) occurs in a setting of absolute or relative insulin deficiency. Estimated annual incidence is 4 to 8 episodes per 1000 patients with diabetes. It is seen primarily in patients with type 1 diabetes; however, it is increasingly seen in patients with type 2 diabetes, with approximately one-third of DKA admissions in the USA occuring in type 2 patients. Specific clinical settings should generate a high index of suspicion for the disorder. Interruptions of normal insulin delivery due to purposeful reduction in insulin dosage or interference with the delivery system (eg, kinking in pump tubing) are frequent precipitating events, as are reduced insulin sensitivity in the setting of systemic infection, myocardial infarction, burns, trauma, or pregnancy. In a significant percentage of patients, DKA is the presenting feature of diabetes. In these instances, clinical suspicion and accurate interpretation of the initial laboratory studies will usually lead to the correct diagnosis. Measurement of HbA_{1C} (hemoglobin A_{1C}) levels may help in assessing the chronicity of the diabetes. Mortality in DKA is less than 5% in experienced centers. Prognosis worsens at the extremes of age and in the presence of coma or hypotension.

Diagnosis

DKA is characterized metabolically by two prominent features: hyperglycemia and ketoacidosis (see Chapter 17). Patients with DKA present with evidence of volume contraction (eg, dry mucous membranes, thirst, orthostatic hypotension) and labored breathing (Kussmaul respiration) related to the underlying acidosis. The breath often has a fruity odor, reflecting the presence of acetone. Patients may have abdominal pain mimicking an acute abdomen, nausea, and vomiting. The latter symptoms may be related to elevated gastrointestinal prostaglandins that accrue in the presence of insulin deficiency. Presentation may be dominated by symptoms of the precipitating illness (eg, urinary tract infection, pneumonia, or myocardial infarction).

Plasma glucose levels are elevated, usually to over 250 mg/dL. This reflects impairment in glucose utilization (discussed earlier), increased gluconeogenesis and glycogenolysis, and reduced renal clearance of glucose in the setting of decreased glomerular filtration rate (GFR). Osmotic diuresis related to glucose excretion results in reduction in intravascular volume and depletion of total body water, sodium, potassium, phosphate, and magnesium. In general, the relative depletion of water is roughly twice that of the solutes it contains. Hypertonicity in the extracellular fluid compartment, although typically not as severe as that seen in hyperosmotic nonketotic coma (discussed later), can be significant. Calculated plasma osmolalities greater than 340 mOsm/kg are associated with coma. Older studies suggest that plasma osmolality correlates most closely with state of consciousness in DKA (Figure 24–3); however, more recent studies have forged a stronger link between acidosis and altered consciousness. At present the etiology of coma is unsettled.

Arterial blood pH is low and, in the absence of coexistent respiratory disease, is partially compensated by a reduction in PCO_2. The acidosis is metabolic in origin and accompanied by an anion gap that is calculated by subtracting the combined concentrations of chloride and bicarbonate from serum sodium concentration. Anion gaps greater than 12 mEq/L are considered abnormal. Keto acids account for most of the unmeasured anions that generate the abnormal gap, although under conditions of extreme volume contraction and hypoperfusion, lactate accumulation may also contribute. Levels of serum and urinary ketones (measured using the nitroprusside reagent) are typically high in DKA. It should be recalled, however, that this reagent reacts strongly only with acetoacetate, less strongly with acetone (which is not a keto acid and does not contribute to the anion gap), and not at all with β-hydroxybutyrate. Thus, paradoxically, the most extreme levels of ketoacidosis may be accompanied by relatively modest levels of ketones measured by this method. As a corollary of this, resolution of severe DKA may be linked to transient increases in measurable ketone levels as β-hydroxybutyrate is converted to the more readily detectable acetoacetate. Direct measurement of β-hydroxybutyrate, which is available in most clinical labs, provides a more accurate assessment of ketogenesis.

Serum sodium levels may be high, normal, or low, but in all instances total body sodium is depressed. Estimates of depletion range from 7 to 10 mEq/kg body weight. As blood glucose levels rise in DKA, they create an osmotic gradient that draws water, as well as intracellular solutes, into the extracellular space. This results in moderate hyponatremia, which can be corrected to account for the dilutional effect of the transmembrane flux of water by adding 1.6 mEq/L (more recent studies suggest that the correction factor is closer to 2.4 mEq/L) to the sodium concentration for every 100 mg/dL increment in plasma glucose above a basal concentration of 100 mg/dL.

$$\text{Corrected Na}^+ = \text{Measured Na}^+ + 1.6\left(\frac{\text{Plasma glucose} - 100}{100}\right)$$

The decrease in serum sodium partially offsets the increase in tonicity that accompanies the elevation in plasma glucose. This results in a net increase in plasma osmolality of 2 mOsm/kg H_2O per 100 mg/dL elevation in plasma glucose.

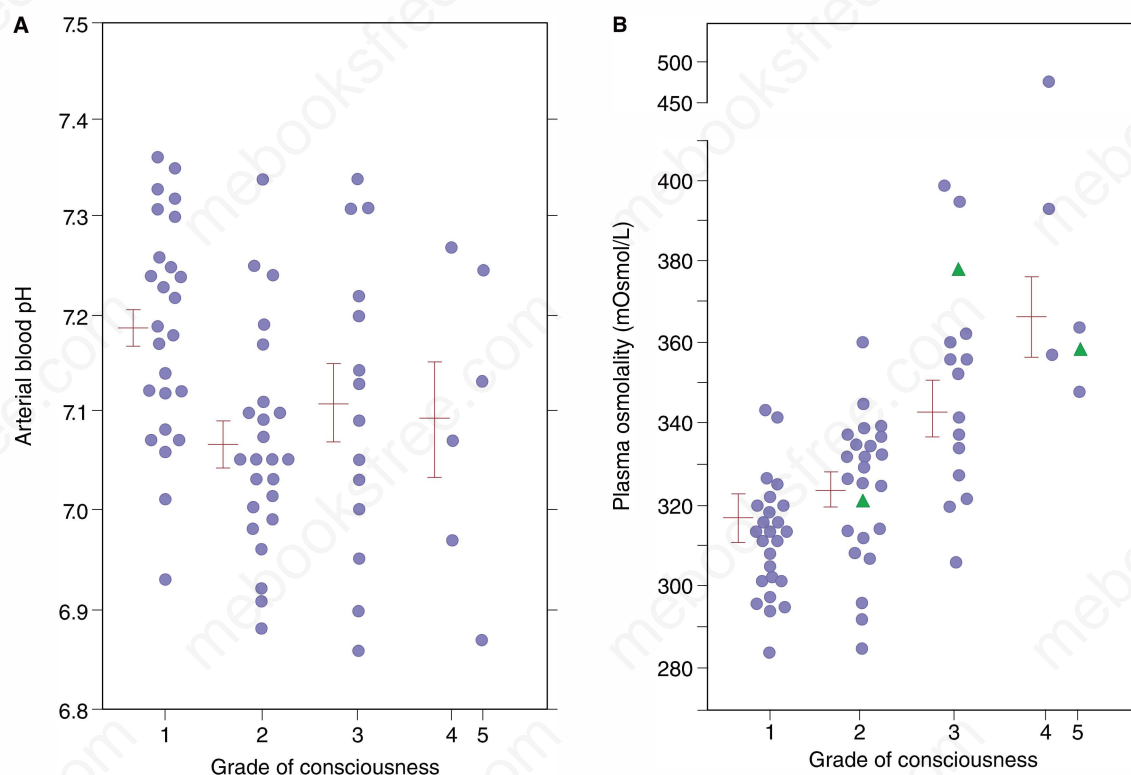
Total body potassium levels are also severely depleted in DKA to an average of 5 to 7 mEq/kg body weight. This results from a number of factors, including exchange of intracellular potassium for extracellular hydrogen ion, impaired movement of K^+ into cells in the insulinopenic state, increased urinary potassium excretion secondary to the osmotic diuresis and, in those instances where


FIGURE 24–3   A: Relationship between state of consciousness and blood pH in patients with diabetic ketoacidosis. **B:** Relationship between state of consciousness and plasma osmolality in diabetic ketoacidosis. (Reproduced with permission from Fulop M, Tannenbaum H, Dreyer N. Ketotic hyperosmolar coma. *Lancet.* 1973 Sep 22;2(7830):635-639.)

intravascular volume contraction is present, secondary hyperaldosteronism. Serum potassium levels may be high, normal, or low depending on the severity and duration of DKA, the status of extracellular fluid volume, and the adequacy of renal perfusion and excretory function. A low-serum potassium at presentation generally indicates severe potassium deficiency and, in the presence of adequate renal function, is an indication for early and aggressive repletion (discussed later). Potassium depletion can result in muscle weakness and cardiac arrhythmias, including ventricular fibrillation.

The H$^+$ excess in DKA titrates endogenous buffer systems including serum bicarbonate, resulting in reduction in concentrations of the latter. Chloride levels may also be low, reflecting the osmotic diuresis alluded to above. Ketone bodies have been estimated to account for one-third to one-half of the osmotic diuresis seen in DKA. Electrolyte depletion is further aggravated by the obligate cation (eg, sodium) excretion required to maintain electrical neutrality. In patients who have maintained adequate hydration during the development of DKA or in those who are aggressively resuscitated with normal saline, chloride levels may be elevated and the anion gap narrowed. This reflects the enhanced clearance of the keto anions in the kidney, converting the system from an anion gap acidosis to a hyperchloremic, nongap acidosis (ie, the hydrogen ion excess persists despite clearance of the anion). Because the excreted keto anions represent a lost source of bicarbonate regeneration, correction of the hyperchloremic

acidosis may proceed slowly. The hyperchloremic acidosis is inconsequential from a clinical standpoint.

Total body magnesium and phosphate levels are also depleted by the osmotic diuresis in DKA. Phosphate depletion is amplified by diffusion of the anion from the intracellular to the extracellular compartment in the absence of insulin. Phosphate depletion can result in muscle weakness, rhabdomyolysis, hemolytic anemia, respiratory distress, and altered tissue oxygenation (due to reduction in 2,3-diphosphoglycerate levels in the red blood cell).

Management

Treatment of DKA is focused on two major objectives. The first is restoration of normal tonicity, intravascular volume, and solute homeostasis. The second is correction of the insulinopenic state with suppression of counterregulatory hormone secretion, glucose production, and ketogenesis and improved utilization of glucose in target tissues. The steps outlined in Table 24–7 provide a general approach to the management of this disorder.

Because depletion of intracellular and extracellular fluids may be severe in DKA (typically in the range of 5-10 L), early and aggressive resuscitation with fluids is mandatory. The goal should be to replace the total volume loss within 24-36 hours with half of the replacement given in the first 12 hours. This is usually initiated with administration of 1 to 2 L of isotonic normal saline (0.9% NaCl) over the first hour of therapy. As intravascular

TABLE 24–7   Management of diabetic ketoacidosis.

Fluid administration
(1) 1-2 L of normal saline over the first hour. Repeat if clinically significant volume contraction persists after the first hour.
(2) Change to half-normal saline, 500-1000 mL/h, depending on volume status. Continue for about 4 h. Decrease rate to 250 mL/h as intravascular volume returns to normal.
(3) Convert fluids to D_5W when plasma glucose falls to 250 mg/dL.

Insulin
(1) Administer 10-20 U of regular insulin IV.
(2) Mix 50 U of regular insulin in 500 mL of normal saline (1 U/10 mL). Discard first 50 mL of infusion to accommodate insulin binding to tubing. Administer through *piggyback* line along with parenteral fluids at a rate of 0.1 U/kg/h.
(3) Double the infusion rate after 2 h if there is no improvement in plasma glucose levels.

Potassium
(1) Administer supplemental potassium chloride once renal function is established; provide 20 mEq/L of fluids for patients who are initially normokalemic, 40 mEq/L for those who are hypokalemic at presentation. In the latter case, hold insulin until serum potassium levels begin to increase.
(2) Gauge subsequent replacement based on serum K^+ measurements at 2-h intervals.

Bicarbonate
(1) Sodium bicarbonate only for patients with blood pH <7.0.
(2) Add 1 ampule of sodium bicarbonate (44 mEq) to 500 mL of D_5W or half-normal saline. Administer over 1 h.

volume is restored, renal perfusion increases, with a consequent increase in renal clearance of glucose and a fall in plasma glucose levels. If volume contraction is severe, another liter of normal saline can be administered. If not, half-normal saline (0.45% NaCl) can be initiated at a rate of 250 to 500 mL/h depending on intravascular volume status. Because water is typically lost in excess of solute in DKA, half-normal saline addresses both the volume depletion and the hypertonicity. Half-normal saline can be continued until intravascular volume has been restored or plasma glucose levels fall to 250 mg/dL, at which point D_5W should be started. The latter maneuver reduces the likelihood of insulin-induced hypoglycemia and avoids the theoretical complication of cerebral edema due to osmotically induced fluid shifts from plasma into the central nervous system. This complication is, in fact, seen rarely in adults and uncommonly in children with DKA. It is important to account for ongoing urinary volume and electrolyte losses in assessing fluid requirements.

Once fluid resuscitation has been initiated, insulin should be administered. Only short-acting insulin should be used. A number of different insulin regimens have demonstrated efficacy in the treatment of DKA; however, a commonly used regimen includes a loading dose (10-20 U) of short-acting insulin intravenously followed by a continuous infusion at a rate of 0.1 U/kg/h. The need for a loading dose is controversial and may not be required in the majority of cases. It is not recommended for children with ketoacidosis. If intravenous access is problematic, maintenance insulin can be given intramuscularly (0.1 U/kg/h). This regimen provides plasma insulin levels in a physiologic range (100-150 mU/mL) with minimal risk of hypoglycemia or

hypokalemia. It restores plasma glucose levels at rates equivalent to those obtained with regimens using higher insulin doses. Plasma glucose levels should fall at a rate of 50 to 100 mg/dL/h. Failure to achieve this end point over a 2-hour period should lead to doubling of the infusion rate with reevaluation an hour later. When plasma glucose concentrations reach 250 mg/dL, the insulin infusion rate should be reduced to 0.02-0.05 units/kg/h and fluid repletion with D_5W is begun to prevent hypoglycemia (discussed earlier). The insulin infusion is continued to suppress ketogenesis, close the anion gap and allow restoration of normal acid-base balance.

As noted earlier, total body potassium stores are depleted in DKA (~3-4 mEq/kg), and plasma K^+ levels fall with treatment. Repletion of K^+ is almost always indicated in management of DKA (one notable exception being DKA that occurs in the setting of chronic renal insufficiency); however, the timing of repletion varies as a function of the plasma K^+ level. If the initial K^+ level is less than 4 mEq/L, K^+ depletion is severe, and repletion should begin with the first administration of parenteral fluids if renal function is adequate. Twenty milliequivalents of potassium chloride can be added to the first liter of normal saline if the serum K^+ is in the 3.5 to 4 mEq/L range; 40 mEq should be added for K^+ levels less than 3.5 mEq/L. Particular attention should be devoted to patients in this latter state, because K^+ levels may plummet to very low levels with initiation of insulin therapy. To avoid this, insulin therapy should be postponed in this group until K^+ repletion has begun and serum K^+ levels are on the rise. The general goal of therapy should be to keep the K^+ in a near-normal range. This may require several hundred milliequivalents of potassium chloride administered over several days.

The administration of bicarbonate in the setting of DKA has been controversial. Acidosis, in addition to increasing ventilatory work (Kussmaul respiration), may also suppress cardiac contractile function. Therefore, restoration of normal pH would seem to make sense in DKA. However, there is considerable risk associated with the use of sodium bicarbonate in this setting, including paradoxical acidification of the central nervous system due to the selective diffusion of CO_2 versus HCO_3^- across the blood–brain barrier and an increase in intracellular acidosis, which may worsen rather than ameliorate cellular function. Volume overload related to the high tonicity (44.6-50 mEq/50 mL) of the bicarbonate solution, hypokalemia resulting from overly rapid correction of the acidosis, hypernatremia, and rebound alkalosis are also potential complications of bicarbonate therapy. In general, pH of 7.0 or greater is not life-threatening to the average patient with DKA and will resolve with appropriate volume expansion and insulin therapy. For pH less than 7.0, many clinicians would argue for a limited administration of sodium bicarbonate. If bicarbonate is used, careful patient monitoring looking for alterations in mental status or cardiac decompensation is indicated. The goal of therapy should be to maintain pH greater than 7.0, not to return pH to normal.

Similarly, phosphate administration, once considered a key component in the management of DKA (estimated deficit ~5-7 mmol/kg), has come under closer scrutiny. Phosphate depletion definitely occurs in DKA for the reasons outlined earlier, and in

the past, repletion of phosphate (much of it as potassium phosphate salts) had been advocated to forestall the development of muscle weakness and hemolysis and to promote tissue oxygenation through generation of 2,3-diphosphoglycerate in erythrocytes. However, the administration of phosphate salts has been associated with the development of clinically significant hypocalcemia and deposition of calcium phosphate precipitates in soft tissues, including the vasculature. Thus, in general, parenteral phosphate repletion is not routinely provided for patients with DKA unless plasma phosphate falls to very low levels (<1 mmol/L). In this case, 2 mL of a mixture of KH_2PO_4 and K_2HPO_4 solution, containing 3 mmol of elemental phosphorus and 4 mEq of potassium, may be added to 1 L of fluids and introduced over 6 to 8 hours. In no instance should all K^+ repletion be in the form of potassium phosphate salts. In general, renewal of food ingestion and insulin therapy complete restoration of total body phosphate stores and return plasma phosphate levels to normal over a period of several days.

In pediatric patients (age <20 years), the need for volume expansion needs to be weighed against the potential risk of cerebral edema secondary to aggressive fluid administration, although this is controversial (discussed later). A recent recommendation suggests 10 to 20 mL/kg/h of normal saline during the first 1 to 2 hours with limitation of total fluid administration to 50 mL/kg over the first 4 hours. The remaining fluid deficit is corrected over the next 48 hours. Normal saline or half-normal saline (depending on serum Na^+ levels) usually accomplishes this with a rate of 5 mL/kg/h. The decrease in serum osmolality should not exceed 3 mOsm/kg H_2O/h. An insulin bolus prior to initiating the insulin infusion (0.1 U/kg/h) is usually not required in children.

Finally, it is necessary to actively seek out and treat the precipitants of DKA when they are identified. This includes appropriate cultures of urine and blood (and cerebrospinal fluid, if indicated) and empiric antibiotic therapy directed against the most likely pathogenic organisms (pending the results of the cultures). The presence of fever is typically a good marker for infection or other inflammatory process because it is not a feature of DKA per se. Elevated white blood cell counts, on the other hand, are frequently seen with DKA alone. Hyperamylasemia is common but rarely reflects pancreatitis—the amylase is usually of salivary origin. Other precipitants should also be sought. Myocardial infarction, which is often clinically silent in diabetic patients, is an uncommon but life-threatening precipitant of DKA in patients with established diabetes.

Complications

Aggressive resuscitation with isotonic or hypotonic fluids is a theoretical but uncommon cause of fluid overload during management of DKA. Careful attention to the cardiovascular examination, chest x-ray, and urine output should aid in preventing this complication.

Hypoglycemia is relatively rare in the current era given the low doses of insulin used in management and appropriate initiation of glucose-containing fluids as plasma glucose levels fall below 250 mg/dL.

Cerebral edema due to rapid correction of plasma hypertonicity has usually been reported with plasma glucose levels below 250 mg/dL. Clinically significant cerebral edema is relatively uncommon in adult patients. Milder forms of cerebral edema have been noted in many patients being treated for DKA but have not been strongly correlated with changes in extracellular tonicity. At present, in a symptomatic adult patient, it would appear prudent to treat hypertonicity exceeding 340 mOsm/kg aggressively with hypotonic fluids to avoid complications related to plasma hyperviscosity. Further correction from that point to normal plasma osmolality (about 285 mOsm/kg) can probably be accomplished in slower fashion over several days. Cerebral edema occurs in 1% to 2% of children with DKA, frequently with devastating results. Approximately one-third of children with clinically significant cerebral edema die during the acute illness, and another third sustain permanent neurologic impairment. The predilection for young children may reflect, in part, immaturity of the autoregulatory mechanism that governs cerebral blood flow. There is increased risk in children less than 5 years of age, and those with low Pco_2 or high blood urea nitrogen at presentation. Cerebral edema in children may be associated with high initial rates of fluid resuscitation (>4 L/m^2/d) and rapid falls in plasma sodium (or corrected sodium) concentration, although it can occur in clinical settings without an apparent cause, and mild degrees of cerebral edema have been noted in DKA even prior to initiation of therapy. In the absence of definitive trial data to guide therapy, lower rates of fluid administration (<2.5 L/m^2/d) with volume resuscitation spread over a longer time interval would seem appropriate if the clinical situation permits. Insulin administration has also been linked to the development of cerebral edema. Current recommendations do not include the use of insulin boluses in children with DKA. When signs of cerebral edema appear—deterioration in level of consciousness, focal neurologic signs, hypotension or bradycardia, sudden decline in urine output after an initial period of apparent recovery following treatment for DKA—fluid administration should be reduced and mannitol (0.2-1 g/kg given intravenously over 30 minutes) should be administered with repetition at hourly intervals based on response. CT or MRI scan of the brain can be done once therapy has been initiated to confirm the diagnosis. Hyperventilation has not been shown to alter the course of this complication once it develops.

Patients with DKA are also prone to develop acute respiratory distress syndrome, presumably reflecting the sequelae of a damaged pulmonary endothelium and elevated capillary hydrostatic pressures following fluid resuscitation. Patients who present with rales at the time of initial diagnosis may be at higher risk for the development of this complication. Patients may also be at increased risk for development of pancreatitis as well as systemic infection, including fungal infections (eg, mucormycosis).

Abdominal pain and gastric stasis seen in DKA may put a semi-stuporous patient at risk for aspiration. Up to 25% of patients with DKA have emesis that may be guaiac positive. The latter finding appears to result from hemorrhagic gastritis. Patients who are believed to be at risk with regard to airway protection should have a nasogastric tube in place for evacuation of stomach contents.

Finally, patients with DKA are at risk for recurrence of the disorder if insulin is withdrawn prematurely. The current infusion protocols, because they raise plasma insulin only to physiologic levels, have a very short half-life for control of blood glucose and ketogenesis. Premature cessation of insulin therapy before depot insulin (eg, NPH or glargine insulin) can exert its effect may allow the patient to regress into ketoacidosis. To preclude this possibility, subcutaneous regular and intermediate-acting insulin should be provided on the morning when feeding is to be resumed. The insulin drip should be continued for 1 hour following this injection to provide coverage until the depot insulin becomes effective.

HYPEROSMOLAR NONKETOTIC COMA

Clinical Setting

Hyperosmolar nonketotic coma, like DKA, is a consequence of uncontrolled diabetes mellitus; however, a number of features of this disorder clearly distinguish it from DKA. First, plasma glucose levels in ketoacidosis are usually in the 250 to 400 mg/dL rather than the 700 to 1000 mg/dL range that can be seen with hyperosmolar nonketotic coma. Second, the time course for development of hyperosmolar nonketotic coma typically takes a week or longer, whereas ketoacidosis can develop over 1 to 2 days. Third, ketosis is rare in hyperosmolar nonketotic coma. Circulating insulin levels are probably adequate to control ketogenesis in the latter, although they are incapable of establishing euglycemia. Fourth, hyperosmolar nonketotic coma tends to occur more commonly in the elderly population, often in those receiving chronic care who have difficulty reporting symptoms or maintaining adequate hydration. Mortality remains high in hyperosmolar nonketotic coma (perhaps as high as 20% vs 1%-2% in DKA); in both cases, mortality increases with age.

Precipitants of hyperosmolar nonketotic coma include many of the same complicating illnesses that lead to DKA. Infections (pneumonias are said to be the most common precipitating infection in 40%-60% of cases, with urinary tract infections representing 5%-16% of the total), myocardial infarction, cerebrovascular accident, pancreatitis, burns, heat stroke, and endocrine dysfunction (eg, Cushing syndrome, acromegaly) are frequently associated with hyperosmolar nonketotic coma. Up to 20% of patients with hyperosmolar nonketotic coma do not have a previous diagnosis of diabetes mellitus. Administration of hyperosmolar fluids (eg, tube feedings, total parenteral nutrition, peritoneal dialysis) can precipitate hyperosmolar nonketotic coma, as can medications that impair insulin secretion or action (eg, β-adrenergic blocking agents, phenytoin, corticosteroids, diazoxide, or atypical antipsychotics). Diuretics, particularly thiazides, can reduce intravascular volume, reduce GFR (the dominant mechanism for glucose clearance), and activate counterregulatory hormones (eg, catecholamines), all of which promote development of the hyperosmolar state. Finally, limited access to free water intake, particularly in patients who are dependent on others to provide access to water, is a major determinant in the progression of the hyperosmolar state.

These factors interact in a highly variable fashion to promote hyperosmolar nonketotic coma. In a typical scenario, poorly controlled diabetes—or undiagnosed diabetes presenting for the first time—is aggravated by coincident infection (or other precipitant). This results in significant hyperglycemia as the balance of counterregulatory hormones versus insulin shifts in favor of the former. Hyperglycemia promotes increased insulin resistance and further elevations in blood glucose levels. This leads to an osmotic diuresis in the kidney as plasma glucose levels exceed the threshold for tubular reabsorption. This threshold typically increases with age, leading to even higher plasma glucose levels in the elderly. The osmotic diuresis results in a progressive loss of water and, to a lesser degree, solutes (eg, Na^+, Cl^-, K^+) in the urine. As with DKA, the water loss is buffered initially by an osmotically driven movement of water out of the cells into the extracellular compartment. As the diuresis continues, however, contraction of intravascular volume ensues and glomerular filtration falls, shutting off the body's primary mechanism for controlling plasma glucose levels in this setting. Glucose levels increase dramatically; often to extraordinarily high levels (normal renal excretory function generally limits elevations in plasma glucose to 500-600 mg/dL). Nausea and vomiting, related to the infection, uremia, or hyperosmolality per se, may further aggravate intravascular volume contraction. Factor into this an elderly patient with age-dependent suppression of the thirst mechanism and difficulty communicating a sense of thirst to caregivers, and the stage is set for the severe dehydration of hyperosmolar nonketotic coma.

Diagnosis

Current diagnostic criteria from the American Diabetes Association include plasma glucose greater than 600 mg/dL, effective plasma osmolality greater than 320 mOsm/kg and absence of ketoacidosis. The diagnosis is usually based on strong clinical suspicion and laboratory assessments of plasma glucose levels and serum osmolality. The typical patient may be a patient with known type 2 diabetes (often taking an oral hypoglycemic agent), who has shown a subtle but steady deterioration over several days immediately preceding admission. The patient demonstrates significant dehydration, somnolence, stupor, or coma. The course may be marked by a precipitating illness, as described earlier. Tachycardia and low-grade fever may be present, but blood pressure and respiratory rate are normal. Urine output typically is reduced to low levels as the hyperosmolar state progresses.

The clinical presentation is usually dominated by the central nervous system findings. Patients with hyperosmolar nonketotic coma are lethargic and weak, with an altered sensorium. True coma is less common and usually does not appear until plasma osmolality is significantly elevated (discussed later). Hallucinations are occasionally present, and seizures, particularly focal seizures, may occur in 25% of patients. Focal findings suggesting cortical ischemia may also be seen. A minority of these reflect true cerebrovascular accidents related to thromboembolic complications (discussed later). Most represent low-flow states in areas of baseline cerebrovascular ischemia that recover with correction of the metabolic abnormality.

Plasma glucose levels are typically high (occasionally >1000 mg/dL). Measured plasma osmolality is often greater than 350 mOsm/kg. These measurements usually include the contribution of urea, which may accumulate to significant levels in the setting of volume contraction and prerenal azotemia; however, urea does not contribute to the osmotic force that drives fluid movement across cellular membranes because it is freely permeable in these membranes and distributes itself in equivalent concentrations in the intracellular and extracellular compartments. A more accurate measure of the effective osmolality, or tonicity, is obtained from the following formula:

$$\text{Effective osmolality} = 2Na^+ + \frac{\text{Glucose}}{18}$$

where Na^+ and glucose are the concentrations of sodium ion and glucose, respectively. Normal effective osmolalities are in the range of 275 to 295 mOsm/kg. Hyperosmolar nonketotic coma is diagnosed with an effective osmolality greater than 320 mOsm/kg, whereas coma itself is seen with osmolalities greater than 340 mOsm/kg. Coma at effective osmolalities less than or equal to 340 mOsm/kg suggests some other cause (eg, meningitis, cerebrovascular accident, or other metabolic abnormality).

Anion gap acidosis is usually not a major component of hyperosmolar nonketotic coma, because ketogenesis is suppressed (discussed earlier). If gap acidosis is present, it may suggest lactate accumulation due to tissue hypoperfusion, low-output state, metformin toxicity, or coexistent renal failure or toxic ingestion. Measurement of serum lactate levels, standard renal function tests, or a screen for toxic substances in blood (if a suggestive history is obtained) should help discriminate among these possibilities.

Management

Therapy is in some ways similar to that for DKA except that there is less concern about correction of the acidosis, which is mild or nonexistent with most conventional cases of hyperosmolar nonketotic coma, and greater emphasis is placed on restoration of intravascular volume and serum osmolality. It is also important to address the potentially life-threatening precipitants of nonketotic coma.

Resuscitation of intravascular volume is initiated with parenteral fluids. Over the first hour 1 to 2 L of normal saline are administered. If the patient is profoundly hyperosmolar (>330 mOsm/L), half-normal saline (0.45% NaCl) should be substituted for normal saline. Volume status is reassessed based on blood pressure, urine output, or central venous pressure. If volume contraction persists, normal saline (or half-normal saline if hypertonicity persists) can be continued at a rate of 1 L/h. Once blood pressure and urine output have been restored, hypotonic fluids (eg, half-normal saline) can be substituted for isotonic saline at a rate of 250 to 500 mL/h depending on the need for continued volume resuscitation. The total free water deficit can be approximated using the following formula:

$$\text{Water deficit} = \frac{\text{Plasma osmolality} - 295}{295} \times 0.6 \,(\text{Body weight})$$

where plasma osmolality is in milliosmoles per kilogram, body weight in kilograms, and water deficit in liters. Fluid rates should be adjusted to correct half of the free water deficit in the first 12 hours and the remainder over the ensuing 24 to 36 hours. As with DKA, glucose-containing fluids (eg, D_5W) should be started when plasma glucose levels fall to 250 mg/dL.

Insulin therapy is of secondary importance in the management of hyperosmolar nonketotic coma. It is imperative that insulin therapy not be initiated until volume resuscitation is well under way (eg, following 1-2 L of saline). Insulin promotes movement of glucose, electrolytes, and water into the intravascular compartment. In the absence of adequate volume resuscitation, this can lead to hypotension and cardiovascular collapse. Therapy should be initiated with a loading dose of 10 to 20 U intravenously followed by a drip delivering 0.1 U/kg/h. Given the theoretical risk of brain edema with rapid reduction in plasma osmolality, it is recommended that glucose levels be maintained at approximately 300 mg/dL in the acute setting. Conversion back to the outpatient regimen once the acute event has resolved can be accomplished using a strategy similar to that outlined earlier for DKA.

Electrolytes (ie, Na^+, K^+, Cl^-, PO_4^{3-}, and Mg^{2+}) are significantly depleted in hyperosmolar nonketotic coma due to the osmotic diuresis. These should be repleted as needed (beginning with the first liter of fluids if necessary). Once again, parenteral phosphate should be administered with care, keeping serum phosphate above 1 mg/dL until feeding can re-establish phosphate balance.

Complications

A. Thromboembolic events Coagulopathies related to increased platelet aggregation, hyperviscosity of circulating blood, or disseminated intravascular coagulation can develop in hyperosmolar nonketotic coma. The most appropriate therapy is resuscitation of intracellular volume and treatment of systemic infections. Focal neurologic findings that fail to improve with fluid resuscitation should be further investigated with appropriate consultation and imaging studies, if indicated. Some investigators have recommended low-dose heparin anticoagulation in patients with hyperosmolar nonketotic coma to guard against thromboembolic sequelae. If such therapy is initiated, patients should be closely monitored for development of gastrointestinal bleeding.

B. Cerebral edema This is a serious—although fortunately uncommon—complication of fluid resuscitation in hyperosmolar nonketotic coma (and DKA; discussed earlier). It occurs more commonly in children than in adults and frequently follows an overly aggressive management strategy involving administration of large amounts of parenteral fluids. The pathogenesis is not completely defined but probably relates to the increase in cortical capillary hydrostatic pressure and the osmotic gradient engendered by the aggressive use of hypotonic fluids in this setting. Cerebral edema rarely appears with serum glucose levels above 250 mg/dL. Appropriate introduction of glucose-containing

fluids into the management strategy when plasma glucose approaches this level is an effective way to guard against this complication.

Clinically, brain edema develops after an initial period of improvement. It is often heralded by the development of headache, altered mental status, and seizure activity. If untreated, this can progress to herniation, with respiratory arrest and death. Recognition of the syndrome and appropriate treatment with mannitol, dexamethasone, and furosemide can be life saving in this setting.

HYPERCALCEMIC CRISIS

Clinical Setting

Severe hypercalcemia, defined arbitrarily as a total Ca^{2+} greater than 14 mg/dL, can occur in the setting of a known hypercalcemic illness but may represent the initial manifestation of such a disorder. Patients present initially with polyuria and polydipsia and, with a more protracted course, develop evidence of intravascular volume contraction with decreased urine output. Alterations in the sensorium dominate the clinical picture and range from behavioral changes and drowsiness to stupor and coma. Bradyarrhythmias and heart block are major cardiac sequelae of hypercalcemia. Hypercalcemia also potentiates digoxin activity, increasing the risk of cardiac glycoside toxicity. Gastrointestinal complaints are prominent. Anorexia, nausea, and vomiting, which further aggravate the volume contraction, are frequently present. Abdominal pain may be of sufficient intensity to mimic an acute abdomen.

Most chronic hypercalcemia is caused by primary hyperparathyroidism and is usually detected as a result of routine laboratory screening. Cancer-related hypercalcemia, most of which is caused by parathyroid hormone–related protein (PTHrP), is a less frequent but important cause of chronic hypercalcemia (see Chapter 21). In acute hypercalcemic crises, malignancy emerges as the major cause of the elevations in serum calcium. Other causes of hypercalcemia (eg, vitamin D intoxication, thiazides, or Addison disease) are either too uncommon or cause such small increments in serum calcium that they rarely need to be considered in the differential diagnosis (see Chapter 8).

Hypercalcemia due to any cause creates a state of nephrogenic diabetes insipidus by uncoupling vasopressin from its receptor-effector system in the kidney (Table 24–8). It also promotes an increase in urinary sodium excretion. This results in a salt and water diuresis that eventually promotes intravascular volume contraction and reduced GFR, effectively suppressing the only route of egress for calcium mobilized from bone or transported across the gut lumen. Thus, volume contraction is in large part responsible for the very high levels of serum calcium found in hypercalcemic crisis. By inference, resuscitation of intravascular volume (discussed later) represents an excellent initial intervention to improve renal perfusion and tubular clearance of Ca^{2+}.

TABLE 24–8 Pathogenesis of hypercalcemic crisis.

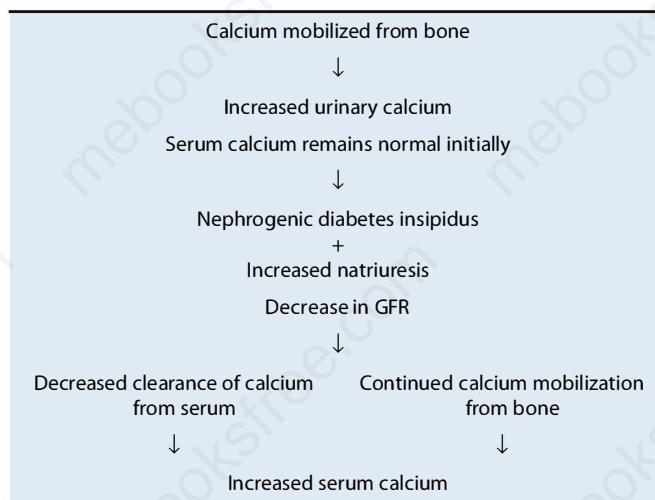
Nephrogenic diabetes insipidus
+
Increased natriuresis
Decrease in GFR
↓

Decreased clearance of calcium from serum	Continued calcium mobilization from bone
↓	↓

Increased serum calcium


Hypercalcemic crisis should be considered in any patient with disseminated malignancy, particularly squamous carcinomas of the head, neck, and lung. This is especially true when there is a change in the patient's mental status or general clinical condition that cannot be explained by tumor progression, infection, or other metabolic abnormality (eg, uremia). It should also be considered in patients with known primary hyperparathyroidism, particularly in a clinical setting characterized by vomiting, diarrhea, or dehydration (eg, due to thiazide therapy).

Diagnosis

The diagnosis is confirmed by measurement of a total or ionized serum calcium level. The latter may be preferable in the presence of low serum albumin, the predominant Ca^{2+}-binding protein in blood, because hypoalbuminemia may mask an elevation in the free fraction if only total calcium levels are assessed. Albumin-corrected calcium levels can be derived by increasing the total calcium by 0.8 mg/dL for each 1 g/dL decrease in serum albumin, based on a normal albumin level of 4 g/dL. The albumin-adjusted calcium does not always correlate with the measured ionized calcium, however, and should not be relied on for more than a rough estimate of the free calcium fraction, particularly if reliable ionized calcium measurements are available.

On the initial presentation with hypercalcemia, plasma samples should be sent for measurement of intact parathyroid hormone (PTH), PTHrP, and, if the clinical setting is suggestive, 25-hydroxyvitamin D or 1,25-dihydroxyvitamin D levels. Primary hyperparathyroidism is a common disease, and even in a patient with known malignancy it should be excluded as a potentially curable cause of the hypercalcemia.

Management

Intravenous fluids represent the first avenue of approach for management of severe hypercalcemia (Table 24–9). Normalization of intravascular volume improves GFR and increases renal excretion

TABLE 24–9 Therapy for hypercalcemic crisis.

0.9% NaCl (250-500 mL/h) plus furosemide if required

of calcium. Sodium and calcium handling are closely linked in the distal nephron. Fluid resuscitation with normal saline (0.9% NaCl) both restores GFR and promotes natriuresis and calciuresis by controlling transporter mechanisms responsible for sodium and calcium handling in the distal nephron. Over the first hour 500 to 1000 mL of normal saline is given, with rates of 250 to 500 mL/h thereafter, depending on the state of volume contraction. The latter can be assessed based on clinical examination, urine output, and assessment of renal function. Several liters of fluid are frequently required before intravascular volume is restored. Continued infusions should be matched with urine outputs to avoid fluid overload. Loop diuretics (eg, furosemide) may be used to accomplish this in patients with an underlying predilection toward fluid retention (eg, congestive heart failure). Saline and loop diuretics can increase urinary calcium excretion by as much as 800 mg/d. This is typically accompanied by a moderate but significant reduction in serum calcium levels (1-3 mg/dL). Careful attention should be devoted to detection of signs of fluid overload. Potassium and magnesium depletion related to the diuresis should be corrected. If loop diuretics are used, it is important that the volume of normal saline administered should at least match urine output. Diuretic-induced volume contraction may lead to reduced GFR and worsening hypercalcemia.

At this point, more definitive and specific therapy should be introduced (see Chapter 8). Severe hypercalcemia is almost always a result of increased mobilization of calcium from bone. Therefore, most effective therapies for hypercalcemia have been directed against the osteoclasts of bone. Bisphosphonates represent the mainstay of therapy. Pamidronate administered at a dose of 60 to 90 mg in 250 mL of saline over 1 to 4 hours (4 hours for outpatients) is effective in reducing serum calcium levels, often into the normal range. A newer generation bisphosphonate, zoledronic acid (4 mg intravenous infusion over 15-30 minutes) is heavily used for management of hypercalcemia. In comparison to pamidronate, it is more potent, with a similar safety profile. In addition, it has the advantage of a shorter infusion period and longer duration of antihypercalcemic activity in head-to-head comparisons with pamidronate. The effect of intravenous bisphosphonates can take 2 to 4 days to peak, and the duration of the response is

variable, lasting from 1 week to several months. Retreatment for recurrent hypercalcemia is usually successful. Side-effects of therapy include inflammation at the infusion site; low-grade fever with flu-like syndrome; osteonecrosis of the mandible and maxilla with long-term or frequent infusions; renal insufficiency; and transient depression of serum calcium, phosphate, and magnesium. Bisphosphonates are also attractive because of their efficacy in controlling pain and fracture in myeloma and osteolytic metastases from breast cancer and other solid tumors. The mechanism here is thought to involve suppression of tumor-induced osteoclastic activity in the neighborhood of the metastases.

Denosumab can be an effective alternative to bisphosphonate therapy. It is a monoclonal antibody (against the RANK ligand; see Chapter 8) which acts through interference with the RANK ligand-dependent osteoclastic bone resorption. Denosumab has been shown to be effective in managing hypercalcemia that is refractory to bisphosphonates. Standard dose is 120 mg administered subcutaneously with repeat dosing no sooner than 7 days following the first administration. Reduction in serum calcium is seen within 2 to 4 days following administration of denosumab. Denosumab has been associated with bone pain, nausea, diarrhea, and osteonecrosis of the jaw—though the latter is typically associated with more prolonged use of this agent. There is also a theoretical risk of infection which is based on the role of the RANK ligand in signaling the inflammatory response.

Calcitonin has a long history of use in the management of hypercalcemia. It has a direct effect on the osteoclast to suppress bone resorption. It is given either subcutaneously or intramuscularly at a dose of 2 to 4 U/kg body weight every 6 to 12 hours after administration of a test dose to exclude hypersensitivity to the drug. In general, the response to calcitonin, which should be noted after 6 to 12 hours, is modest in magnitude (decrease in serum calcium levels of 1-2 mg/dL) and declines with increasing duration of therapy (tachyphylaxis). Coadministration of glucocorticoids with calcitonin may limit this latter effect and extend the duration of the hypocalcemic effect. Calcitonin is useful largely as adjunctive therapy in controlling hypercalcemia in the acute setting until the effects of more powerful but slower acting agents (eg, bisphosphonates) become available.

Cinacalcet, a calcium receptor agonist, can be useful in the management of PTH-dependent hypercalcemia such as that seen with parathyroid carcinoma. Doses are typically in the range of 30 to 60 mg bid or higher.

Plicamycin is a tumoricidal antibiotic with pronounced hypocalcemic properties at nontumoricidal doses. It presumably targets the osteoclast and its bone-resorptive activity. It is administered as an infusion at a dosage of 15 to 25 μg/kg body weight over 4 to 24 hours. Calcium levels fall, often into the normal range, within 24 to 48 hours in a majority of patients treated. Plicamycin has significant renal and hepatic toxicity, and it induces platelet abnormalities that may result in clinically significant hemorrhage. Toxicity tends to increase with repeated administration, limiting chronic use of the drug. Given the ready availability of less toxic treatment modalities, plicamycin is rarely used in the management of severe hypercalcemia.

Gallium nitrate has shown efficacy in the management of tumoral hypercalcemia in clinical trials. Like the bisphosphonates and plicamycin, gallium is apparently targeted at the osteoclast. Patients are infused with gallium nitrate at a dosage of 200 mg/m^2 over a 5-day period. Gallium's major limitations are the duration of the infusion (often requiring hospitalization) and the potential for significant nephrotoxicity, particularly if it is used in the setting of other nephrotoxic agents. For these reasons it, like plicamycin, has largely been supplanted by newer agents for management of hypercalcemia. Other nonselective treatment modalities that are available for management of hypercalcemic crisis include steroids, phosphate, and dialysis. Aside from their potentiation of calcitonin's effects, as described earlier, steroids are usually effective only in the management of hypercalcemia due to lymphoproliferative disease (eg, multiple myeloma) or vitamin D toxicity (eg, due to ingestion of vitamin D or disseminated granulomatous disease). They are best suited for chronic management of hypercalcemia associated with these disorders. Parenteral phosphate effectively reduces serum calcium levels, although often at the expense of deposition of calcium phosphate salts in parenchymal tissues, and cannot be recommended. Peritoneal or hemodialysis against a low-calcium bath is also very effective in reducing serum calcium levels and is the treatment of choice for severe hypercalcemia in renal failure patients incapable of tolerating or responding to saline diuresis. In clinically tenuous patients not in renal failure undergoing maximal saline diuresis, persistent hypercalcemia may be an indication for hemodialysis as a tool to bridge the interval until more definitive therapy (eg, bisphosphonates) can achieve its maximal effect.

Finally, some effort should be taken to addressing the primary cause of the hypercalcemia. In some instances (eg, disseminated malignancy), therapeutic options may be limited and ineffective in controlling serum calcium levels. In other instances (eg, primary hyperparathyroidism), a definitive surgical approach can be curative and limit further morbidity. Thus, careful investigation of the source of the hypercalcemia is warranted. Such investigation—even in patients with an obvious potential source of hypercalcemia (eg, malignancy)—may identify correctable problems and, at the very least, assist in the development of long-term management strategies once the acute crisis has resolved.

ACUTE HYPOCALCEMIA

Clinical Setting

Hypocalcemia may be seen in a number of disorders affecting the synthesis or action of PTH or vitamin D or following sequestration of calcium into a functionally inaccessible compartment (see Chapter 8). Many of these represent chronic illnesses where hypocalcemic symptoms develop insidiously or where the complication of hypocalcemia is anticipated early and appropriate treatment initiated prior to acute decompensation. However, in selected situations, acute hypocalcemia may dominate the clinical presentation. Appropriate recognition of the high-risk clinical setting should lead to earlier diagnosis and therapeutic intervention with reduced morbidity and mortality.

Probably the most important cause of PTH-deficient hypocalcemia occurs in the postoperative setting following neck surgery for treatment of malignancy or resection of adenomatous or hyperplastic parathyroid glands. This may reflect accidental or purposeful (eg, radical neck dissection) removal of all functioning parathyroid tissue or inadvertent vascular compromise of tissue left in the neck. Residual normal parathyroid tissue can also be functionally atrophied in a patient undergoing surgery for hyperparathyroidism. It can take 1 to 2 days for PTH secretion and calcium levels to return to normal following resection of the adenoma.

Magnesium deficiency can compromise both PTH secretion from the parathyroid gland and PTH action at target tissues in the periphery. Magnesium repletion in patients with low serum magnesium and calcium should be undertaken before launching an exhaustive workup of the hypocalcemia.

Hypocalcemia can be seen in chronic renal insufficiency. Hyperphosphatemia and reduced 1-α-hydroxylase activity result in deficient 1,25-dihydroxyvitamin D$_3$ generation and consequent hypocalcemia. Aggressive management of the hyperphosphatemia (eg, with phosphate binders) and calcitriol are generally useful in promoting normal calcium balance.

Acute sequestration of calcium into bone or nonphysiologic compartments can lead to severe hypocalcemia. Hypocalcemia following removal of a parathyroid adenoma may reflect a hypoparathyroid or aparathyroid state, as discussed earlier. Alternatively, in patients with severe osteitis fibrosa cystica, the bones, in the absence of PTH-driven bone resorption, serve as a sink for extracellular calcium deposition, as previously unmineralized osteoid becomes calcified. This results in the syndrome termed hungry bones or recalcification tetany. It is usually distinguished from PTH deficiency by measurements of the hormone (PTH is typically elevated in the hungry bones syndrome). A similar sequestration phenomenon is seen in osteoblastic metastases (eg, in breast or prostatic carcinoma). Typically, osteoclastic activity in these metastases is abrogated through some specific therapeutic intervention, leaving unmineralized matrix to calcify at the expense of extracellular calcium levels.

Sequestration may also occur in nonphysiologic settings such as the peritoneal cavity in acute pancreatitis, where deposition of calcium soaps leads to a subsequent reduction in serum calcium levels. A similar phenomenon occurs in damaged muscle following rhabdomyolysis. Deposition of calcium salts in damaged muscle beds leads to a reduction in serum calcium levels. Interestingly, serum calcium returns to normal or even elevated levels during the recovery phase, reflecting dissolution of the precipitates as the muscle undergoes repair.

Hypocalcemia occurs in the setting of acute systemic illness with a prevalence of nearly 80% in the ICU setting. It has been linked to the cytokine-mediated inflammatory response that frequently dominates this clinical setting. Other potential contributors include increased calcium binding to albumin (eg, as seen with alkalosis), relative PTH deficiency, and decreased renal 1-α-hydroxylase activity. It has also been associated with specific drugs, including antineoplastic agents such as doxorubicin and cytarabine and other agents such as ketoconazole, pentamidine, and foscarnet.

Diagnosis

Symptomatic hypocalcemia presents with a predictable constellation of signs and symptoms. Most of these findings are related to the increased neuroexcitability that is seen with reductions of extracellular calcium levels (Table 24–10). Symptoms frequently begin as circumoral paresthesias or paresthesias of the fingers or toes. This is followed by increased muscle cramping and spasm (particularly carpopedal spasm) (see Figure 8–18) and diffuse hyperreflexia. The increased propensity for muscle spasm can provoke generalized tetany which if extended to the laryngeal muscles can lead to laryngospasm and respiratory arrest. Increased excitability in the central nervous system can result in seizures, particularly in patients with a history of seizure disorder.

Physical examination looking for evidence of neuromuscular hyperexcitability is often revealing (see Table 24–10). Chvostek sign is evoked by repetitive tapping of the area overlying the facial nerve approximately 2 cm anterior to the ear lobe below the zygomatic arch. A positive test is contraction of musculature innervated by the facial nerve. The extent of the contraction is roughly proportionate to the severity of the hypocalcemia. Trousseau sign is triggered by inflating a blood pressure cuff on an upper extremity to a level that roughly equates with the systolic blood pressure for 3 to 5 minutes. Spasm of the hand musculature (see carpopedal spasm, discussed earlier) due to transient ischemia of hyperexcitable nerves innervating the hand is regarded as a positive test. Of the two, a positive Trousseau sign is regarded as more specific for hypocalcemia than is the positive Chvostek sign.

Hypocalcemia can also have significant effects on cardiovascular function, including decreased blood pressure, impaired cardiac contractility, and conduction disturbances. On the electrocardiogram, significant hypocalcemia can manifest as prolongation of the QT interval. In extreme cases this can lead to ventricular arrhythmias, including torsades de pointes. Evidence of sequelae of chronic hypocalcemia may also identify individuals who are at risk for acute hypocalcemia. Subcapsular cataracts and basal ganglia calcification are features associated with long-standing hypocalcemia.

Measurement of total serum calcium, albumin, or ionized calcium, if available, leads quickly to the correct diagnosis.

TABLE 24–10   Symptoms and signs of acute hypocalcemia.

Symptoms
Perioral numbness
Tingling paresthesias in distal extremities
Hyperreflexia
Muscle cramps
Carpopedal spasm
Laryngospasm
Seizures
Coma

Signs
Chvostek sign
Trousseau sign
Hypotension
Bradycardia
Prolonged QT interval
Arrhythmias

Measurement of plasma PTH, 25-hydroxyvitamin D, and 1,25-dihydroxyvitmin D assists in identifying deficiency of PTH secretion, adequacy of vitamin D stores, or impaired synthesis of bioactive vitamin D, respectively. Mg^{2+} levels should be obtained to exclude hypomagnesemia. Magnesium depletion can present with the same symptoms as hypocalcemia. If present, magnesium repletion should be initiated before additional diagnostic tests are undertaken.

Examination of the medication list looking for drugs with hypocalcemic properties (eg, bisphosphonates, calcitonin, asparaginase, cisplatin, foscarnet) should be performed.

Measurement of serum amylase and lipase should aid in identifying pancreatitis as a source of the hypocalcemia. Creatine kinase and aldolase levels can be used to exclude the presence of rhabdomyolysis.

One area of potential confusion is the evaluation of patients in the immediate postparathyroidectomy period. Differentiating a hypoparathyroid or aparathyroid state from hungry bones syndrome can be difficult acutely. As pointed out earlier, measurement of plasma PTH levels (high in hungry bones syndrome and low in hypoparathyroidism) provides the most definitive separation of the two, but outside of referral centers this typically takes several days and, therefore, is usually not helpful in the acute setting. Measurement of serum phosphate (elevated in hypoparathyroidism and low-normal or low in hungry bones syndrome) or urinary phosphate (often low or absent in hypoparathyroidism) may be useful in identifying the source of hypocalcemia. Fortunately, the treatment of hypocalcemia in these two conditions is largely the same. Thus, establishment of a definitive diagnosis is important mainly for planning the subacute and long-term management of the patient's disease.

Management

In a life-threatening situation (eg, cardiovascular collapse) or in the setting of frank generalized tetany, 10 mL of calcium gluconate (93 mg of elemental calcium) can be administered intravenously over a 5- to 10-minute period and repeated if necessary. Less acute but recurrent hypocalcemic episodes can be managed with continuous calcium infusions. Nine hundred and thirty milligrams (10 ampules) of calcium gluconate can be mixed in 500 mL of D_5W. Infusion rates are established empirically. The initial infusion rate is typically 0.3 mg/kg/h but may be increased to as much as 2 mg/kg/h in patients with high demands for calcium (eg, hungry bones syndrome). Intravenous calcium should be given through a central vein since extravasation of the infusate can lead to tissue sloughing. Caution should also be exercised in infusing calcium in patients with hyperphosphatemia (precipitation of calcium phosphate salts in soft tissues), hypokalemia, or those on digoxin therapy (increased risk of cardiac arrhythmias).

As the acute situation resolves, selected patients become candidates for chronic replacement therapy. Those with minor hypocalcemia may be treated with calcium supplements alone. Administration of 1 to 3 g of elemental calcium (calcium carbonate contains about 40% elemental calcium by weight) may suffice to restore calcium to the low-normal range and eliminate hypocalcemic symptoms. In those with more refractory hypocalcemia—a

category that includes most patients with hypoparathyroidism—the addition of some form of vitamin D or a derivative is required. If ergocalciferol (vitamin D_2) is employed to manage patients with hypoparathyroidism, supraphysiologic doses (50,000 U/d or higher) may be required, reflecting the limited capacity for 1-α hydroxylation of the vitamin D pro-hormone in the hypoparathyroid state. 1,25-Dihydroxycholecalciferol (calcitriol) works faster than vitamin D_3 and circumvents the 1-α-hydroxylase blockade, but it is more expensive and the risk of acute hypercalcemia may be higher. It is given in a dose of 0.25 to 1 μg daily.

In all cases the goal of therapy should be to alleviate hypocalcemic symptoms and restore serum calcium levels to the low-normal range. This can usually be accomplished with some combination of vitamin D and supplemental calcium. The latter allows the practitioner additional flexibility in controlling serum calcium levels without requiring frequent dose modification of the longer-acting vitamin D. Efforts to push calcium levels higher may come at the expense of significant hypercalciuria and increased risk of renal stone formation. Difficulty in maintaining calcium even in the low-normal range without unacceptable hypercalciuria may be managed by addition of a thiazide diuretic (hydrochlorothiazide, 25-100 mg/d) to the regimen. These agents reduce hypercalciuria and, secondarily, raise serum calcium levels. If thiazides are used, careful follow-up is required to guard against the possibility of iatrogenic hypercalcemia. More refractory patients may be managed with recombinant PTH (1-34) or PTH (1-84) (see Chapter 8). Use of these agents is often successful in restoring normocalcemia and/or reducing doses of more conventional medications used in this setting. Efforts should be made to restore calcium to the target range and maintain it at this level indefinitely. Chronic hypocalcemia is associated with development of subcapsular cataracts and basal ganglia calcification which, in some cases, leads to the development of a parkinsonism-like syndrome.

HYPONATREMIA

Clinical Setting

Hyponatremia is the most frequent electrolyte problem observed in hospitalized patients (see Chapter 5). It is often relatively asymptomatic when mild to moderate in severity and subacute to chronic in its time course of development. However, significant hyponatremia (<120 mEq/dL) of rapid onset is frequently symptomatic and can be life-threatening.

Hyponatremia typically occurs in one of three clinical settings, each of which is linked to a specific pathophysiologic paradigm (Table 24–11). Hypovolemic hyponatremia is associated with volume contraction. As intravascular volume is reduced by more than about 9%, there is a nonosmotic stimulation of antidiuretic hormone (ADH; vasopressin) release as the body attempts to retain water to support intravascular volume. Hyponatremia of this type is seen with protracted vomiting, diarrhea, or excessive sweating, particularly when fluid losses are replenished with water or hypotonic fluids alone. Volume contraction and hyponatremia may also be seen with disorders of renal sodium handling (eg, diuretic

TABLE 24–11   Classification of hyponatremia.

Hypovolemic
Extrarenal volume loss
Excessive perspiration
Losses due to widespread skin involvement (eg, burns)
Vomiting
Diarrhea
Renal volume loss
Diuretic use
Salt-wasting nephropathy
Cerebral salt wasting
Osmotic diuresis with selective repletion of water
Hypervolemic
Congestive heart failure
Nephrotic syndrome
Cirrhosis with ascites
Chronic renal failure
Normovolemic
Syndrome of inappropriate antidiuretic hormone secretion
Intracranial disease
Pulmonary disease
Drugs (eg, opioids)
Severe pain or emotional distress
Nausea and vomiting
Postsurgical
Resetting of the osmostat
Adrenal insufficiency (may be hypovolemic in presence of severe mineralocorticoid deficiency)
Hypothyroidism
Water intoxication
Psychogenic polydipsia
Non-psychogenic polydipsia
Excessive administration of parenteral hypotonic fluids
Post-transurethral prostatectomy

use, mineralocorticoid deficiency, or other salt-wasting syndromes). Urinary Na^+ concentration is typically elevated (>20 mEq/L) in these latter disorders, whereas in the former, urinary Na^+ concentration is low, reflecting aggressive resorption of Na^+ in all tubular segments.

Hypervolemic hyponatremia includes those edematous disorders typified by paradoxical retention of Na^+ and water in the face of a total body excess of each. Specific causes of hyponatremia in this group include congestive heart failure, cirrhosis of the liver with ascites, and nephrotic syndrome. Hyponatremia in this setting presumably results from perceived hypoperfusion by baroreceptors in the arterial and venous circulation. Neural impulses transmitting this information to the hypothalamus trigger an increase in ADH release and net water retention.

Normovolemic hyponatremia is probably the most heterogeneous category and the most difficult to define pathophysiologically. It includes the syndrome of inappropriate ADH secretion (SIADH), hypothyroidism, glucocorticoid insufficiency (eg, secondary adrenal insufficiency), psychogenic polydipsia, postoperative hyponatremia, and hyponatremia seen following transurethral resection of the prostate (see Table 24–11).

Diagnosis

Acute hyponatremia, developing over the course of 24 hours or less, presents with headache, nausea, vomiting, lethargy,

restlessness, hyporeflexia, seizures, and altered sensorium, which may progress to stupor and coma. Hyponatremic encephalopathy is responsible for 30% of new-onset seizures in the ICU. These findings are thought to result from cerebral edema as the hypotonic extracellular compartment shifts water into the cerebral cortical cells. Such fluid shifts are opposed early through a reduction in intracellular electrolyte concentration and later by depletion of intracellular solutes (eg, amino acids). This acts to reduce the osmotic gradient and limit the net movement of fluid into brain. With chronicity, such solute shifts can reduce brain water content to near-normal. Thus, the acuteness of the reduction in serum Na^+ concentration and the magnitude of the reduction are important markers of potential morbidity in this disorder. Young menstruating women are particularly susceptible to the deleterious effects of cerebral edema in the postoperative setting. They are 25 times more likely than postmenopausal women or men to die or have permanent brain damage. This increased susceptibility may reflect the effects of estrogen and progesterone to promote solute accumulation in the cells of the central nervous system. Such accumulation would be predicted to increase the osmotic drive that leads to cerebral edema in these patients. Other patient groups at particular risk include children and patients with hypoxia or hepatic disease.

The first step in making the diagnosis is to exclude the presence of pseudohyponatremia. The latter results from high circulating concentrations of triglycerides or osmotically active solutes (eg, glucose or proteins) in circulating plasma. Hypertriglyceridemia artifactually lowers serum sodium by physically excluding it from the sizable nonaqueous phase of the sample being measured. This is usually readily detected in the laboratory (eg, by noting the presence of lactescent serum) and is corrected by centrifuging the sample prior to measuring Na^+ concentration in the aqueous phase. Osmotically active solutes, like glucose, draw water from the intracellular to the extracellular compartment, where it may transiently lower existing electrolyte (eg, Na^+) concentrations (see Diabetic Ketoacidosis, discussed earlier).

Assuming that the presence of hyponatremia is confirmed, an attempt to examine the different diagnostic possibilities listed earlier should be initiated. Evidence of congestive heart failure, cirrhosis, or nephrotic syndrome is usually apparent on physical examination and confirmable with standard laboratory or imaging studies. Similarly, renal dysfunction should be excluded using conventional renal function tests. Thiazide diuretic use is a frequent cause of hyponatremia and should be investigated early in the evaluation. A careful history of water consumption should be obtained and measurements of water intake in a monitored setting made to exclude psychogenic polydipsia or dipsogenic diabetes insipidus. Hypothyroidism can be excluded with measurement of plasma TSH and free thyroxine levels and glucocorticoid deficiency through an ACTH stimulation test (see Chapters 7 and 9).

Nonosmotic, non-volume-driven ADH secretion is found in SIADH. This is typically a diagnosis of exclusion in non-volume-contracted individuals without evidence of edema, renal insufficiency, hypothyroidism, or adrenal insufficiency. Serum Na^+ and osmolality are low in the face of a concentrated urine (at least >100

mOsm/kg). Urine Na^+ may be modestly elevated (>40 mEq/L with normal dietary NaCl intake), reflecting activation of natriuretic pathways responding to the increase in total body fluid volume. If findings are equivocal, an abnormal water load test (inability to excrete at least 90% of a 20 mL/kg water load in 4 hours or failure to dilute urine osmolality to below 100 mOsm/kg) can be used to confirm the diagnosis. Hypouricemia and low blood urea nitrogen levels are suggestive but not diagnostic of SIADH. Serum uric acid less than 4 mg/dL in the presence of hyponatremia has a positive predictive value for SIADH of greater than 70%. SIADH is seen with a variety of disorders affecting the central nervous system (eg, encephalitis, multiple sclerosis, meningitis, psychosis), the pulmonary system (eg, tuberculosis, pneumonia, aspergillosis), or as a paraneoplastic process associated with a number of solid tumors (eg, small cell carcinoma of the lung, carcinoma of the pancreas, bladder, or prostate). It may also be seen with certain types of drugs (eg, cyclophosphamide, vinca alkaloids, opioids, prostaglandin synthesis inhibitors, tricyclic antidepressants, carbamazepine, clofibrate, serotonin reuptake inhibitors and the recreational drug "ecstasy," 3,4 methylene dioxymethamphetamine) and in clinical situations associated with pain, stress, nausea, vomiting, hypoxemia, hypercapnia, hypoglycemia, and the perioperative state.

Some difficulty may be encountered in differentiating SIADH from a second hyponatremic syndrome called cerebral salt wasting. The latter is also associated with central nervous system disease, particularly subarachnoid hemorrhage. It is thought to be due to a centrally mediated renal wasting of sodium with consequent volume contraction, volume-dependent activation of ADH secretion, and hyponatremia. A recent study that used central venous pressure to separate groups with SIADH versus cerebral salt wasting (CVP <5 cm water defined volume contraction of cerebral salt wasting) in patients with subarachnoid hemorrhage and hyponatremia, 63% were thought to be due to SIADH and only 6.5% to cerebral salt wasting. It has been suggested that atrial natriuretic peptide or brain natriuretic peptide may play a central role in mediating the natriuresis associated with this disorder. Comparison of the features of these two disorders (Table 24–12) suggests that clinical or biochemical evidence of volume contraction is the major way to differentiate cerebral salt wasting from the euvolemic hyponatremia of SIADH. This is an important distinction, because therapy in cerebral salt wasting involves intravascular volume repletion, whereas in SIADH fluid restriction may represent first-line therapy. There is also a relative contraindication to volume depletion in patients with SAH due to the risk of vasospasm. In this instance administration of hypertonic saline (3% NaCl) may represent an effective approach to correction of the hyponatremia, regardless of etiology.

Management

When the primary stimulus provoking water retention (eg, diuretic use) or consumption (eg, psychogenic polydipsia) can be identified, specific therapy represents the most rational approach for long-term management.

TABLE 24–12 Comparison of laboratory findings in SIADH with CSW.

	SIADH	CSW
Intravascular volume contraction[a]	No	Yes
Serum sodium	↓	↓
Urine sodium	↑	↑↑
Urine volume	N or ↓	↑

Urea nitrogen, serum	N or ↓	↑
Serum uric acid	↓	N or ↑

[a]Based on clinical assessment or direct measurement of plasma volume.

Abbreviations: ADH, antidiuretic hormone; ANP, atrial natriuretic peptide; CSW, cerebral salt wasting; N, normal; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

When the cause of hyponatremia is unclear or unaddressable (eg, SIADH), a more generic approach may be adopted. Patients with asymptomatic (eg, mild or chronic) hyponatremia can be managed with water restriction, athough noncompliance and lack of efficacy when urine osmolality is greater than 500 mOsm/kg or urine-to-plasma Na concentration is greater than 1, limit its usefulness. Calculations of daily water intake should incorporate that included in nonliquid foods consumed by the patient. For patients who are symptomatic, non-acute but unable to adhere to water restriction, treatment with an oral vasopressin antagonist, tolvaptan (15-60 mg/d), or demeclocycline (600-1200 mg/d in divided doses), an antibiotic that uncouples ADH from activation of its receptor, may be sufficient to control serum Na$^+$ levels. Use of tolvaptan is limited to 30 days due to potential hepatotoxicity, and it should not be used in patients with liver disease. Water restriction is not required with demeclocycline therapy and may even be deleterious. Such therapy should be carefully monitored to guard against precipitous dehydration and renal insufficiency. Alternatively, patients can be managed with regular administration of a loop diuretic (eg, furosemide), which leads to excretion of urine approximately half the tonicity of plasma (loop diuretics disrupt the osmotic gradient required for urine concentration). Loop diuretics should be used concomitantly with NaCl supplementation (2-3 g/d) to increase urinary solute excretion and in that way amplify urinary water loss.

Symptomatic acute hyponatremia is an indication for hypertonic saline (3% NaCl) administration. Estimates of excess total body water can be made using the following formula:

$$\text{Excess water} = \frac{295 - \text{Plasma osmolality}}{295} \times 0.6 (\text{Body weight})$$

with plasma osmolality in milliosmoles per kilogram, excess water in liters, and body weight in kilograms.

The rise in serum sodium affected by 1 L of 3% saline infusate can be calculated by the following formula from Adrogue and Madias:

$$\Delta Na^+ = \frac{\text{Influsate } Na^+ - \text{Serum } Na^+}{\text{Total body water} + 1}$$

where ΔNa^+ is the change in sodium concentration effected by administration of 1 L of infusate; infusate Na^+ is the concentration of Na^+ in the infusion (eg, 513 mmol/L for 3% NaCl); and total body water is body weight (kg) × 0.6 (children or nonelderly men), × 0.5 (nonelderly women and elderly men), or × 0.45 (elderly women). The +1 in the denominator accounts for the volume of the infusate. Based on the calculated ΔNa^+, one can adjust the infusion rate to provide the desired increase in serum Na^+ over a fixed time interval. An alternative guide to initial therapy estimates that 1 mL/kg of 3% NaCl will increase serum Na^+ by approximately 1 mEq/L. Infusion rate algorithms are intended only as a guide and should be adjusted, based on actual Na^+ measurements, to raise serum Na^+ levels by no more than 0.5 mEq/h (total <8-12 mEq/d) to diminish the risk of central demyelination (see next). If necessary, infusion rates can be adjusted to increase serum sodium by 1 to 2 mEq/h for short periods of time in symptomatic patients; however, the limitation to 8 to 12 mEq/d should be adhered to, if possible. Furosemide can be administered, if necessary, to avoid intravascular fluid overload; however, given the ability of this drug to promote excretion of a hypotonic urine, the clinician should be aware that the plasma osmolality may increase faster than predicted by the formula set forth earlier. Once serum Na^+ reaches 130 mEq/L, hypertonic saline infusion should be terminated and fluid restriction or normal saline (0.9% NaCl) plus furosemide used for the final correction of serum osmolality.

For moderately symptomatic hyponatremia in a patient requiring parenteral medication, the vasopressin receptor antagonist conivaptan may be used (20 mg IV initially followed by infusion of 20 mg/d for 1 to 3 days; infusion rate may be increased to 40 mg/d if serum sodium fails to increase appropriately). Moderate fluid restriction is recommended to facilitate reaching serum sodium goal.

It is important to mention that interventions directed at the cause of the hyponatremia (vs treatment of the hyponatremia itself) also require close monitoring. Rapid correction of hyponatremia through administration of glucocorticoids in adrenal insufficiency or volume repletion in thiazide-induced hyponatremia, for example, may be associated with central myelinolysis. Careful monitoring of serum Na^+ levels in the post-treatment period is mandatory. If Na^+ appears to be rising too rapidly (>1 mEq/h), administration of hypotonic fluids or a small dose of desmopressin acetate (0.25-1 μg parenterally) may be indicated.

Complications

Central pontine myelinolysis was first described in alcoholics and malnourished patients. In the original descriptions it was

characterized by demyelination confined to the pons, resulting in quadriplegia and, not infrequently, death. Subsequent observational studies linked it to the treatment of hyponatremia. The classic presentation is of a patient who is aggressively treated for hyponatremia with resolution of the presenting findings (ie, those of cerebral edema), only to develop symptoms of mutism, dysphasia, spastic quadriparesis, pseudobulbar palsy, delirium, and, in many cases, death. Surviving patients often have severe neurologic sequelae. More recent studies using CT and MRI indicate that myelinolysis is not confined to the pons but present in many extrapontine locations as well. Lesions are typically symmetrically distributed and clustered in areas where there is close juxtaposition of gray and white matter.

There has been considerable controversy about the prevalence of this particular syndrome and its relationship to the treatment of hyponatremia. However, both animal and human studies are strongly suggestive of a link between this syndrome and rapid, aggressive correction of hyponatremia. Given the imperfect state of our understanding of this disorder, it would seem prudent to approach the correction of chronic hyponatremia, where solute distribution and water content in the brain are undoubtedly altered because of the chronicity of the disorder, cautiously, with rates of correction no greater that 0.5 mEq/h, as indicated earlier. The risk of solute redistribution in documented acute hyponatremia (ie, duration <24 hours) is substantially reduced. Clinical signs of cerebral edema in this setting may be approached more aggressively, although repletion rates greater than 1 mEq/h with a maximal correction of 12 mEq over the first 24 hours should be avoided if possible.

DIABETES INSIPIDUS

Clinical Setting

Diabetes insipidus is a disorder that is due to absolute or relative deficiency in the circulating levels or bioactivity of ADH (vasopressin) (see Chapter 5).

ADH release is normally suppressed at plasma osmolalities below 285 mOsm/kg, leading to generation of a maximally dilute urine (<100 mOsm/kg). Above 285 mOsm/kg, ADH secretion increases linearly with plasma osmolality. At a plasma ADH level of 5 pg/mL, which corresponds to a plasma osmolality of about 295 mOsm/kg, the urine is maximally concentrated. Despite the fact that plasma ADH levels continue to rise beyond this point, there is no further concentration of the urine. At approximately 295 mOsm/kg, the osmotic threshold for the thirst mechanism is activated. Thirst also rises linearly with increasing plasma osmolality. It provides the body's main defense against hypertonicity, much as suppression of ADH secretion guards against hypotonicity. Provided that the patient remains awake and able to drink and provided that the thirst mechanism remains intact, even complete deficiency of ADH secretion can be adequately compensated by increased water intake.

Defects in ADH secretion (central diabetes insipidus) may occur on a heritable basis, occasionally in association with diabetes mellitus, optic atrophy, and sensorineural deafness (DIDMOAD,

or Wolfram syndrome). It may also be seen as a component of a polyendocrine autoimmune syndrome (see Chapter 2). Secondary causes of central diabetes insipidus include head injury (often with stalk section), pituitary surgery, granulomatous disease (sarcoidosis, tuberculosis, histiocytosis X), infections, vascular aneurysms and thrombosis, and tumors (craniopharyngioma, dysgerminoma, meningioma, metastatic disease from breast, lung, or gastrointestinal tumors).

Osmoreceptors for ADH release are believed to reside in the organum vasculosum of the lamina terminalis, whereas those controlling thirst are believed to lie in an independent but neighboring location. Thus, those patients with an isolated defect in ADH secretion (either in the osmoreceptors or the secretory nuclei) are protected from severe dehydration by activation of the thirst mechanism. In those with combined involvement of both ADH secretion and the osmoreceptors controlling thirst (hypodipsic or adipsic diabetes insipidus), the risk of volume contraction and severe dehydration is extreme (discussed later).

Adequacy of the renal response to ADH requires adequate delivery of glomerular filtrate to distal tubular segments, adequacy of tubular function in the ascending limb of the loop of Henle (to establish and maintain the gradient of medullary tonicity and to generate free water for excretion), and a normal response to vasopressin (ie, intact signal transduction mechanism) in the collecting duct. Unresponsiveness to ADH can be due to genetic lesions in the V_2 receptor (X-linked recessive diabetes insipidus) or the functionally linked aquaporin-2 water channel (autosomal recessive diabetes insipidus). It may also be seen in an acquired form with hypokalemia or hypercalcemia, in various forms of intrinsic renal disease (eg, medullary cystic disease) and following therapy with demeclocycline or lithium.

Diagnosis

The presentation of diabetes insipidus in an alert, conscious patient is typically an abrupt onset of polyuria and polydipsia. Hypertonicity is avoided as long as the thirst mechanism remains intact and water intake is able to keep up with urinary losses. In a patient who is unconscious or otherwise incapable of communicating the need for fluids or in patients with coexistent adipsia, polyuria is transient and quickly followed by evidence of severe dehydration and hyperosmolality. Urine volumes in this setting may be normal or even reduced. The clinical findings in hypernatremia associated with diabetes insipidus are dominated by the effects of cellular dehydration and contraction of intravascular volume. In the brain, this can lead to increased traction on dural veins and venous sinuses. This may result in avulsion of vessels from their cranial attachments and intracranial hemorrhage. Other findings include irritability, lethargy, weakness, muscle twitching, hyperreflexia, seizures, and coma.

The diagnosis of polyuria is usually reserved for urine outputs greater than 2.5 L/d. A careful history should be taken to document oral fluid intake (particularly beer or other hypotonic fluids) or parenteral fluid administration (eg, in a postoperative setting). Neurologic or endocrine symptoms that might suggest either a hypothalamic or intrasellar mass, use of medications that could

impair water reabsorption (eg, furosemide, demeclocycline, or lithium) or intercurrent conditions that might mimic diabetes insipidus (eg, osmotic diuresis associated with diabetes mellitus or resolving obstructive uropathy) should also be investigated.

Initial evaluation should include measurement of serum sodium, plasma osmolality, and urine osmolality. Diabetes insipidus is typically associated with a high-normal or elevated serum sodium and osmolality in the face of submaximally concentrated urine. Plasma glucose measurement and standard renal function tests should help exclude osmotic diuresis as contributing to the polyuria. Measurement of serum K^+ and Ca^{2+} assists in excluding polyuria resulting from hypokalemia and hypercalcemia, respectively.

In patients with equivocal initial tests, a water deprivation test may be performed. This involves serial measurements of serum Na^+, urine volume, and osmolality in the absence of fluid intake until serum Na^+ is greater than 146 mmol/L or urine osmolality plateaus (<10% change with three successive determinations), and the patient has lost more than 2% of body weight. The test should be stopped if the decrease in body weight reaches 3% or the patient demonstrates orthostatic hypotension. Patients with diabetes insipidus become progressively more hypertonic with water deprivation but fail to increase urine osmolality. Administration of desmopressin promotes water retention and an increase in urine osmolality in patients with central but not nephrogenic diabetes insipidus. Increases in osmolality of more than 50% indicate central diabetes insipidus, whereas responses of less than 10% suggest nephrogenic diabetes insipidus. Responses between 10% and 50% are equivocal. Plasma ADH levels may be of assistance in defining the nature of the diabetes insipidus in the latter setting. In the presence of high plasma but low urine osmolality, increased plasma ADH levels are associated with nephrogenic diabetes insipidus, whereas subnormal levels are found with central diabetes insipidus. It may be difficult to establish the diagnosis of mild partial central diabetes insipidus. These patients can often achieve maximally concentrated urine during extreme dehydration, reflecting reduced GFR, and stimulated vasopressin secretion; however, as plasma osmolality is corrected and intravascular volume is restored, they typically begin to dilute their urine at a plasma osmolality that is well above normal.

Coexistence of glucocorticoid deficiency may mask the presence of central diabetes insipidus. The development of polyuria with the initiation of glucocorticoid replacement should alert the clinician to the possible presence of diabetes insipidus.

In the 48 hours following pituitary surgery or head trauma, transient diabetes insipidus with polyuria is not uncommon. Over the ensuing 2 to 14 days, a period of antidiuresis and hyponatremia may dominate the clinical course. This in turn may be followed by persistent polyuria. The first phase is thought to result from transient dysfunction or stunning of the ADH-producing neurons of the hypothalamus, the second from leakage of ADH from damaged or dying neurons, and the third from permanent loss of ADH-secretory neurons. Not all patients progress through the entire series of events. It is important to recognize the existence of this syndrome and the natural progression of the disorder in evaluating the need for chronic therapeutic intervention.

In pregnancy, there is a resetting of the osmostats controlling both ADH and thirst, resulting in a state of physiologic hypo-osmolality (about 10 mOsm/kg below that seen in the nonpregnant state). In addition, elevations in placental vasopressinase may rarely promote polyuria in patients with otherwise compensated partial central diabetes insipidus. The appropriate treatment for this disorder is desmopressin acetate, an ADH analog that is resistant to degradation by vasopressinase.

Virtually anything that increases the rate of tubular flow (eg, primary polydipsia or central diabetes insipidus) may create a state of functional nephrogenic diabetes insipidus. This is due to washout of the medullary tonicity responsible for generating the osmotic gradient that promotes movement of water from the tubular lumen into the medullary interstitium as well as down regulation of aquaporin-2 water channels as a result of vasopressin deficiency. A therapeutic trial of 1-deamino-8-D arginine vasopressin (DDAVP) for 1 to 2 days often restores medullary tonicity and facilitates the diagnostic workup. Primary polydipsia (eg, psychogenic polydipsia or dipsogenic diabetes insipidus) presents with a dilute urine, but plasma osmolality and serum Na^+ levels are typically low or low-normal and ADH levels are low. Moreover, due to the elevation in tubular flow rates, the response to desmopressin may be limited in magnitude (<10%, which is less than that predicted for central diabetes insipidus). This may make it difficult to differentiate primary polydipsia from partial forms of nephrogenic diabetes insipidus. Plasma ADH levels may be of assistance in making this distinction (elevated in nephrogenic diabetes insipidus and suppressed in psychogenic polydipsia).

Management

Acute diabetes insipidus is characterized by polyuria in the presence or absence of plasma hyperosmolality. As noted earlier, the presence of hyperosmolality is determined by the adequacy of the patient's thirst mechanism. When a hyperosmolar state with clinical evidence of severe dehydration is present, it is necessary to correct intravascular volume. This is accomplished by administering hypotonic fluids (eg, D_5W), which restore intravascular volume and move plasma osmolality back toward normal. The rate at which the hyperosmolality is corrected is dictated in part by the severity of the clinical symptoms and by the chronicity of the disorder. Chronic hyperosmolality (>24 hours) leads to the accumulation of idiogenic osmoles (eg, taurine and myoinositol) in the central nervous system that serve to offset the osmotically driven movement of water out of that compartment. Aggressive correction of the hyperosmolar state can lead to cerebral edema if the rate of hypotonic fluid administration greatly exceeds the rate at which the neurons in the central nervous system eliminate these idiogenic osmoles. If severe volume contraction is present and blood pressure is reduced, intravascular volume should be repleted initially with normal saline (0.9% NaCl). Following expansion of intravascular volume with normal saline, correction of plasma osmolality

with D5W at a rate of 0.5 to 1 mOsm/h—not to exceed 15 mOsm within the first 24-hour period—appears to be reasonably effective in reducing plasma tonicity without incurring an increased risk of cerebral edema. Typically, higher infusion rates are used early in the course when serum osmolalities are highest and reduced as osmolality decreases into the range of 330 mOsm/kg. Correction of the total free water deficit should be spread over about 48 hours. Total water deficit is defined earlier in the section dealing with DKA. Calculation of hypotonic fluid infusion rates can be made using the formula for change in serum sodium set out in the preceding section, substituting 0 mmol/L for D_5W, 77 mmol/L for 0.45% NaCl, or 154 mmol/L for 0.9% NaCl into the equation, as needed, to calculate the net reduction in serum Na^+. Again, based on the calculated ΔNa^+, one can adjust the rate of delivery of the infusate to provide a specific increment in serum Na^+ concentration over a defined time interval. If signs of cerebral edema (see Hyponatremia, discussed earlier) appear, hypotonic fluids should be discontinued and appropriate administration of hypertonic fluids (eg, mannitol) initiated.

If the diagnosis of central diabetes insipidus has been established, the patient should receive parenteral desmopressin acetate. The initial dose, in the range of 1 to 2 μg every 24 hours (administered intravenously or intramuscularly), should be given in the evening with the aim of controlling nocturia and maintaining daily urine output under 2 L. If polyuria returns well before the end of the 24-hour dosing interval, the single dose can be increased or split doses can be administered every 12 hours. Ideally, one would like to see some degree of breakthrough polyuria at the end of the dosing interval. This serves to guard against the development of iatrogenic hyponatremia. If this proves difficult to achieve, a dose can be skipped every 48 to 72 hours. Once the patient has been stabilized on a fixed dose of parenteral desmopressin, conversion to a formulation more suitable for the outpatient setting is indicated. Desmopressin acetate is available in liquid form for insufflation through a nasal cannula or as a fixed-dose (10 μg) nasal spray. The former has the advantage of greater flexibility in adjusting the nasal dose, whereas the latter offers greater convenience for some patients. Parenteral desmopressin is generally about 10 times more potent than the nasally administered drug; however, intranasal doses should be titrated for each individual patient. Desmopressin is also available in an oral form. Effective doses can range widely (50-1200 μg/d in divided doses) and should be adjusted for the individual patient.

Treatment of nephrogenic diabetes insipidus is more complex because the problem is one of resistance to—rather than deficiency of—the endogenous hormone. If possible, one should attempt to address the underlying cause of ADH resistance. This can be accomplished by correcting electrolyte abnormalities (eg, hypokalemia or hypercalcemia) or discontinuing medications (eg, demeclocycline, lithium) that are likely to contribute to ADH insensitivity. Failing this, administration of a thiazide diuretic together with salt restriction often reduces the polyuria. This is assumed to result from contraction of intravascular volume with increased proximal reabsorption of fluids and solutes and, consequently, limited availability of fluid in distal nephron

segments for free water generation and excretion; however, there may be a second, ADH-independent effect on the aquaporin-2 channels in the collecting duct. Prostaglandins are endogenous antagonists of ADH activity in the collecting duct. Administration of cyclooxygenase inhibitors (eg, indomethacin, 100 mg/d in divided doses) may improve sensitivity to endogenous ADH and reduce polyuria. If the impairment in ADH responsiveness is mild, higher doses of synthetic desmopressin (DDAVP) occasionally prove effective in promoting water retention. Amiloride is the preferred treatment for lithium toxicity. It is thought to prevent the uptake of lithium in collecting duct cells. However, lithium-induced diabetes insipidus may not abate following discontinuation of the drug.

Disorders of thirst in the setting of central diabetes insipidus deserve special mention with regard to therapy. Excessive thirst due to altered osmoreceptor function or behavioral conditioning (eg, before desmopressin treatment) may result in severe hyponatremia once desmopressin treatment is initiated. The patient should be cautioned about excessive consumption of water, and fluid must be restricted if necessary.

Adipsic diabetes insipidus is probably one of the most difficult therapeutic problems faced by endocrinologists. Affected patients have essentially lost all ability to regulate water metabolism on their own. This function must be taken over by the medical team providing their care. Desmopressin is administered in a fixed parenteral dose that is sufficient to reduce urine output to 1.5 to 2 L/d with a fluid intake of 2 to 2.5 L. The difference here is intended to cover the daily insensible losses (about 500-1000 mL) and may need to be adjusted empirically to maintain normal fluid homeostasis. After plasma osmolality and sodium are in the normal range, fluid intake is balanced against urine output. Any net change in urine output over an 8-hour period (this may be extended as the patient's fluid requirements become more predictable) is accommodated by modifying the fluid orders for the ensuing 8 hours. The patient should also be weighed daily. Any alteration in weight is usually reflective of net changes in water retention and can be corrected through modification of fluid intake. Plasma osmolality and serum sodium should be monitored once or twice weekly and appropriate changes in fluid administration made depending on the direction and magnitude of the shift in osmolality. With this system of redundant monitoring, urine volumes and plasma osmolality can be reasonably well controlled for protracted periods of time.

Complications

If left untreated, polyuria secondary to diabetes insipidus can lead to dilation of the collecting system, hydronephrosis, and renal dysfunction. This is the dominant reason for treating polyuria even in patients with an intact thirst mechanism who are capable of controlling plasma osmolality through water ingestion.

Overly rapid correction of the hyperosmolality can result in cerebral edema. The relative risk of this complication should be minimized by careful attention to the rate at which the water deficit is corrected (discussed earlier).

ACTH	Adrenocorticotropic hormone		**MRI**	Magnetic resonance imaging
AIDS	Acquired immunodeficiency syndrome		**NRTI**	Nucleoside reverse transcriptase inhibitor
BMD	Bone mineral density		**NNRTI**	Non-nucleoside reverse transcriptase inhibitor
CMV	Cytomegalovirus		**PI**	Protease inhibitor
CRH	Corticotropin-releasing hormone		**PPARγ**	Peroxisome proliferator-activated receptor γ
CVD	Cardiovascular disease		**PTH**	Parathyroid hormone
DHEA	Dehydroepiandrosterone		**RANK**	Receptor activator of nuclear factor kappa
DXA	Dual energy x-ray absorptiometry		**REE**	Resting energy expenditure
FSH	Follicle-stimulating hormone		**RXR**	Retinoid X receptor
GH	Growth hormone		**SAT**	Subcutaneous adipose tissue
GHRH	Growth hormone-releasing hormone		**SREBP1**	Sterol regulatory enhancer-binding protein 1
GnRH	Gonadotropin-releasing hormone		T_3	Triiodothyronine
HAART	Highly active antiretroviral therapy		T_4	Thyroxine
HDL	High-density lipoprotein		**TBG**	Thyroxine-binding globulin
HIV	Human immunodeficiency virus		**TNF**	Tumor necrosis factor
IGF	Insulin-like growth factor		**TRH**	Thyrotropin-releasing hormone
IL	Interleukin		**VAT**	Visceral adipose tissue
IMT	Intima media thickness		**VLDL**	Very low density lipoprotein
LDL	Low-density lipoprotein			
LH	Luteinizing hormone			
M/I	Glucose disposal adjusted for insulin level			

Symptoms consistent with endocrine disorders and alterations in endocrine laboratory values are not unusual in individuals infected with the human immunodeficiency virus (HIV). Some of these changes are common to any significant systemic illness; others appear to be more specific to HIV infection or its therapies. Alterations can be found even before clinically significant immunocompromise occurs. As the infected individual becomes immunocompromised, particularly with development of the acquired immunodeficiency syndrome (AIDS), opportunistic infections and neoplasms—as well as the agents used in the treatment of these disorders—can give rise to further changes in endocrine function. Finally, hepatitis C (HCV) coinfection occurs in approximately 1/3 of HIV-infected patients; HCV also induces

changes. Herein we discuss alterations in endocrine function that can accompany HIV/AIDS, focusing on evaluation and interpretation of clinical and laboratory findings.

THYROID DISORDERS

In the era of highly active antiretroviral therapy (HAART), clinical thyroid dysfunction is relatively uncommon in stable HIV-infected patients. In several large studies, the prevalence of hypothyroidism was 1% to 2.5% and hyperthyroidism was 0.5% to 1%. The prevalence of subclinical disease was higher, with subclinical hypothyroidism between 3.5% and 20% and subclinical

hyperthyroidism less than 1%; definitions varied between studies. These data do not support screening for thyroid disease above standard guidelines. With advanced HIV disease, alterations in thyroid function tests do occur, but generally do not result in clinical dysfunction. In patients with AIDS, the effects of opportunistic infections and neoplastic involvement of the thyroid, as well as the effects of some medications used to treat HIV-infected patients, should be considered.

Alterations in Thyroid Function Tests

HIV-infected patients can show alterations in thyroid function tests that are largely asymptomatic. Some of the changes are similar to those seen in the classic euthyroid sick syndrome, whereas others are unique to HIV. Advanced HIV is associated with decrease in thyroid hormone levels, triiodothyronine (T_3) and thyroxine (T_4), similar to that seen in the euthyroid-sick syndrome. When HIV-infected patients were stratified by weight loss and the presence of secondary infection, a decline in T_3 levels corresponded to the severity of disease, consistent with the euthyroid sick syndrome. Deterioration in nutritional status can also contribute to the decrease in T_3 and T_4, because there is a strong correlation between albumin levels and both free T_4 and total T_3 levels. In the euthyroid sick syndrome, there is impaired peripheral T_4 to T_3 conversion by 5' deiodinase. In HIV-infected patients, decreases in free T_4 and free T_3 may be due to decreased extrathyroidal conversion of T_4 to T_3, an increase in serum binding proteins, and/or decreased secretion of TSH.

Despite the similarities in serum thyroid hormone levels between HIV and the euthyroid sick syndrome, significantly ill HIV-infected patients often do not demonstrate the elevated reverse T_3 levels characteristic of the euthyroid sick syndrome. The significance of this difference is unknown.

Thyroxine-binding globulin (TBG) levels are increased in HIV-infected patients, rising progressively with advancing immunosuppression. TBG levels correlate inversely with the CD4 lymphocyte count. The increase in TBG does not appear to be due to generalized changes in protein synthesis, increases in sialylation and altered clearance of TBG, or changes in estrogen levels. The significance of the increased TBG found in HIV-infected patients is unknown. However, increases in TBG affect total T_4 and T_3 measurements, which should be considered when interpreting these tests in HIV-infected patients.

Subtle alterations in TSH dynamics have been reported in stable HIV-infected patients. Despite normal TSH and free T_4 levels, these individuals demonstrate significantly higher TSH values and lower free T_4 values than uninfected controls. In circadian studies, HIV-infected individuals have higher TSH pulse amplitudes with unchanged pulse frequency as well as a higher peak TSH in response to thyrotropin-releasing hormone (TRH) stimulation. These studies are consistent with a subtle state of compensated hypothyroidism; the mechanisms underlying these alterations have not been elucidated.

The typical pattern of alterations in thyroid function tests in HIV-infected patients is outlined in Table 25–1.

TABLE 25–1 Thyroid function tests in HIV-infected patients.

	Basal	After TRH Stimulation
T_3	↓	
T_4	Normal	
Reverse T_3	Normal or ↓	
TBG	↑	
TSH	Normal	↑ Pulse amplitude

↓, decreased; ↑, increased.

Opportunistic Infections and Neoplasms

Opportunistic pathogens and neoplasms can invade the thyroid in HIV-infected individuals but generally do not cause clinical thyroid dysfunction. Autopsy of 100 AIDS patients prior to the era of HAART showed the presence of *Mycobacterium tuberculosis* in 23% of patients' thyroids, followed by cytomegalovirus (CMV) (17%), *Cryptococcus neoformans* (5%), *Mycobacterium avium* (5%), *Pneumocystis carinii* (4%), and other bacteria or fungi (7%).

A few of these pathogens are noteworthy because they have been associated on occasion with both hyper- and hypothyroidism. *P. carinii* has been associated with inflammatory thyroiditis accompanied by hypothyroidism in seven cases, hyperthyroidism in three cases and normal thyroid function in one case. Antithyroid antibodies were negative in all six cases in which they were measured. Radionuclide scanning in seven cases revealed poor visualization of the entire thyroid gland in patients with bilateral disease and nonvisualization of the affected lobe in patients with unilateral disease. Two patients with hyperthyroidism had normalization of thyroid function after treatment of the *P. carinii* infection. Kaposi's sarcoma has also been reported to infiltrate the thyroid gland and resulted in significant destruction and hypothyroidism in at least one case. In two cases, lymphoma was associated with thyroid infiltration, causing thyroidal enlargement. HCV coinfection may increase the prevalence of thyroid disease and perhaps cancer.

Medication Effects

Several medications used to treat HIV-infected patients (eg, rifampin, phenytoin, ketoconazole, and ritonavir) can alter the clearance of thyroid hormone by inducing hepatic microsomal enzymes. Patients with normal thyroid function should not be clinically affected, although decreases in T_4 may be observed. However, patients receiving L-thyroxine may require increased doses, and patients with decreased pituitary or thyroid reserve may develop clinically apparent hypothyroidism. Isolated, well documented reports of need for increased thyroxine doses after starting ritonavir and decreased doses after indinavir have been published; these medications affect glucuronidation, but given the common use of high doses of these drugs in the past it is surprising how rarely problems present. Interferon-alpha, a therapy used for

TABLE 25–2 Medications used in HIV-infected patients that can affect the endocrine system.

Thyroid	**Pancreas-glucose**
Rifampin	Indinavir
Phenytoin	Full dose ritonavir
Ketoconazole	Possibly lopinavir/ritonavir
Possibly ritonavir	Pentamidine
Possibly indinavir	Trimethoprim-
Interferon-alpha	sulfamethoxazole
Adrenals, electrolytes	Dedeoxyinosine (ddI)
Rifampin	Dedeoxycytosine (ddC)
Ketoconazole	Megestrol acetate
Ritonavir	Growth hormone
Megestrol acetate	**Lipids**
Trimethoprim	Ritonavir
Pentamidine	Efavirenz
Sulfonamides	Nevirapine
Amphotericin B	Stavudine
Foscarnet	Tenofovir

Foscarnet	
Pentamidine	
Trimethoprim-sulfamethoxazole	
Ketoconazole	
Rifampin, rifabutin	

Kaposi's sarcoma, has been associated with autoimmune diseases of the thyroid, including hyperthyroidism and hypothyroidism. Medications used in HIV-infected patients that can affect the endocrine system are listed in Table 25–2. Nelfinavir inhibits RET and has *in vitro* activity against medullary thyroid cancer. With the advent of HAART, there have been case report series of newly diagnosed autoimmune diseases such as Graves disease, Hashimoto's thyroiditis, and alopecia areata. Immune reconstitution with HAART raises the possibility of subsequent induction of autoimmune diseases. The cases appeared late after immune reconstitution (8-32 months). Possible theories include thymic regeneration or peripheral T lymphocyte expansion causing irregularities in tolerance, leading to autoimmune dysfunction. Other studies, however, did not link autoimmune thyroid disease to HAART, and the low prevalence in large studies suggests that increased screening above standard guidelines may not be warranted.

ADRENAL DISORDERS

Opportunistic infections commonly involve the adrenal glands but rarely occupy enough of the gland to cause adrenal insufficiency. Impaired adrenal reserve without overt symptoms of adrenal insufficiency has been described in patients with HIV. There is controversy over when to give baseline replacement glucocorticoids (or mineralocorticoids) or increased doses in

stressful situations to patients with a subnormal response to dynamic testing, especially when baseline levels are normal or elevated. With restoration to health by treatment of opportunistic infections or HIV, most of these patients no longer have adrenal insufficiency.

Opportunistic Infections and Neoplasms

Opportunistic organisms are found commonly in the adrenal glands of patients dying of AIDS although they rarely cause clinical adrenal insufficiency. CMV has been associated with necrosis of the adrenal gland, although the amount of tissue affected rarely reaches the 90% thought necessary to cause clinical adrenal insufficiency. In one study, the presence of CMV retinitis was associated with an increased rate of adrenal insufficiency compared with AIDS patients without retinitis. Less common opportunistic infections involving the adrenals include *Mycobacterium tuberculosis, Mycobacterium avium-intracellulare, Cryptococcus neoformans, Histoplasma capsulatum, P. carinii,* and *Toxoplasma gondii.* In addition, Kaposi's sarcoma and lymphoma can involve the adrenals, but rarely induce adrenal insufficiency.

Glucocorticoids

Classic clinical symptoms of adrenal insufficiency are seldom seen, but some clinicians view the weakness and weight loss observed in patients with AIDS as an indicator of adrenal insufficiency. HIV-infected patients usually have normal or, even more commonly, elevated basal cortisol levels, which occur most commonly in advanced disease as a stress response, but this is confounded by an increase in cortisol-binding globulin. Adrenocorticotropic hormone (ACTH) levels are usually normal or elevated in patients with elevated cortisol levels, although some reports of low levels exist. Some of these alterations may be mediated by multiple cytokines; both interleukin (IL)-1 and tumor necrosis factor (TNF) directly stimulate cortisol secretion, while IL-1 and IL-6 stimulate ACTH and corticotropin-releasing hormone (CRH) release. On the other hand, IL-2 and IL-4 increase sensitivity to cortisol. Increased cortisol levels may be a direct response to HIV infection itself. The HIV envelope protein gp120 increases cortisol. HIV Vpr, and Tat may increase cortisol sensitivity. An increased cortisol to dehydroepiandrosterone (DHEA) ratio correlates with body weight loss and malnutrition.

Subclinical abnormalities in hypothalamic pituitary axis dynamics are often present. Nearly all HIV-infected patients have a normal cortisol response to the standard dose (250 μg) ACTH stimulation testing. Other studies have shown that stimulation with low-dose cosyntropin (1 μg) yields results suggesting glucocorticoid insufficiency in roughly 10% to 20% of outpatients with HIV and up to 50% of critically ill HIV-infected patients, especially in HIV-infected patients with CD4 counts less than 500/μL. The abnormalities of decreased reserve either at the pituitary or at the adrenal level in HIV infection are similar to those that occur in other infections or serious illnesses.

Although clinically significant abnormalities in glucocorticoid secretion appear to be uncommon, subtle alterations in adrenal

biosynthesis may be more common. HIV-infected patients have reduced products of the 17-deoxysteroid pathway (corticosterone, deoxycorticosterone, and 18-hydroxydeoxycorticosterone) with normal or elevated products of the 17-hydroxy pathway (cortisol) before and after ACTH stimulation. It is not known whether this alteration represents an early indication of evolving adrenal insufficiency or is an adaptive response that shifts adrenal synthetic activity to steroids that are crucially needed under conditions such as HIV infection that impose physical stress. Twenty-four hour urine free cortisol levels do not predict the subtle adrenal alterations in HIV-infected patients, but may indicate adequate adrenal function.

Glucocorticoid resistance has been described in HIV-infected patients. This syndrome is characterized by symptoms of weakness, fatigue, weight loss, and hyperpigmentation, with elevated cortisol levels and mildly increased ACTH levels. Decreased lymphocyte glucocorticoid receptor affinity for glucocorticoids has been described in these patients. A similar state is seen in glucocorticoid-resistant asthma patients. Increased expression of the beta form of the glucocorticoid receptor, which inhibits the alpha form, has also been reported. Partial glucocorticoid resistance could explain the finding of increased basal cortisol in some HIV-infected patients, but the prevalence and clinical significance of this syndrome are uncertain.

Adrenal Androgens

HIV-infected patients have decreased basal adrenal androgen levels and impaired adrenal androgen responses to ACTH stimulation. Decreased adrenal androgens have been seen at all stages of HIV infection, as well as in HIV-negative intensive care unit patients. Thus, this change may not be specific to HIV infection but may instead be a feature of the physiologic response to illness. A fall in DHEA levels predicts progression to AIDS independent of CD4 cell counts. DHEA has been shown *in vitro* to inhibit HIV replication, which raised the possibility that the decreased DHEA levels observed in HIV-infected patients might influence the effects of the HIV infection. However, the efficacy of DHEA replacement in HIV-infected patients has never been demonstrated. Adrenal androgens may be decreased in women with HIV infection; low dose testosterone replacement has been shown to induce small improvements in lean mass, depression and sexual function.

Mineralocorticoids

Although electrolyte disturbances are not uncommon in HIV-infected patients, provocative testing of the mineralocorticoid axis has revealed few abnormalities. In contrast to glucocorticoid levels, basal and ACTH-stimulated aldosterone levels have been found to be normal in almost all HIV-infected patients studied, including inpatients. Case reports of hypo- and hyperaldosteronism appear in the literature, but there is no evidence that these disorders are increased in HIV infection. Longitudinal studies suggest that the aldosterone response to ACTH stimulation may diminish with progression to later stages of HIV infection in up to half of HIV-infected patients; however, basal levels of aldosterone and plasma renin activity remain normal, and clinically significant hypoaldosteronism does not develop.

TABLE 25–3 Usual pattern of adrenal hormones in HIV infection.

	Basal	After ACTH Stimulation
Glucocorticoids	Normal or ↑ cortisol; ↓ 17-deoxysteroids	Normal cortisol response
Mineralocorticoids	Normal	Normal
Androgens	↓	↓

↓, decreased; ↑, increased.

The usual pattern of alterations in adrenal hormones is shown in Table 25–3.

Medication Effects

Several medications used in the treatment of HIV-related disorders can alter glucocorticoid metabolism. Ketoconazole and itraconazole inhibit the cytochrome P450 enzymes P450scc and P450c11, decreasing cortisol synthesis and leading to adrenal insufficiency in patients with decreased adrenal reserve. Rifampin increases hepatic metabolism of steroids and may lead to adrenal insufficiency in patients with marginal adrenal reserve.

Megestrol acetate has intrinsic cortisol-like activity, decreasing serum cortisol and ACTH levels through suppression of the hypothalamic-pituitary-adrenal axis centrally. Patients taking megestrol have decreased cortisol and ACTH levels in response to metyrapone testing. They may become frankly Cushingoid as well and may show signs of adrenal insufficiency upon its rapid discontinuation. Some HIV protease inhibitors (PIs) block the metabolism of the inhaled steroids fluticasone and budesonide or injected triamcinolone by CYP3A4 and can lead to Cushing syndrome; there are reports of adrenal insufficiency after discontinuation of these therapies. PIs do not affect plasma cortisol levels. However, there is debate about whether these agents change urinary free cortisol or 17-hydroxycorticosteroid excretion.

Medications used to treat HIV-related illnesses can lead to electrolyte disturbances mimicking disorders of mineralocorticoids. Trimethoprim impairs sodium channels in the distal nephron, decreasing potassium secretion, which can result in hyperkalemia. Pentamidine has also been associated with hyperkalemia in rare instances, perhaps through nephrotoxicity. Sulfonamides are associated with interstitial nephritis and hyporeninemic hypoaldosteronism. Finally, amphotericin B causes renal potassium and magnesium wasting.

Medications used in HIV-infected patients that can affect the endocrine system are listed in Table 25–2.

Summary of Adrenal Disorders

In summary, there is little evidence for clinically significant impairment of adrenal steroid excretion in HIV infection. The subtle alterations in the glucocorticoid and androgen synthesis pathways may be an adaptive response to physiologic stress and may occur with other illnesses. Patients with HIV infection who

exhibit symptoms consistent with adrenal hormone deficiency should undergo provocative testing in the same manner as uninfected individuals. Patients with both low baseline and abnormal glucocorticoid or mineralocorticoid responses to provocative testing should be treated with physiologic replacement doses of oral glucocorticoids or mineralocorticoids. Patients on replacement should be covered with higher ("stress") doses of glucocorticoids during episodes of severe illness. Electrolyte abnormalities should prompt evaluation for medication effects and the presence of renal disease.

The HIV-infected patient with a minimally elevated or frankly high basal cortisol who does not increase significantly after ACTH stimulation poses a difficult problem. Most of these individuals have normal responses to prolonged ACTH stimulation, and seronegative patients with significant illness can have similar patterns that revert to normal after treatment of the illness. Chronic glucocorticoid therapy may have significant adverse consequences in these individuals, who are already immunocompromised. Most HIV-infected patients with this pattern and even many with baseline low levels during acute illness do not appear to require long-term glucocorticoid replacement. Consideration could be given to administering short courses of steroid therapy during significant illness for individuals with indeterminate stimulation results based on clinical judgment and individual patient circumstances.

BONE AND MINERAL DISORDERS

Osteopenia and Osteoporosis

There is evidence of low bone mass and increased osteoporosis in HIV-infected patients either without therapy or while receiving HAART, but the etiology remains controversial. The incidence of fractures may be increased, but there are too few studies of fracture incidence to know with certainty. Therapy with bisphosphonates is effective at increasing bone mineral density (BMD) in HIV-infected patients, but there are no convincing data on fracture prevention.

Prior to the introduction of HIV PIs, low BMD was not commonly observed in HIV-infected patients. The few clinical studies on the effects of HIV on bone mineralization suggested that HIV had relatively little effect on BMD. One study followed 45 HIV-infected men for 15 months and found no change in lumbar spine and hip BMD. However, histomorphometric analysis of bone biopsies from AIDS patients showed some evidence of decreased bone formation and bone turnover; these changes were more marked in more severely affected patients. HIV itself may have an indirect effect on BMD by activating the receptor activator of nuclear factor kappa B ligand (RANK-L), which activates osteoclasts and their precursors. Activated T cells express the receptor for RANK-L—that is RANK. The cytokines TNF-alpha and IL-1, whose levels may be increased in HIV infection, also have been shown to activate RANK-L.

After the introduction of PI-based HAART, some cross-sectional studies suggested that patients on PIs had a higher prevalence of osteoporosis and osteopenia compared to HIV-infected patients not taking PIs. However, other studies did not find a specific association of PIs with decreased BMD by dual energy x-ray absorptiometry (DXA). Most cross-sectional studies have found that both HIV-infected men and women on any form of HAART have lower BMD or a higher prevalence of osteopenia, compared to gender- and ethnicity-matched control subjects. In one meta-analysis of 20 papers, the prevalence of reduced BMD was 67%, and the prevalence of osteoporosis was 15% in HIV-infected patients, which represents a 6.4-fold greater prevalence of reduced BMD and 3.7-fold greater prevalence of osteoporotic T scores compared to controls. Furthermore, those treated with ARV had a 2.5-fold higher prevalence of reduced BMD than those who were ARV-naïve. A randomized longitudinal study showed that continuous ARV therapy, used to suppress HIV, was associated with greater loss of bone mass and perhaps more fractures than intermittent ARV therapy designed to reduce drug exposure. However, the absolute rate of BMD loss by DXA was actually quite small in those on continuous ARV therapy (−0.5%/year at the hip and −0.7%/year at the spine). Other data indicate that initiation of ARV use per se is associated with decreases in BMD. However, the role of specific ARV drugs as a cause of bone demineralization remains debated, as many studies fail to show an association between osteopenia and most drugs or drug classes. More recently, the use of tenofovir has been associated with greater loss of BMD during ARV therapy, with improvement on switch to tenofovir-sparing regimens. Tenofovir has also been shown to reduce BMD in HIV-seronegative persons when used as prophylaxis against HIV infection (PReP). Tenofovir can also induce hypophosphatemic osteomalacia.

A meta-analysis found that the effect of HIV infection was mostly accounted for by decreased weight. The increased smoking found among HIV-infected patients also contributes to low BMD. Other studies have found associations of hypogonadism, HCV coinfection, vitamin D deficiency, low albumin, and past steroid use with low BMD. Use of PI and inhaled or injected steroids with induction of Cushing syndrome has led to osteoporosis and fracture. In a large database analysis, the fracture rate was increased 1.7-fold in HIV-infected Caucasian men and 1.4-fold in HIV-infected Caucasian and African-American women compared to their respective controls. HCV coinfection is associated with increased fracture, even after adjusting for advanced liver disease and cirrhosis.

Treatment for HIV-associated osteoporosis with bisphosphonates has been examined. Multiple studies have shown that the bisphosphonates alendronate and zoledronic acid given, either with or without calcium and vitamin D supplementation, to HIV-infected patients with osteopenia or osteoporosis, improved BMD in the lumbar spine and hip after 1 to 2 years of therapy. Teriparatide also increased BMD in HIV infection.

The effects of treatments for other HIV-related problems on BMD or bone turnover markers have also been assessed. Eugonadal men with AIDS wasting syndrome treated with intramuscular testosterone for 3 months had small increases in lumbar spine BMD; however, high doses of testosterone were associated with decreases in high density lipoprotein (HDL) cholesterol levels. Recombinant growth hormone (GH) treatment for 24 weeks in HIV wasting syndrome did not affect BMD. Short-term growth

hormone-releasing hormone (GHRH), used to treat HIV-infected men with abdominal fat accumulation, was associated with an increase in bone turnover markers. The effect of GHRH use on BMD remains to be determined.

Osteonecrosis

Osteonecrosis has been reported both in adults and in children infected with HIV, and there is concern about the rising prevalence of osteonecrosis. The most likely reason for the apparent rise in prevalence of the syndrome is increased awareness among clinicians. The annual incidence has been reported to be between 0.08% and 1.3%, which is much higher than the annual incidence in the general population (0.01%-0.135%). A study of 339 HIV-infected patients examined with magnetic resonance imaging (MRI) found a prevalence of 4.4% for asymptomatic osteonecrosis.

The clinical presentation and anatomic distribution are similar to HIV-negative patients. The most common location for osteonecrosis is the hip, but other locations include the humeral heads, femoral condyles, and scaphoid and lunate bones. In HIV infection, the majority of large joint involvement is bilateral. Cases of osteonecrosis of the jaw/oral cavity have also been reported.

Plain film x-rays often underdiagnose osteonecrosis as changes are confined to advanced stage (III and IV) disease; MRI is more effective at finding early stage disease. Some data support treatment with bisphosphonates in early disease involving major joints to reduce pain, but there are inadequate randomized, controlled trials to assess whether such therapy prevents progression. Core decompression with or without bone graft has had some success. Total joint replacement may be the only recourse in late disease (eg, following collapse of the femoral head).

Possible etiologies include those that may be more frequent in patients with HIV infection (corticosteroid use, HIV-associated vasculitis, chemotherapy, and irradiation) and other traditional risk factors (ethanol use, sickle cell disease, hemoglobinopathies, and clotting disorders). An association between osteonecrosis and PIs was initially reported; however, subsequent studies have failed to show a causal relationship with PI use. Use of PI with inhaled or injected steroids inducing Cushing syndrome has led to osteonecrosis.

Calcium and Phosphate Homeostasis

Calcium, phosphate, and calciotropic hormone disturbances are associated with several HIV-related illnesses and medications. Hypercalcemia with an elevated 1,25-dihyroxyvitamin D level has been associated with both AIDS-related lymphoma and infections with *M. tuberculosis, M. avium-intracellulare, P. jiroveci, C. neoformans, and Coccidioides immitis.* This hypercalcemia is due to increased extra-renal 1-alpha hydroxylation of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D by inflammatory macrophages or tumor cells. In CMV infection, activated T cells or proinflammatory cytokines may secrete factors that activate osteoclasts, causing hypercalcemia. The syndrome has also been reported after starting antiretroviral therapy, with improvements in lymphocyte function, as part of the immune reconstitution syndrome. Recombinant

human GH treatment has been associated with slight increases in serum calcium levels in some studies.

Mild hypocalcemia has been associated with HIV disease. HIV-infected patients have been shown to have low 1,25-hydroxyvitamin D and 25-hydroxyvitamin D levels, but normal vitamin D-binding protein levels, suggesting an impairment in 1-alpha hydroxylation and a compromised nutritional state. Low 1,25-hydroxyvitamin D levels are associated with advanced disease stage and increased TNF-alpha levels.

Inadequate parathyroid hormone (PTH) responses (ie, functional hypoparathyroidism) may also contribute to the hypocalcemia seen with HIV. PTH levels have been shown to be decreased in HIV-infected patients compared to controls. Parathyroid cells may be targeted by HIV infection: they express CD4 receptors which when activated affect PTH secretion. Invasion of the parathyroid gland by neoplasms and infections can also rarely occur.

Severe hypocalcemia is usually due to medications used to treat opportunistic infections. Variations on Fanconi syndrome are reported increasingly. Hypocalcemia and hypophosphatemia have been reported with tenofovir (used to treat HIV) and cidofovir (used to treat CMV). Hypocalcemia has also been seen during therapy with foscarnet for CMV retinitis. Foscarnet can complex ionized calcium and may have mineral wasting effects at the level of the renal tubule, leading to concurrent hypomagnesemia and hypokalemia. Hypocalcemia and hypomagnesemia have also been reported during pentamidine treatment, and the combination of foscarnet and pentamidine can result in severe, even fatal, hypocalcemia. Trimethoprim-sulfamethoxazole, ketoconazole, and aminoglycosides are also associated with hypocalcemia. Ketoconazole and rifampin can alter vitamin D metabolism but usually do not produce clinically significant effects. Ketoconazole can reduce serum levels of 1,25-dihydroxyvitamin D and lower total—but not ionized—calcium levels. Rifampin and rifabutin can decrease 25-hydroxyvitamin D levels, but usually do not appear to significantly change calcium or PTH levels; one case has been reported of severe osteomalacia attributed to rifabutin.

Medications used in HIV-infected patients that can affect the endocrine system are listed in Table 25–2.

GONADAL DISORDERS

Testicular Function

Testicular atrophy is common in AIDS patients. Histopathologic changes include decreased spermatogenesis, thickened basement membrane, and an interstitial infiltrate. Possible causes of testicular atrophy include opportunistic infection by *M. avium-intracellulare, Toxoplasma*, and CMV, hypogonadism, HIV infection itself, and chemotherapy toxicity. HIV-infected men generally have oligoteratospermia, and as the disease state becomes more severe, the sperm can become grossly abnormal. Hence, male fertility decreases with advancing disease.

Semen washing has been used as a technique for HIV-discordant couples to reduce the risk of viral transmission. There have been several thousand published cases of semen washing

followed by either intrauterine or *in vitro* fertilization. These observational reports have shown that semen washing is a relatively safe and effective means of establishing pregnancy in HIV-negative women. Still, there is concern that the risk of infection is not completely eliminated after washing.

Hypogonadism is a common finding in men, particularly with advanced HIV disease. Prior to the introduction of HAART, hypogonadism was observed in approximately 40% of HIV-infected men. With the widespread use of HAART, the prevalence of hypogonadism has declined to 20%. Early in HIV infection, testosterone levels are normal or even elevated. In the later stages of HIV infection, low serum testosterone levels are seen, often accompanied by symptoms of decreased libido or erectile dysfunction. Because hypogonadism is associated with loss of lean body tissue and muscle mass, it is thought to contribute to AIDS wasting syndrome. Hypogonadal men infected with HIV tend to have low or normal LH and follicle-stimulating hormone (FSH) levels, similar to that seen in hypogonadotropic hypogonadism. However, GnRH testing in hypogonadal men with HIV has been normal in most cases. Primary hypogonadism with elevated LH and FSH levels has been observed but is far less common.

Several etiologies of the hypogonadism in men infected with HIV have been proposed. In many cases, the cause of hypogonadism is multifactorial. Chronic illness and weight loss can alter the hypothalamic-pituitary axis. HIV infection increases the levels of the cytokines IL-1 and TNF, which have been shown to suppress hypothalamic pituitary function. Direct pituitary or hypothalamic invasion by toxoplasmosis or CMV is rare. There are divergent data on the extent to which treatment with ARV drugs increases testosterone levels.

Medications can also alter testicular function. Ketoconazole inhibits gonadal steroidogenesis, resulting in lower testosterone levels, oligospermia, and gynecomastia. Megestrol acetate, a progesterone-like agent, can lead to decreases in testosterone in HIV-infected men, perhaps through central feedback on gonadotropins. Opiate and methadone use in HIV may also cause low testosterone. Medications used in HIV-infected patients that can affect the endocrine system are listed in Table 25–2.

Most of the studies of testosterone replacement have been performed in the context of AIDS wasting syndrome in which muscle and fat mass are decreased. Testosterone therapy in hypogonadal men with HIV increases lean body mass, but only small improvements in strength are seen. Most studies find that testosterone replacement therapy results in improved sexual functioning, mood, and energy. As in the non-infected population, most HIV-infected patients who are given testosterone have not had their hypogonadism adequately evaluated.

Ovarian Function

Women represent one of the fastest growing populations with HIV infection. Two key issues are the effects of reproductive function on the natural history of HIV disease, and conversely, the effects of HIV on reproductive function. Recent studies found that women infected with HIV possess 30% to 50% lower HIV-1 RNA levels than men. Limited data suggests that the ovulatory

cycle affects HIV infection in women. Early studies suggested no association between the menstrual cycle and HIV-1 RNA levels but may have included women with anovulatory cycles. In ovulating women, HIV-1 RNA levels have been shown to decline from the early follicular phase to the luteal phase. Menopause does not seem to affect the progression of HIV disease or the response to therapy.

In addition to affecting HIV-1 RNA levels, the menstrual cycle may also affect the pharmacokinetics of drugs used to treat HIV infection. Zidovudine levels have been shown to be negatively correlated with estradiol levels, suggesting that the menstrual cycle may affect zidovudine glucuronidation. Further studies are warranted.

Pregnancy does not seem to have a deleterious effect on maternal progression of HIV disease. In those who do not have suppressed HIV, HIV-1 RNA levels may increase in the early postpartum period, and pregnancy may increase the rate of detection of HIV-1 in the genital tract. When HIV-1 is identified in the genital tract, the risk of perinatal transmission has been consistently shown to increase. Simple ARV regimens at the time of delivery have been shown to significantly reduce transmission of HIV to the child.

It is unclear whether HIV infection itself causes menstrual irregularities and/or amenorrhea. Early studies reported menstrual irregularities in HIV-infected women. However, these studies relied on self-report of menstrual symptoms and cycles, and many studies had enrolled an inadequate number of HIV-negative women as controls. Recent studies suggest that HIV may alter menstrual function only slightly. One large study of 802 HIV-infected and 273 HIV-negative women, matched for demographic characteristics, body mass index, and substance abuse, found that HIV infection increased the odds of having a very short or long cycle. There were no differences in amenorrhea between the two groups. Another study of 197 HIV-infected women and 189 HIV-negative women found that HIV was not associated with menstrual dysfunction.

It is also uncertain whether HIV has an effect on the onset and symptoms of menopause. The average age at menopause in HIV-infected women has been reported to be between 46 and 50 years. While some studies contrast that to reported average age at menopause in controls being slightly greater than 50, the range in multiple population studies is actually 48 to 51. The diagnosis of menopause is complicated by the occurrence of amenorrhea lasting more than 1 year (which meets the clinical definition of menopause) in HIV-infected women who do not have ovarian failure as indicated by normal FSH and LH levels. Factors associated with such amenorrhea include opiate use, low body mass index, and low serum albumin levels, suggesting hypothalamic dysfunction and malnutrition as causes rather than menopause. Other studies implicate increased smoking in HIV-infected persons and HCV coinfection as contributors to early menopause. There are conflicting data concerning whether HIV is associated with increased or decreased symptoms of menopause.

With HIV infection, fertility rates decline. Quantifying the rate of decrease in fertility in the United States has been difficult due to confounding factors such as sociodemographics, drug use,

weight loss, systemic illness, and sexually transmitted diseases. In Africa, where therapy for HIV was rare, there are numerous studies establishing an association between untreated HIV infection and infertility in virtually all age groups. In sub-Saharan Africa, HIV infection has been shown to account for a population-attributable decline in total fertility of 0.37% for each percentage point of HIV prevalence.

Like men, women infected with HIV have a decline in serum testosterone and adrenal androgen levels with progression of HIV disease and development of complications. Approximately 50% of women with AIDS-related wasting have low androgen levels. Androgen-deficient women may have subtle symptoms of decreased energy, libido, mood, strength, and bone mass. Clinical laboratory diagnosis of androgen deficiency remains difficult in the female population with advanced disease. Total testosterone levels may be increased due to elevations in sex hormone-binding globulin in HIV-infected women, whereas free testosterone levels for women are not well-standardized.

Hormonal contraception is affected by ARV therapy. The estrogen component is metabolized by CYP3A4 enzyme. Many of the PIs and some non-nucleoside reverse transcriptase inhibitors (NNRTIs) either inhibit or induce CYP3A4, thus altering ethinyl estradiol and norethindrone levels. Other medications used to treat opportunistic infections such as rifabutin and rifampicin can also induce CYP3A4. There are very few studies on the effects of these medications on ovulation in subjects taking oral contraceptives. The Centers for Disease Control and Prevention recommend using barrier methods or condoms in addition to or in place of oral contraception.

PITUITARY DISORDERS

Opportunistic Infections and Neoplasms

In autopsy series of AIDS patients, nearly 10% of pituitary glands demonstrate some degree of infarction or necrosis; infectious organisms such as CMV, *P. carinii, Cryptococcus, Toxoplasma*, and *Aspergillus* have been observed. Antemortem pituitary function was not reported in these patients.

Anterior Pituitary Function

Hypopituitarism appears to be rare in AIDS patients; stimulation with TRH, GnRH, or CRH results in normal pituitary responses in almost all patients. Likewise, prolactin levels generally have been found to be normal, with a normal response to TRH stimulation.

The GH axis has received particular attention in children with HIV who can have poor growth velocity, especially when symptomatically ill. Most of these children demonstrate normal GH levels, although low insulin-like growth factor (IGF)-I levels can be seen. Low IGF-I in the setting of relatively normal GH is often seen in states of malnutrition, which may partially explain this finding. In adults, IGF-I levels may be low in malnourished or symptomatic HIV-infected patients but are usually normal in clinically stable individuals. Circadian GH secretion does not

appear to be altered in adults with HIV infection, except in the presence of visceral obesity.

Posterior Pituitary Function

Posterior pituitary function may be altered in HIV infection. Hyponatremia is common in both inpatients and outpatients with HIV. Inappropriately high serum antidiuretic hormone levels have been seen in euvolemic AIDS patients with hyponatremia; however, many of these patients had pulmonary or cerebral infections, which themselves can cause the syndrome of inappropriate antidiuretic hormone secretion. As with any patient, destruction of the neurons with projections to the posterior pituitary gland by infection or tumor can lead to central diabetes insipidus; this appears to be rare in HIV infection.

AIDS WASTING SYNDROME

Prior to the introduction of HAART, weight loss and tissue wasting were commonly observed complications of AIDS in up to 30% of patients infected with HIV. A characteristic feature of this syndrome is wasting of muscle, which is directly associated with increased morbidity and mortality. Muscle is disproportionately lost compared to fat in men. In contrast, women start with higher fat mass, and fat depletion dominates muscle loss until fat reserves are decreased. Weight loss can either be gradual or rapid in nature. Gradual weight loss has been associated with gastrointestinal disease, whereas rapid weight loss is usually seen during opportunistic infections.

The pathogenesis of wasting remains poorly understood. Several etiologies have been proposed including starvation, cachexia, hypermetabolic state, and hypogonadism. Starvation implies solely a limitation of calories, which may occur due to decreased appetite or decreased intake due to gastrointestinal infections with marked diarrhea. Cachexia refers to a state in which muscle is disproportionately lost due to direct effects on muscle. A hypermetabolic state has been proposed as a cause of AIDS wasting syndrome, because resting energy expenditure (REE) has been observed to be increased in HIV infection. However, the increase in REE is also seen in HIV-infected subjects with stable weight. HIV patients with either opportunistic infections or gastrointestinal disease have decreased caloric intake, but do not show the protective decrease in REE that occurs in pure starvation. Hence, the combination of decreased caloric intake and hypermetabolism is the driving force for wasting. The persistent metabolic defects make recovery from wasting incomplete, and recurrent events lead to progressive, step-wise wasting.

Hypogonadism is a prominent finding in up to 50% of men and women with AIDS wasting. A direct correlation between testosterone levels and decreased muscle and fat mass exists. Resistance to GH has also been demonstrated in patients with more than a 10% loss in body weight.

Because a 10% loss of weight is associated with increased morbidity and mortality in patients infected with HIV, clinical trials have targeted the restoration of appetite, weight, and lean body mass. The cannabinol derivative dronabinol increased subjective appetite in patients with AIDS wasting syndrome, but had little or

no effect to promote weight gain. Megestrol acetate increased appetite and weight, but resulted in mostly gain of fat.

Currently, recombinant GH therapy is the only Food and Drug Administration-approved treatment specifically approved for AIDS wasting syndrome that increases lean body mass. At high doses (0.1 mg/kg/d), 3 months of GH therapy increased lean body mass by 3 kg and weight by 1 kg. However, patients did experience side-effects including swelling and joint pain. In a lower dose study (1.4 mg/d), patients had no significant increase in lean body mass after 12 weeks, which suggests that high-dose GH therapy is required. Therapy with recombinant GH is costly, especially if given at higher doses.

Androgen therapy has been studied extensively, because almost half of patients with AIDS wasting syndrome exhibit decreased levels of testosterone. In a meta-analysis of six clinical trials, testosterone therapy was shown to increase lean body mass and weight, especially when the therapy was given intramuscularly as opposed to transdermally. However, there have been no studies in which subjects have been randomized to different routes of administration of testosterone. Because testosterone may decrease HDL cholesterol levels, there is some concern about the long-term effects of testosterone therapy on lipid profiles and cardiovascular risk. However, no other side-effects were reported in these small, short-term studies.

Anabolic steroids have similar effects on the AIDS wasting syndrome. Nandrolone decanoate is an injectable testosterone derivative that is approved for treating anemia in patients with chronic renal failure. Studies of nandrolone decanoate in men found that weight, lean body mass, and strength significantly increased without evidence of acute toxicity. Therapy using oral anabolic steroids oxandrolone and oxymetholone also increases lean body mass and weight in men and women, but it is associated with significant hepatic transaminitis as well as dyslipidemia, especially low HDL.

Another approach has been to use anticytokine therapies to treat patients with AIDS wasting syndrome, but the results have been disappointing. Two studies reported small increases in weight after treatment with thalidomide, a TNF inhibitor. However, TNF levels actually increased and the patients experienced significant side effects including rash, fever, and increased viral load.

ABNORMALITIES OF FAT DISTRIBUTION ASSOCIATED WITH HIV

Shortly after the introduction of HAART with PIs, a variety of symptoms appeared including abdominal obesity, lipoatrophy in the extremities and face, dorsocervical fat pads (buffalo hump), gynecomastia, breast enlargement, increased neck circumference, and lipomas along with insulin resistance and dyslipidemia. These changes were proposed to be a single syndrome reminiscent of the metabolic syndrome and named HIV lipodystrophy.

In retrospect, some of these changes are not related to HAART with PIs. The appearance of lipoatrophy, fat accumulation in the dorsocervical fat pad, lipomas, and breast hypertrophy was reported in patients on two NRTIs before the introduction of HAART or PIs. The presence of dorsocervical fat pads and lipomas is striking, but their prevalence is low.

Furthermore, the original description of the HIV lipodystrophy syndrome has been refuted, as it has been shown definitively that the major changes in fat (lipoatrophy and abdominal obesity) are not part of the same syndrome, but have different causes. Unfortunately, there is still no widely-accepted definition of HIV lipodystrophy that is used in the literature. Depending on the definition of HIV lipodystrophy, the prevalence of these findings varies widely (11%-83%). Part of the confusion is due to differences in methodology used to report fat loss or gain. Many early studies relied on the patient's self-report and/or the clinician's subjective assessment. Later studies quantified fat by anthropometrics or DXA. Neither technique permits the isolation of subcutaneous adipose tissue (SAT) in the abdomen and trunk from visceral fat (VAT); therefore computed tomography and MRI are needed and have been utilized more recently to separately quantify fat in these compartments. Because changes in fat may take years to develop, many studies in the field are cross-sectional rather than prospective in design. In these cross-sectional studies, it is unclear how to match patients to a control group with "normal" fat distribution, given that most healthy adults are overweight.

Despite these challenges, it has become apparent that fat loss with the lower body affected more than the upper body, but involving the face, does occur with increased frequency in patients taking HAART. In one study, 50% of HIV-infected subjects fell below the lowest decile (10%) of leg SAT in controls. In contrast, it is not clear that VAT mass is increased in HIV infection. Furthermore, recent cross-sectional and prospective data showed that increased VAT is not linked to loss of SAT.

Several etiologies have been proposed for the development of lipoatrophy associated with HIV, but to date no mechanism has been definitively linked to the disorder. The thymidine-based nucleoside analogs, stavudine and zidovudine, have the strongest association with the development of lipoatrophy. These NRTIs have been proposed to cause lipoatrophy through mitochondrial injury by inhibiting mitochondrial DNA polymerase-γ or depleting mitochondrial DNA. Fortunately, the use of stavudine and zidovudine has decreased. Abacavir is the NRTI with the least effect on fat. Some PIs (eg, indinavir) and NNRTIs (eg, efavirenz) may contribute secondarily to the lipoatrophy observed with NRTI therapy, but there are not enough trials to understand fully the effects of each ARV drug.

The development of central lipohypertrophy is even less well understood. While central lipohypertrophy has been attributed to PI use, the evidence is controversial. In the first reports of appearance of buffalo hump, half of the patients were not on PI therapy or HAART. Recent data suggest that increased VAT may be due to restoration to health and normal aging.

Much research has focused on the treatment of the fat changes associated with HIV. Fat loss, especially in the face, can reveal the HIV status of a patient and lead to social stigmatization. The metabolic sequelae can also predispose the patient to the development of hypertriglyceridemia and atherosclerosis. One proposed strategy is to reverse the peripheral lipoatrophy by switching ARV drugs. Substituting another NRTI for a thymidine NRTI, such as

stavudine or zidovudine, causes a minimal, albeit statistically significant increase in subcutaneous fat. In one study, switching from stavudine or zidovudine to abacavir caused a 0.4-kg increase in total limb fat after 24 weeks and a 1.3-kg increase in total limb fat after 104 weeks. However, that gain is insufficient to reach the levels seen in control populations. Lipoatrophy does not fully resolve. Switching from PIs to nevirapine, efavirenz, or abacavir did not improve lipoatrophy. The newer NRTIs, tenofovir and emtricitabine, have been associated with less peripheral lipoatrophy than stavudine.

Thiazolidinediones are potentially attractive agents for treatment of lipoatrophy and insulin resistance. As ligands for the transcription factor peroxisome proliferator activator receptor gamma (PPARγ), thiazolidinediones promote adipocyte differentiation. Unfortunately, two randomized studies found no improvement and a third showed minimal improvement in lipoatrophy after thiazolidine treatment for at least 24 weeks. However, the studies did show the expected improvement in insulin resistance.

Reconstructive therapy is available for peripheral lipoatrophy. Injectable skin fillers for the face include bioabsorbable and permanent fillers. Bioabsorbable fillers such as poly-L-acetic acid stimulate collagen production. In one open-label, single-arm study, 43% of patients had an increase in cutaneous thickness greater than 10 mm in the face after 96 weeks of therapy. The effects on collagen production last for approximately 18 months. Hyaluronic acid has also been used to a lesser extent in the treatment of facial lipoatrophy. Side-effects include easy bruisability, redness, and swelling. Permanent fillers are generally not recommended due to the dynamic nature of fat loss in peripheral lipoatrophy. More invasive procedures include autologous fat transplants.

Central lipohypertrophy has been treated with GH and GHRH analogues. At high doses (6 mg/d), GH decreased VAT by 21% to 24% but also decreased SAT. However, a significant number of patients experienced joint swelling, fluid retention, and deterioration in glucose tolerance. A lower dose of GH (3 mg/d) also reduced VAT and SAT, although to a lesser extent. With further dose reduction, GH (1 mg/d) decreased SAT, but did not significantly alter VAT content. A GHRH analogue, tesamorelin, limits the side-effects of excessive GH by increasing the endogenous pulsatility of GH secretion. Tesamorelin (2 mg/d) given for 26 weeks decreased VAT by 15%, but had little effect on SAT. Unlike GH therapy, tesamorelin did not induce insulin resistance; there were fewer GH-like symptoms of joint and fluid retention. GH or tesamorelin therapy is very expensive, and the effects reverse when therapy is stopped.

DISORDERS OF GLUCOSE AND LIPID METABOLISM

Shortly after the introduction of HAART, reports of impaired fasting glucose, glucose intolerance, diabetes, and hyperlipidemia appeared in the HIV literature. Given the close temporal relationship to the introduction of PIs, studies focused on the association with PIs. However, other factors such as restoration of health, genetic predisposition, immune reconstitution, and body composition changes (including lipoatrophy and VAT hypertrophy) may also contribute to the disturbances in metabolism. To clarify these issues, several groups have given HIV antiretroviral drugs to healthy, HIV-seronegative volunteers in order to define direct drug effects. Another approach has been "switch studies," where patients with suppressed viral load are randomized to change antiretroviral drugs, eliminating the effects of suppression of HIV. In the sections below, the results in HIV-infected subjects will be compared to those in healthy volunteers to understand the effects of drug versus disease. These studies have led to the conclusion that metabolic effects are specific to certain drugs and not an effect of the PI class as a whole.

Insulin Resistance, Glucose Intolerance, and Diabetes

With the reports of rapid onset of diabetes after introduction of HAART with a PI, researchers looked for effects of PI on insulin resistance, hepatic glucose production, and insulin secretion.

Several factors contribute to the development of insulin resistance in the setting of HIV. Unlike other infectious states, in which insulin resistance is common, early in the epidemic, AIDS was found to be associated with an increase in insulin sensitivity (Table 25–4). Compared with healthy controls, insulin sensitivity was higher in stable patients with symptomatic HIV. However, with asymptomatic HIV infection, another early study found that there was no change in insulin sensitivity compared with healthy controls. Insulin resistance is common in healthy subjects. Thus, improvement of HIV infection alone may contribute to an observed decrease in insulin sensitivity. Subsequent studies found insulin resistance in ARV-naïve, HIV-infected subjects. Insulin resistance correlates with CD4 count.

Body composition influences insulin sensitivity. Patients studied early in the epidemic, were thin, if not cachectic. In recent studies body weight was higher, even in many ARV-naïve patients. Increased VAT has been linked to insulin resistance and worsened glucose tolerance in subjects with or without HIV disease. Upper

TABLE 25–4 Effect of HIV and AIDS status on glucose and lipid metabolism prior to the introduction of HAART.

	Insulin Resistance	Total Cholesterol	Triglyceride	VLDL	LDL	HDL
HIV	↔	↓	↑ (8%)	↑ (7%)	↓ (16%)	↓↓↓ (36%)
AIDS	↓	↓	↑↑↑↑ (99%)	↑↑↑↑ (98%)	↓↓↓ (31%)	↓↓↓ (37%)

↔, No effect; ↑ or ↓, 0%-20%; ↓↓↓, 30%-40%; ↑↑↑↑, >40%. Percentage increases or decreases are denoted when available in the literature.

trunk and neck SAT are also independently, strongly associated with insulin resistance. Likewise, severe lipoatrophy has been linked to insulin resistance and glucose intolerance regardless of HIV status. The lesser levels of lipoatrophy seen in most HIV-infected patients also contribute. Other traditional risk factors, such as physical inactivity, also play a role in HIV-infected subjects. It should be recognized that each of these factors may contribute in an additive way to insulin resistance.

Much attention has focused on the role of individual therapies in the induction of insulin resistance. Some PIs have been reported to decrease insulin-mediated glucose disposal (M/I during the hyperinsulinemic, euglycemic clamp, a technique during which insulin is infused at a steady rate and glucose infused to maintain euglycemia, which directly measures insulin action). In a double-blind, placebo-controlled study in healthy normal volunteers, a single dose of indinavir has been shown to decrease insulin-mediated glucose disposal by 34% (Table 25–5). Indinavir for 4 weeks has also been shown to cause a 17% decrease in insulin-mediated glucose disposal as well as deterioration in glucose tolerance. A single, full dose of ritonavir decreased insulin sensitivity by 15%. Lopinavir boosted by lower dose ritonavir likely has less of an effect on insulin sensitivity (see Table 25–5). In two studies, lopinavir/ritonavir given for 4 weeks caused no change in insulin sensitivity, whereas in shorter studies, lopinavir/ritonavir given for 1 to 5 days was associated with a 13% to 24% decrease in insulin sensitivity.

Of note, not all PIs decrease insulin-mediated glucose disposal. In double-blind, placebo-controlled studies, atazanavir and amprenavir had no effect on insulin sensitivity in healthy normal volunteers (see Table 25–5). NNRTIs have not been associated with insulin resistance. In studies where PIs are replaced with NNRTIs, insulin resistance improved.

The mechanism of insulin resistance with PIs includes the acute blockade of the peripheral insulin-regulated glucose transporter (GLUT)4. In vitro studies have shown that PIs (indinavir, ritonavir, and amprenavir) selectively inhibit 2-deoxyglucose transport into 3T3-L1 adipocytes without affecting early insulin signaling events or the translocation of intracellular GLUT4 to the surface. Indinavir has also been shown to block partially GLUT2, the glucose transporter postulated to be involved in glucose-sensing in the pancreas and regulation of insulin secretion. Recently, an analog of the peptidomimetic phenylalanine moiety found in all PIs has been shown to inhibit GLUT4-induced glucose transport in vitro. Because serum levels of PIs vary, some PIs, such as amprenavir, may block GLUT4 in vitro but have no effect in patients.

Increased insulin resistance has also been found in HIV-infected subjects on NRTI therapy. However, it is unclear if the effects of NRTIs are a direct effect of the drug, reactivation of the immune system, restoration of health, or changes in body composition. When stavudine was given to healthy volunteers, there was no decrease in M/I.

In addition to peripheral insulin resistance, impairment in insulin secretion was reported in HIV patients on PI therapy. In HIV-infected subjects treated with several PIs, beta cell function assessed by first-phase insulin secretion showed a 25% decrease.

However, insulin secretion in the HIV-infected patients was higher than controls before PI therapy and was reduced only to that of controls after PI therapy. The HIV-infected patients had suppression of HIV RNA levels and increases in CD4 counts. More recently, healthy normal volunteers were given lopinavir/ritonavir for 4 weeks, and no effect was seen on first-phase insulin secretion. Thus, it is unlikely that currently used PIs alter insulin secretion.

Hepatic glucose production is also increased in some patients on PIs. Endogenous glucose production, comprised mostly of hepatic gluconeogenesis and glycogenolysis, is the largest determinant of fasting glucose. In studies of healthy normal volunteers, indinavir increased endogenous glucose production in the fasting state and blunted insulin suppression of endogenous glucose production during a hyperinsulinemic, euglycemic clamp. In humans, full dose ritonavir has a small detrimental effect on endogenous glucose production, while amprenavir had no effect.

Increased plasma levels of the NNRTI efavirenz, particularly in those with the slow metabolizing mutation in CYP2b6 are associated with higher glucose levels. In contrast, there was no relation between levels of lopinavir or stavudine and glucose parameters.

Adipocytokine levels in HIV infection may explain some of the results in glucose metabolism. Adiponectin, a hormone secreted by adipocytes, has been shown to increase peripheral and hepatic insulin sensitivity. Adiponectin levels inversely correlate with the amount of VAT in HIV-negative subjects. In patients with HIV-associated lipoatrophy, adiponectin levels are reduced; thus, low adiponectin levels have been proposed to mediate some of the insulin resistance in HIV. The mechanism which reduces adiponectin levels is unknown. Some have attributed the reduction to PI therapy. In vitro studies of cultured fat cells have suggested that PI treatment suppresses adiponectin mRNA and protein expression. However, two studies in healthy normal volunteers found that in fact adiponectin levels were increased during chronic treatment with the PIs indinavir or lopinavir/ritonavir; because adiponectin increases insulin sensitivity, the higher levels may explain why less insulin resistance is seen after 4 weeks of treatment compared to acute dosing. Levels of leptin, another hormone secreted by adipocytes, correlate with insulin resistance. However, some diseases with very low leptin levels also have insulin resistance. Leptin levels have been shown to be decreased in HIV patients with peripheral lipoatrophy.

HCV and possibly Hepatitis B (HBV) coinfection are also associated with increased fasting glucose levels and prevalence of diabetes. Treatment of HCV mono-infection with newer antiviral drugs reduces fasting glucose levels.

Epidemiological studies of diabetes in HIV infection have shown contradictory results for specific antiretroviral drugs, but similar results for other risk factors. Some studies have implicated the PIs indinavir, ritonavir or saquinavir, and the NRTIs stavudine or didanosine as associated with diabetes, but individual studies have found different drugs to be associated with diabetes and some found the very same drugs to be protective. Pre-therapy BMI, use of effective combination therapy, increase in or higher CD4 counts, weight gain with therapy, decreased physical activity, the presence of lipoatrophy, higher triglycerides and older age are associated with incident diabetes.

TABLE 25–5 Effect of protease inhibitors (PI), nucleoside reverse transcriptase inhibitors (NRTI), non-nucleoside reverse transcriptase inhibitors (NNRTI), and integrase inhibitors on glucose and lipid metabolism.[1]

[1]Percentage changes are provided when available from the published literature. The most effective measure of a drug's direct effects comes from studies where individual drugs were given to healthy, HIV-negative volunteers. Some effects were not precisely quantified in publications or have to be inferred from comparative regimens or switch studies. ↑ or ↓, small; ↑↑ or ↓↓, moderate; ↑↑↑ or ↓↓↓, large change. ↔/↑ signifies disagreement in the literature.

[2]Insulin resistance is expressed as M/I from euglycemic hyperinsulinemic clamp data as explained in the text. An increase in insulin resistance is reflected in a negative M/I and an upward arrow.

[3]LDL increases in patients with HIV infection who start with low LDL. There is little effect of PI in healthy, HIV-negative subjects.

[4]In healthy, HIV-negative subjects given one to five doses. No effect after 4 weeks.

Abbreviations: HDL, high-density lipoprotein; LDL, low-density lipoprotein; NA, not available; TG, triglyceride.

Current guidelines set forth by the Infectious Disease Society of America and similar European guidelines suggest measuring fasting glucose levels and/or hemoglobin A1c before and during anti-retroviral therapy. Given the controversies over which ARV induce diabetes, current guidelines refer to all patients with HIV. Hemoglobin A1c may not accurately reflect glucose levels in the presence of anemia of HIV.

Treatment of diabetes in HIV infection should follow the American Diabetes Association guidelines. There are studies of

therapy of patients who have HIV-associated lipoatrophy and lipohypertrophy. Thiazolidinediones improve insulin resistance in patients with HIV-associated lipoatrophy and lipohypertrophy. Proliferation of lipomas has been reported in one patient with HIV-associated lipoatrophy. Given the recent findings that thiazolidinediones decrease BMD and may increase fracture risk, caution is warranted in HIV-infected patients as they may be at higher risk for bone loss and fracture. Metformin decreases hepatic glucose production and peripheral insulin resistance. Metformin should be used with caution in combination with NRTI therapy, because there is an increased rate of lactic acid production with NRTIs, especially stavudine and didanosine. Cases of severe acidosis have been reported when these drugs were used in combination with metformin. Dolutegravir, an HIV integrase inhibitor, slows metabolism of metformin by 50%; lower doses of metformin should be used in patients on dolutegravir. Leptin has been shown to improve glucose tolerance in lipoatrophic patients with or without HIV, but is not yet approved by the FDA.

Medications used to treat opportunistic infections are associated with hyperglycemia and hypoglycemia. Pentamidine, including that administered by aerosol delivery systems, causes pancreatic beta cell toxicity, acutely leading to hypoglycemia. Over the long term this medication causes diabetes mellitus. Hypoglycemia during pentamidine treatment is associated with increased length of treatment, higher cumulative doses, and renal insufficiency. Patients who develop hypoglycemia on pentamidine are at increased long-term risk of developing diabetes mellitus. These patients have low C peptide levels, suggesting beta cell destruction. Pentamidine, trimethoprim-sulfamethoxazole, and the nucleoside analogs didanosine and zalcitabine have been associated with acute pancreatitis. Megestrol acetate, which has intrinsic glucocorticoid activity, may be associated with diabetes mellitus in HIV-infected patients, perhaps through its glucocorticoid activity, although the rate of hyperglycemia in controlled clinical trials appears to be low. GH can also cause insulin resistance, leading to hyperglycemia and diabetes. Medications used in HIV-infected patients that can affect the endocrine system are listed in Table 25–2.

Lipid Disorders

Alterations in lipid and lipoprotein profiles are common in patients infected with HIV. The observed changes can be due to HIV infection itself, antiviral medications, body composition changes, and immune reconstitution. A rational approach to disturbances in lipid metabolism is to assess each of the factors in a given patient. The following section reviews the lipid and lipoprotein profiles individually, with an emphasis on studies prospectively measuring fasting lipid levels.

HIV infection is associated with a mild increase in triglyceride and very low density (VLDL) cholesterol levels (see Table 25–4). Triglyceride and VLDL cholesterol levels rise in association with advancing HIV disease and correlate with HIV RNA levels. The host response to viral infections like HIV is induction of interferon alpha; in those with detectable viral loads, interferon alpha levels correlate with triglyceride levels. Decreased clearance of triglycerides and, to a lesser extent, increased VLDL production. Interferon alpha has been shown to induce these changes in animals.

Several antiviral medications can increase triglyceride levels. Full-dose ritonavir can cause a two- to threefold increase in triglyceride levels, probably by increased VLDL production (see Table 25–5). Because of its ability to inhibit the hepatic enzyme CYP3A4, ritonavir is used to increase the pharmacologic doses of other PIs metabolized through the same cytochrome system. Boosting doses of ritonavir (100 mg twice daily) have also been shown to increase triglycerides, albeit to a lesser extent. The combination lopinavir/ritonavir given to healthy normal volunteers increased triglycerides and VLDL cholesterol levels by 83% and 33%, respectively. Ritonavir-boosted tipranavir and fosamprenavir produce similar increases to those of lopinavir/ritonavir. Ritonavir-boosted atazanavir and darunavir appear to induce less increase in triglycerides. Not all unboosted PIs alter triglyceride levels; in healthy normal volunteers, administration of indinavir and atazanavir resulted in no change in triglyceride levels (see Table 25–5). The data are not clear for unboosted amprenavir and nelfinavir, but they are not commonly used as monotherapy.

The NNRTI efavirenz is associated with increased triglycerides. Again, this is not a class effect as other NNRTIs (eg, nevirapine, rilpivirine, and etravirine) have not been associated with alterations in triglyceride metabolism. The HIV integrase inhibitors (eg, raltegravir, dolutegravir, and elvitegravir) have no effect on triglycerides.

The effects of NRTIs on lipid metabolism have not been well studied. In some, but not all studies, stavudine use was associated with increased triglyceride levels. The most informative trial compared stavudine with tenofovir and found an increase in triglycerides in the stavudine arm, but not in the tenofovir arm. Given that all subjects got efavirenz, a likely interpretation is that there was a lipid-lowering effect of tenofovir. Other data support this interpretation, as switch studies or adding tenofovir to an effective ARV regimen lower lipids, but the effect on triglycerides in those studies is small.

The original clinical syndrome of HIV lipodystrophy was reported to be associated with increased triglyceride levels. One study found that 57% of patients with *both* peripheral lipoatrophy and central lipohypertrophy had triglyceride levels above 300 mg/dL. It has long been recognized that visceral obesity in the general population is associated with high triglycerides. However, recent data suggest that lower body fat is protective, as increased levels of lower body fat are associated with lower triglycerides in both HIV-infected patients and controls. Therefore, the loss of lower body fat in HIV-associated lipoatrophy is another reason why triglycerides are high in HIV infection. Hypertriglyceridemia is well known to be multifactorial; genes, diet, alcohol, and physical activity play a role. In HIV infection, one can add the synergistic effects of the host response to HIV itself, treatment with ritonavir and efavirenz, and HIV-lipoatrophy to the pathogenesis.

After the introduction of HAART, a reported increase in low density lipoprotein (LDL) cholesterol levels was largely attributed to PI therapy. It is now clear that factors other than PIs contribute to this rise in LDL cholesterol levels. In the early stages of HIV infection, LDL cholesterol levels fall (see Table 25–4). With effective therapy, LDL levels rise in response to suppression of HIV, independent of the type of therapy. Most, but not all PIs have

been associated with increases in LDL levels, but average levels are not high. Studies in healthy normal volunteers have provided insight into the direct effects of PIs on cholesterol metabolism apart from those associated with HIV infection. Indinavir, ritonavir, lopinavir/ritonavir, and atazanavir all have no effects on LDL levels in healthy normal volunteers (see Table 25–5). In patients with HIV infection, treatment with the NNRTI nevirapine raises LDL levels. Studies that involve switching patients from PIs to the NNRTIs nevirapine or efavirenz found that LDL levels do not change. Hence, the increase in LDL seen in HIV infected patients is not solely an effect of PI therapy, but likely represents suppression of HIV and restoration to health. However, in switch studies, some drugs have been shown to have less of an effect on LDL (the PIs atazanavir, saquinavir, and darunavir; the NNRTIs rilpivirine and etravirine; and the integrase inhibitors). Tenofovir lowers LDL levels in both HIV-infected and non-infected subjects.

HIV infection and the NNRTIs have significant effects on HDL metabolism. Early in the course of HIV infection, prior to the appearance of clinically evident disease, HDL cholesterol levels decline to levels around 25 to 35 mg/dL (see Table 25–4). With advancing HIV disease, HDL levels continue to decline to less than 50% of baseline values. The pathogenesis of these changes is not well understood. Shortly after the introduction of PIs, one cross-sectional study reported decreased HDL levels in HIV-infected patients. However, subsequent studies have failed to show a decrease in HDL levels in either HIV-infected patients or healthy normal volunteers. Indeed, some studies have found modest increases (13%-21%) in HDL levels during treatment with indinavir, nelfinavir, amprenavir, and atazanavir therapy in prospective studies of HIV-infected patients.

More impressive is the nearly 50% increase in HDL cholesterol seen during treatment with the NNRTI nevirapine. Efavirenz has also been shown to increase HDL levels by 15% to 23%. When patients were switched from PIs to the NNRTIs efavirenz and nevirapine, somewhat smaller increases were seen again supporting the concept that HAART with PI induces small increases in HDL. The story is not as clear for the NNRTIs rilpivirine and etravirine, as HDL levels decrease when stable patients are switched from efavirenz to those drugs.

The integrase inhibitors raise HDL, but less than the NNRTI and possibly less than PI. Tenofovir is the NRTI with the least effect on HDL. Combination therapy with tenofovir as the backbone raises HDL less than other NRTI. Switching to tenofovir results in small decreases in HDL.

In some studies, HDL levels have been reported to be lower in patients with HIV-associated lipodystrophy, but the extent to which that decrease is due to HIV or the effects of ARV are not clear. Visceral obesity and upper trunk fat are associated with lower HDL levels.

Several changes in lipoprotein structure and function occur in HIV infection that might promote atherosclerosis. The hypertriglyceridemia of AIDS is accompanied by increases in the prevalence of small dense LDL or LDL-B, even in the absence of obesity. LDL-B is also more common with ARV regimens that increase triglycerides.

Levels of oxidized LDL, which promotes atherosclerosis more than native LDL, and a marker of LDL oxidation, IgG against oxidized LDL, are increased in HIV infection. Their levels are higher on PI regimens compared to NNRTI regimens. HDL from those with HIV infection has less paraoxonase-1 (PON1) activity, which protects LDL from oxidation. PON1 activity has been shown to be proportional to CD4 count and inversely proportional to HIV viral load. Treatment may not restore PON1 to normal, although the increase is highest with NNRTI. PON-3, which has less of a protective effect, is increased in HIV and restored toward normal by NNRTI. Myeloperoxidase levels are elevated; the extent to which they improve with ARV is not clear. Lipoprotein associated phospholipase A2 (Lp-PLA2 or platelet activating factor acetyl-hydrolase) activity is increased in HIV infection. When lipoproteins are oxidized, Lp-PLA2 produces lysophosphatidylcholine, which is pro-atherogenic. Lysophosphatidylcholine levels are elevated in HIV. PI- and NNRTI-based therapy does not restore Lp-PLA2 activity to normal, but integrase inhibitors have a greater effect.

Most studies find that HDL from untreated HIV-infected patients has decreased ability to mediate cholesterol efflux from macrophages, the first step in reverse cholesterol transport, which protects against atherosclerosis. All studies show that antiretroviral therapy improves the ability of HDL to mediate efflux. HIV infection of macrophages decreases their ability to provide cholesterol for HDL-mediated efflux.

Current guidelines recommend a fasting lipid panel be obtained before initiating or switching therapy, and repeated at least 1 month after starting or changing an ARV regimen. In those patients with uncontrollable hyperlipidemia, switching HIV therapy should be considered, if the regimen is one linked to the observed dyslipidemia and it is refractory to conventional treatment.

Hypolipidemic therapy should be tailored to the type of dyslipidemia. For patients with triglyceride levels greater than 500 mg/dL, fibrate therapy is recommended. Gemfibrozil and fenofibrate are effective in reducing triglyceride levels in patients infected with HIV, but those who start at high triglyceride levels do not reach normal levels. Fish oil lowers triglycerides, but raises LDL, leading to no net decrease in CVD risk. Niacin is effective and has the advantage of raising HDL levels as well as lowering triglycerides, but niacin-induced insulin resistance may be problematic in HIV-infected patients. HMG-CoA reductase inhibitors (drugs of the statin class) may be better second-line agents for lowering triglycerides. As with HIV-negative patients, combination pharmacologic therapy may be required to correct extremely elevated triglyceride levels.

HMG-CoA reductase inhibitors are effective, first-line agents for the treatment of hypercholesterolemia. However, there are multiple drug-drug interactions that are important in HIV-infected patients. Some statins are metabolized by CYP3A4 which is induced or inhibited by some ARV drugs. PIs, especially ritonavir, which is used to boost levels of many HIV ARV drugs to therapeutic levels, inhibit CYP3A4 which is the major metabolic pathway for simvastatin and lovastatin. Ritonavir-based regimens

increase simvastatin levels by 5- to 32-fold, and multiple cases of rhabdomyolysis have been reported on such combinations. The combination of PI and simvastatin or lovastatin should not be used. Atorvastatin activity increases twofold, so 80 mg atorvastatin should be avoided.

Lopinavir/ritonavir increases rosuvastatin levels two- to five-fold, and tipranavir/ritonavir increases rosuvastatin levels twofold and atorvastatin levels eightfold by unknown mechanisms. If those PI combinations are used, only low doses of rosuvastatin and atorvastatin should be used. Thus, pitavastatin, pravastatin, and fluvastatin XL are recommended as first-line statins for patients on PI- or ritonavir-based HAART.

The effects of HIV protease inhibitors on glucose and lipid metabolism are shown in Table 25–5.

HIV, Antiretroviral Therapy, and Risk of Atherosclerosis

The changes in lipid and glucose metabolism seen in HIV raise the question about whether atherosclerosis increases due to HIV or its therapies. Multiple retrospective studies report an increased prevalence of CVD in HIV-infected patients. Some early studies also found an association with ARV therapy, particularly PI therapy, in addition to traditional risk factors such as age, gender, smoking, and LDL and HDL levels. A randomized trial of continuous versus intermittent therapy for HIV showed that continuous therapy has fewer cardiovascular complications. Smoking is more prevalent in those with HIV infection versus non-infected controls. Cross-sectional studies of the intima media thickness (IMT) of the carotid and femoral arteries by ultrasound have also shown that traditional CVD risk factors provide the dominant contribution to increased plaque. However, after adjusting for traditional CVD risk factors, HIV infection is an independent risk factor for increased IMT, similar in magnitude to male sex, diabetes, and smoking. As a consequence, a more aggressive to CVD prevention may be warranted.

CONCLUSION

Some of the changes in HIV infection are similar to those seen in other serious illnesses (euhormone-sick syndrome). However, many of the endocrine and metabolic changes that occur with HIV infection are unique to HIV and require careful consideration in diagnosis and treatment. In addition to the HIV disease state itself, several factors contribute to the development of these changes such as opportunistic infections, immune reconstitution, and ARV medications. As patients are living longer due to the introduction of effective ARV therapy, there is increased interest in the long-term implications of metabolic alterations such as insulin resistance, dyslipidemia, and body composition changes. Given the increased atherosclerotic disease in HIV-infected patients, more aggressive treatment of dyslipidemia is warranted, similar to the approach in diabetes or perhaps even for secondary prevention.

INTRODUCTION

Many endocrine diseases are appropriately managed surgically. The details of clinical presentation, diagnosis, and medical management are discussed in other sections of this book. This chapter provides an overview of the principles involved in the surgical therapy for these conditions. The indications for surgical intervention, the relevant procedures, and their risks and benefits are discussed.

THE THYROID GLAND

EMBRYOLOGY AND ANATOMY

The thyroid gland arises in the midline as an endoderm-derived pharyngeal diverticulum around the third week of gestation. The paired median thyroid anlages then descend from their origin at the base of the tongue (foramen cecum) and ultimately form a bilobed thyroid gland anterolateral to the trachea and larynx. The thyroid lobes are connected just below the cricoid cartilage by an isthmus. The connection to the foramen cecum—the thyroglossal duct—separates and is partially resorbed by the sixth week of gestation. Its distal remnant forms the pyramidal lobe. The calcitonin-producing C cells are neuroectodermal in origin, arise from

the fourth branchial pouch, and are located in the lateral superoposterior aspect of the gland.

A number of embryologic or developmental abnormalities of the thyroid have been described and are related to the absence or mutations of thyroid differentiation factors, including thyroid transcription factors 1 and 2 (TTF-1 and TTF-2) and transcription factor Pax 8. Thyroglossal duct cysts are usually found in the midline, just inferior to the hyoid bone. A lingual thyroid results from maldescent of the median thyroid anlage and is often accompanied by agenesis of other thyroid tissue. Rests of thyroid tissue may be found anywhere in the central compartment of the neck, including the anterior mediastinum. *Tongues* of thyroid tissue are often seen to extend off the lower thyroid poles, particularly in large goiters. In contrast to the above, thyroid tissue in the lateral neck lymph nodes (lateral aberrant thyroid) almost always represents metastatic thyroid cancer and is not a developmental abnormality.

The adult thyroid gland is reddish-brown in color and weighs approximately 20 g. The thyroid gland is supplied by paired superior and inferior thyroid arteries. The former arise from the external carotid artery and the latter from the thyrocervical trunk. A thyroid ima artery arises directly from the aorta or innominate artery in approximately 2% of individuals and enters the isthmus, replacing an absent inferior artery.

TABLE 26–1 **Definitions of various thyroid resections.**

Procedure	Description
Nodulectomy or lumpectomy	Removal of lesion with minimal surrounding tissue
Partial thyroidectomy	Removal of lesion and larger rim of normal tissue
Subtotal thyroidectomy	Bilateral removal of >50% of each lobe and an isthmusectomy
Lobectomy or hemithyroidectomy	Complete removal of a lobe and isthmus
Near-total thyroidectomy	Complete removal of one lobe and isthmus and all but 1 g (1 cm) of the contralateral lobe (tissue near ligament of Berry)
Total thyroidectomy	Complete removal of both thyroid lobes, isthmus, and pyramidal lobe

The thyroid is drained by three sets of veins: the superior, middle, and inferior thyroid veins. The first two drain into the internal jugular vein, whereas the last drains into the innominate veins. Both recurrent laryngeal nerves arise from their respective vagus nerves and enter the larynx at the level of the cricothyroid articulation, posterior to the cricothyroid muscle. The left recurrent laryngeal nerve recurs around the ligamentum arteriosum and ascends to the larynx in the tracheoesophageal groove. The right recurrent laryngeal nerve recurs around the subclavian artery and runs 1 to 2 cm lateral to the tracheoesophageal groove at the level of the clavicle and courses obliquely to the larynx. The superior laryngeal nerves also arise from corresponding vagus nerves and divide into internal and external branches. The former provides sensation to the larynx and the latter innervates the cricothyroid muscles. A description of parathyroid embryology and anatomy is presented in the next section.

Prior to discussing indications for thyroidectomy, it is prudent to clarify the definitions of various thyroid resections. A description of these terms is presented in Table 26–1. Of note, nodulectomies are rarely performed, and most surgeons agree that thyroid lobectomy constitutes a minimum resection for any nodule that could be malignant.

INDICATIONS FOR SURGERY

DEVELOPMENTAL THYROID ABNORMALITIES

Thyroglossal duct remnants may become symptomatic, forming cysts, abscesses, and fistulae. There is also a 1% risk of thyroid cancer development in thyroglossal duct cysts. Most are papillary carcinomas, but very rarely a squamous cell carcinoma may develop. Medullary thyroid cancers do not occur at this site.

Treatment of thyroglossal duct remnants is surgical and consists of the Sistrunk procedure, which involves removal of the cyst and duct up to the foramen cecum. Because the duct may pass anterior to, posterior to, or through the hyoid bone, it is generally recommended that the midsection of this bone is also resected in order to reduce the risk of recurrence. Surgery may also be needed for enlarged lingual thyroid tissue causing symptoms such as choking, dysphagia, airway obstruction, and hemorrhage. Prior to resection, care must be taken to determine whether the patient has any other functioning thyroid tissue, usually via a thyroid scan or ultrasound.

HYPERTHYROIDISM

Hyperthyroidism may result from increased thyroid hormone production or release of stored thyroid hormone following injury to the thyroid gland such as that seen in subacute thyroiditis. This is an important distinction, because the former group of disorders leads to increased radioactive iodine uptake (RAIU), whereas the latter are associated with low or normal RAIU. The most common causes of hyperthyroidism are diffuse toxic goiter (Graves' disease), toxic multinodular goiter or a single toxic nodule, all of which cause increased RAIU. Rarer causes of hyperthyroidism with increased RAIU include a TSH–secreting tumor and a hydatidiform mole. Causes of hyperthyroidism without increased RAIU include subacute thyroiditis, excessive ingestion of medicinal thyroid hormone, struma ovarii, and thyroid hormone–secreting metastatic thyroid cancer. These latter conditions present with the usual symptoms and signs of hyperthyroidism but lack the extrathyroidal manifestations of Graves' disease such as ophthalmopathy, pretibial myxedema, and thyroid acropachy.

Diagnostic Tests

Hyperthyroidism is characterized by a suppressed TSH in the presence of elevated free T_4 levels. If free T_4 is normal, free T_3 levels should be measured because they are often elevated early in the course of disease. RAIU can be used to distinguish the various causes of hyperthyroidism. Approximately 90% of patients with Graves' disease have elevated levels of thyroid-stimulating antibodies or immunoglobulins (thyroid-stimulating immunoglobulin).

Management of Hyperthyroidism

Hyperthyroidism may be treated medically with antithyroid medications, but relapse is common when the medical treatment is discontinued. Ablation of the thyroid gland with RAI is the mainstay of definitive treatment in North America for patients over 30 years of age. A dose of 8 to 12 mCi of I-131 taken orally is generally required. However, it is associated with a prolonged latency period before effective action, a slightly increased risk of future benign and malignant thyroid tumors, hyperparathyroidism, worsening ophthalmopathy (particularly in smokers), and unavoidable hypothyroidism (3% per year after the first year, independently of dosage). Furthermore, only about 50% of patients treated with RAI are euthyroid at 6 months. It is contraindicated in pregnant women, of concern in children, and should be avoided in women wishing to become pregnant for up to 1 year after treatment. Surgery overcomes many of the problems

associated with RAI and achieves rapid control of hyperthyroidism with minimal side effects in experienced hands.

Absolute indications for thyroidectomy in patients with Graves' disease include biopsy-proven suspicious or cancerous nodules, local compressive symptoms, severe reactions to antithyroid medications, reluctance to undergo RAI ablation, or fear of recurrence after RAI. Women who want to become pregnant after treatment or who develop side effects from antithyroid drugs during pregnancy are also candidates for thyroidectomy, as are children. Relative indications for thyroidectomy include patients in whom rapid control of the disease is desired; poorly compliant patients; and patients with severe ophthalmopathy, very large goiters, or low RAIU.

Preoperative Preparation

Patients are usually treated with antithyroid medications to render them euthyroid and to prevent the risk of thyroid storm. Propylthiouracil (100-200 mg three times daily) or methimazole (10-20 mg twice daily and then once daily) are the most commonly used medications and are continued up to the day of surgery. In patients who develop agranulocytosis as a complication of these medications, surgery should be deferred until granulocyte counts reach 1000 cells/uL. In addition, patients are also often treated with propranolol (10-40 mg four times daily) to control the adrenergic effects of hyperthyroidism. Relatively large doses may be necessary because of increased catabolism of the drug. Lugol's solution (iodine and potassium iodide) or saturated solution of potassium iodide is also generally started about 7 to 10 days preoperatively to reduce the vascularity of the gland and decrease the risk of precipitating thyroid storm.

Extent of Surgery

The extent of surgery done has traditionally depended on multiple factors. For those patients who experienced severe complications with antithyroid drugs, those who wanted to eliminate the risk of recurrence, and those with coexistent carcinoma or severe ophthalmopathy, total or near-total thyroidectomy was recommended. However, total thyroidectomy results in inevitable hypothyroidism and is potentially associated with higher complication rates when compared to lesser procedures. Thus, the procedure typically preferred by most surgeons for treating patients with Graves' disease was a subtotal thyroidectomy. This was accomplished by bilateral subtotal excision or by unilateral lobectomy and isthmusectomy with subtotal contralateral resection (Hartley-Dunhill procedure). Provided an adequate remnant was left behind, the procedure provided rapid relief of thyrotoxicosis, while maintaining a euthyroid state, without the need for thyroid hormone. However, it was difficult to define what constituted an adequate remnant, although most surgeons considered a 4- to 7-g remnant sufficient in adults. Rates of postoperative hypothyroidism are variable and are primarily determined by remnant size, thyroid antibody titer, and whether hypothyroidism was reported to be subclinical or overt. Remnants less than 4 g were associated with a more than 50% risk of hypothyroidism, and those more than 8 g were associated with recurrence rates of 15%. Therefore, many surgeons now consider avoidance of recurrence, rather than attainment of euthyroidism, as the goal for

thyroidectomy in Graves' disease. Based on the current evidence, recently published guidelines from the American Thyroid Association (ATA) and the American Association of Clinical Endocrinologists (AACE) recommend total or near-total thyroidectomy as the procedure of choice for the surgical management of Graves' disease. Patients who experience recurrence after surgery are usually treated with RAI. Patients with hyperthyroidism secondary to toxic multinodular goiter are managed similar to those with Graves' disease. Subtotal thyroidectomy is generally advised, however, if no normal remnant can be left, a near-total or total thyroidectomy is recommended. Patients with a solitary toxic nodule larger than 3 cm in size are best treated by ipsilateral lobectomy. Patients with smaller *hot* nodules may be managed with antithyroid medication and RAI ablation. Percutaneous ablation of the nodule using ethanol injection has also been proposed, however, long-term outcomes are unknown.

THYROIDITIS

Thyroiditis, an inflammatory disorder of the thyroid gland, may be classified as acute, subacute, or chronic. Acute suppurative thyroiditis is diagnosed by fine-needle aspiration for cytology, smear, Gram stain, and culture and treated by incision and drainage and antibiotics. Acute thyroiditis is usually self-limited. Thyroidectomy, however, is occasionally needed for clinically coexistent suspicious nodules or cancer, local compressive symptoms, or persistent infection. Recurrent acute thyroiditis is often due to a persistent pyriform sinus fistula. Resection of the entire tract is necessary to prevent recurrence. Subacute and chronic thyroiditis is usually managed medically, but surgical resection is occasionally needed for local symptoms or relapse.

GOITER (NONTOXIC)

Goiters may be diffuse, uninodular, or multinodular. Thyroidectomy is indicated for enlarging goiters despite thyroxine suppression, those causing compressive symptoms (choking, dysphagia, hoarseness, dyspnea, or a positive Pemberton's sign—dilation of neck veins and facial erythema on elevation of arms), nodules deemed suspicious by ultrasound, and goiters containing biopsy-proven suspicious or cancerous nodules. Goiters with a significant substernal component (>50%) are considered a relative indication for thyroidectomy. A total or near-total thyroidectomy is the treatment of choice.

THYROID NODULES

Approximately 4% of the North American population develops thyroid nodules. However, the incidence of clinical thyroid cancer is much lower (about 40 patients per million), thus making it imperative to determine which nodules require treatment with thyroidectomy. A thyroid nodule is more likely to be malignant if the patient has a history of therapeutic radiation to the head and neck (6.5-3000 cGy to the thyroid), a family history of thyroid cancer, Cowden syndrome, or MEN 2, and a personal history of thyroid cancer. Other features suggesting cancer include male sex,

young (<20) or old (>70) age; a solitary, *cold* solid (or mixed solid-cystic), hard nodule, a nodule with microcalcifications or irregular edges on ultrasonography; the presence of ipsilateral palpable nodes or vocal cord palsy; and a fine-needle aspiration biopsy (FNAB) suspicious for cancer. Approximately 40% of individuals with a history of therapeutic radiation exposure or a family history of thyroid cancer have a thyroid cancer. The cancer is in the index nodule in 60% and in other nodules in 40% of patients.

Diagnostic Tests

Patients with thyroid nodules should be evaluated with TSH measurement and FNAB. The Besthesda Classification of Thyroid FNAB and the associated risk of malignancy for each category are discussed elsewhere in this book. If the biopsy suggests a follicular neoplasm, and the TSH level is suppressed or is in the low-normal range, an RAI scan should be performed to rule out a *hot* nodule as the risk of malignancy is very low in this setting.

Management

Nodules with any of the worrisome features mentioned above should be removed with—at a minimum—an ipsilateral lobectomy and isthmusectomy. If FNAB confirms a malignancy, total thyroidectomy may be needed based on the final pathology. Patients with benign nodules on FNAB may be treated with exogenous thyroxine in areas with a high prevalence of iodine deficiency, although this practice is not recommended in iodine sufficient populations. Nodules that continue to enlarge or become symptomatic during follow-up may be re-biopsied or removed via a thyroidectomy.

THYROID CANCER

Malignant thyroid tumors include differentiated lesions (which arise from follicular cells); MTC; undifferentiated or anaplastic cancers; and other rare tumors such as lymphomas, squamous cell carcinomas, sarcomas, teratomas, plasmacytomas, paragangliomas, and metastatic thyroid cancers (from melanoma or from breast, kidney, lung, and other head and neck tumors).

1. DIFFERENTIATED THYROID CANCER

This group includes papillary, follicular variant of papillary, follicular, and Hürthle cell tumors. Hürthle cell carcinoma has been considered a subtype of follicular carcinoma by some investigators and a unique differentiated thyroid cancer of follicular cell origin by others.

The characteristics of these tumors are depicted in Table 26–2. The biologic behavior of the follicular variant of papillary thyroid cancer is similar to that of papillary carcinoma. In follicular and Hürthle cell tumors, the diagnosis of malignancy can only be made by the presence of capsular, blood vessel, or lymphatic invasion or when lymph node or distant metastases are present. Familial non-MTCs, especially if there is a family history of more than two affected relatives, have been shown to be more aggressive than their sporadic counterparts.

TABLE 26–2 Characteristics of differentiated thyroid cancers.

Feature	Papillary	Follicular	Hürthle
Frequency	80%	10%-20%	3%-5%
Age group (y)	20-30	40-50	50-60
Multicentric	85%	10%	30%
Lymph node metastases	30%-40%	10%	25%
Distant metastases	2%-14%	33%	15%
RAI uptake	70%	80%	10%
Prognosis (10-y survival)	95%	85%	65%

Surgical Treatment

Papillary carcinomas can be easily diagnosed by FNAB (Bethesda category 6). Patients with occult or minimal papillary carcinomas (<1 cm) have an excellent prognosis and are adequately treated by lobectomy. Lobectomy alone is also considered sufficient treatment for low-risk, unifocal, intrathyroidal cancers in the absence of a history of head and neck irradiation or a family history of thyroid cancer or cervical node metastases. Patients with high-risk cancers (determined by AGES, AMES, or TNM classification; Tables 26–3, 26–4, and 26–5), bilateral cancers, clinically apparent nodal or distant metastases are best treated by total or near-total thyroidectomy. Considerable debate has existed regarding optimal treatment for low-risk differentiated thyroid cancer larger than 1 cm and less than 4 cm without extrathyroidal extension or lymph node metastases.

Proponents of total thyroidectomy argued that this procedure is advantageous for several reasons: (1) RAI can be used to diagnose and treat recurrent or metastatic disease, (2) serum thyroglobulin becomes a sensitive indicator of recurrent disease, (3) the procedure eliminates the risk of growth of occult cancer in the contralateral lobe and reduces the risk of recurrence, (4) it decreases the 1% risk of progression to undifferentiated cancer, and (5) it decreases the risk of reoperation in case of central neck recurrence. On the other hand, those favoring thyroid lobectomy

TABLE 26–3 AGES system of classifying high-risk patients.

Variable	Description
Age	Women older than 50 y Men older than 40 y
Grade	Poorly differentiated Fibrous stroma Insular, mucoid, and tall cell variants
Extent	Invasive into adjacent tissues or distant metastases
Size	Tumor with a maximum diameter of >4 cm

TABLE 26–4 AMES system for classifying high-risk patients.

Variable	Description
Age	Men >40 y, women >50 y
Metastases	Distant metastases
Extent	Invasion of adjacent tissues
Size	>5 cm

noted that (1) total thyroidectomy is associated with a higher complication rate and that 50% of local recurrences can be cured with surgery, (2) less than 5% of recurrences occur in the thyroid bed, (3) multicentricity within the thyroid is not clinically significant, and (4) the prognosis is excellent in patients with low-risk tumors undergoing lobectomy.

Retrospective data indicate that the recurrence rate for patients with low-risk differentiated thyroid cancer is 10% and that the overall mortality rate is approximately 4% at 10 to 20 years. However, among patients who have recurrences, 33% to 50% die from thyroid cancer. Recent studies involving more than 50,000 patients with papillary cancers demonstrated that total thyroidectomy is associated with improved recurrence and survival rates even in patients with low-risk tumors. Furthermore, the most important information regarding risk for recurrence is available only postoperatively. Therefore, 2009 guidelines from the American Thyroid Association also recommend near-total or total thyroidectomy for thyroid cancers larger than 1 cm unless there

TABLE 26-5 Tumor (T), lymph node (N), and distant metastasis (M) classification and staging of thyroid cancer.

Definition of Primary Tumor (T)

Papillary, Follicular, and Hurthle Cell Thyroid Carcinoma

T Category	T Criteria
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor ≤2 cm in greatest dimension limited to the thyroid
T1a	Tumor ≤1 cm in greatest dimension limited to the thyroid
T1b	Tumor >1 cm but ≤2 cm in greatest dimension limited to the thyroid
T2	Tumor >2 cm but ≤4 cm in greatest dimension limited to the thyroid
T3	Tumor >4 cm limited to the thyroid, or gross extrathyroidal extension invading only strap muscles
T3a	Tumor >4 cm limited to the thyroid
T3b	Gross extrathyroidal extension invading only strap muscles (sternohyoid, sternothyroid, thyrohyoid, or omohyoid muscles) from a tumor of any size
T4	Includes gross extrathyroidal extension
T4a	Gross extrathyroidal extension invading subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve from a tumor of any size
T4b	Gross extrathyroidal extension invading prevertebral fascia or encasing the carotid artery or mediastinal vessels from a tumor of any size

Note: All categories may be subdivided: (s) solitary tumor and (m) multifocal tumor (the largest tumor determines the classification).

Definition of Distant Metastasis (M)

M Category	M Criteria
M0	No distant metastasis
M1	Distant metastasis

Definition of Regional Lymph Node (N)

N Category	N Criteria
NX	Regional lymph nodes cannot be assessed
N0	No evidence of locoregional lymph node metastasis
N0a	One or more cytologically or histologically confirmed benign lymph nodes
N0b	No radiologic or clinical evidence of locoregional lymph node metastasis
N1	Metastasis to regional nodes
N1a	Metastasis to level VI or VII (pretracheal, paratracheal, or prelaryngeal/Delphian, or upper mediastinal) lymph nodes. This can be unilateral or bilateral disease
N1b	Metastasis to unilateral, bilateral, or contralateral lateral neck lymph nodes (levels I, II, III, IV, or V) or retropharyngeal lymph nodes

AJCC Prognostic Stage Groups

Differentiated

When age at Diagnosis is...	And T is...	And N is...	And M is...	Then the Stage Group is...
<55 years	Any T	Any N	M0	I
<55 years	Any T	Any N	M1	II
≥55 years	T1	N0/NX	M0	I
≥55 years	T1	N1	M0	II
≥55 years	T2	N0/NX	M0	I
≥55 years	T2	N1	M0	II
≥55 years	T3a/T3b	Any N	M0	II
≥55 years	T4a	Any N	M0	III
≥55 years	T4b	Any N	M0	IVA
≥55 years	Any T	Any N	M1	IVB

were contraindications to this procedure. However, additional studies since then (including a multivariate analysis) have shown that there is no difference in survival based on initial surgical procedure when adjustments were made for complexity/risk and comorbid conditions. In addition, the declining use of RAI ablation in general and greater use of ultrasound and Tg measurements for detecting recurrences led to a revision of the recommendations. The 2015 ATA guidelines indicate that thyroid lobectomy alone may be adequate as initial therapy for low-risk papillary or follicular cancers. Criteria for recommending bilateral surgery include radiation exposure, family history of DTC, older age or the presence of contralateral nodules.

It is not usually possible to distinguish follicular and Hürthle cell carcinomas from corresponding adenomas preoperatively. For patients with lesions that are consistent with follicular or Hurhle cell neoplasm or suspicious for the same (Bethesda category 4) a lobectomy is performed if there are no obvious signs of cancer at surgery (lymphadenopathy or extrathyroidal invasion) as more than 80% of these tumors are benign. If final pathology confirms cancer, a completion thyroidectomy is usually recommended, except in those patients with minimally invasive tumors. Total or near-total thyroidectomy may be performed at the initial operation in individuals with large (>4 cm) tumors, particularly if nodules are present bilaterally. Of note, molecular tests can now be performed on FNAB material to determine the risk of malignancy and guide recommendations for surgical therapy. For nodules classified as "suspicious for cancer" (Bethesda catergory 5), ipsilateral lobectomy with frozen section is performed. Completion thyroidectomy may be indicated based on the diagnosis and extent of the primary lesion.

Postoperative Treatment

After surgical therapy, patients are risk stratified based on current ATA guidelines. Low-risk patients include those with intrathyroidal papillary cancers without vascular invasion, small volume nodal metastases (N_0) or less than 5 N1 micrometastases, (less than 2 mm in largest dimension), encapsulated, intrathyroidal follicular variant of papillary cancers, intrathyroidal well-differentiated follicular cancer with capsular or minor vascular (<4 vessels) invasion and BRAF-mutated or wild-type papillary microcarcinomas. The intermediate-risk category includes patients with microscopic invasion of tumor onto perithyroid soft tissues, vascular invasion, uptake outside the thyroid bed at remnant ablation, aggressive histologies, clinical N2 or less than 5 pathologic N2 with all nodes less than 3 cm, intrathyroidal papillary cancer with a primary 1 to 4 cm that is BRAF-mutated (if known) and multifocal papillary microcarcinoma with extrathyroidal extention and BRAF-mutated (if known). The high-risk category includes patients with macroscopic extrathyroidal extension, incomplete tumor resection, distant metastases, large volume lymph node involvement, follicular cancer with extensive vascular invasion (>4 foci or extracapsular vascular invasion). Long-term cohort studies by Mazzaferri and Jhiang and others demonstrate that postoperative RAI therapy reduces recurrence rates and leads to improved survival even in patients with low-risk tumors. Despite that, in general, there has been a trend toward reduced RAI ablation rates due to concerns regarding risks of secondary malignancies and the general good prognosis of DTC. According to recently revised guidelines from the American Thyroid Association, RAI remnant ablation is not routinely recommended for low-risk patients or those with unifocal or multifocal papillary microcarcinoma in the absence of other adverse features that may modulate risk. RAI adjuvant therapy should be considered after total thyroidectomy in intermediate-risk patients and is routinely recommended for high-risk patients. Thyroxine therapy is not only important as replacement but is given in higher doses to suppress TSH levels to less than 0.1 μU/L in high-risk patients and 0.1 to 0.5 mU/L in intermediate risk patients, thus decreasing the growth stimulus for thyroid cancer cells. For low risk patients with undetectable Tg levels (with or without remnant ablation), or those having had a lobectomy alone, the TSH can be maintained in the low normal reference range (0.5-2 mU/L). If the Tg level is detectable, a TSH target of 0.1 to 0.5 mU/L is recommended. The need for TSH suppression must be balanced with the risks of subclinical thyrotoxicosis, such as exacerbation of angina in patients with ischemic heart disease, increased risk for atrial fibrillation, and osteoporosis in postmenopausal women.

2. MEDULLARY THYROID CANCER

This tumor comprises 7% of thyroid malignancies but accounts for approximately 17% of thyroid cancer–related deaths. It arises from the parafollicular (C cells) of the thyroid, which are derived from the neural crest and secrete calcitonin. MTC may be sporadic (75%) or occur in the setting of MEN 2A, MEN 2B, and familial non-MEN MTC. In the hereditary setting, the tumors are often bilateral and multicentric (90%). Approximately 50% of patients with MTC have nodal metastases in the central or lateral neck at presentation. All patients presenting with MTC should be screened for pheochromocytomas, hyperparathyroidism, and mutations of the *RET* proto-oncogene.

The ATA published revised guidelines for the management of medullary cancers in 2015. In terms of surgical therapy, pheochromocytomas should be treated prior to thyroidectomy to avoid precipitating an intraoperative hypertensive crisis. Total thyroidectomy and bilateral central compartment lymphadenectomy is the treatment of choice due to the high incidence of multicentric disease and ineffectiveness of I-131 therapy for this tumor.

3. UNDIFFERENTIATED (ANAPLASTIC) THYROID CANCER

This tumor type constitutes approximately 1% of all thyroid cancers and is the most aggressive variant. The peak incidence is in the seventh decade of life. Lymph node involvement is early and common (84%), as is local invasion into the larynx, vocal cords, recurrent laryngeal nerve, esophagus, and major vessels. Distant metastases are present in about 75% of patients. Per guidelines from the ATA, in patients without advanced disease, total or near-total thyroidectomy can be performed for cure in a minority of cases. If extrathyroidal disease is present and en bloc resection may be considered if all gross disease can be removed. External beam

radiation and chemotherapy are usually recommended as adjuvant treatment. They can also be used in the neoadjuvant setting in patients with unresectable disease. A tracheostomy is indicated for impending airway loss.

4. THYROID LYMPHOMA AND METASTASES

Most thyroid lymphomas are of the non-Hodgkin B cell type and often develop in patients with longstanding chronic lymphocytic thyroiditis. Chemotherapy and radiotherapy form the mainstay of treatment, with thyroidectomy and node dissection reserved for palliation of airway obstruction or in patients who do not respond to the above therapies. The thyroid gland is a rare site of metastases from tumors of the kidney, lung, breast, and melanoma. In selected patients, thyroidectomy may increase survival.

5. MANAGEMENT OF LYMPH NODES IN THYROID CANCER

Clinically inapparent lymph node metastases may be present in 20% to 90% of papillary thyroid cancers, and a smaller proportion of patients with other tumor subtypes. Several retrospective studies have suggested that lymph node metastases do not have a significant effect on survival in papillary thyroid cancers. Others report that lymph node metastases are associated with poorer survival but only in patients with follicular cancers and papillary cancer greater than 45 years of age. In patients with matted nodes or extranodal invasion, the recurrence rates are higher and the prognosis is worse.

The lymph node regions of the neck are depicted in Figure 26–1. A preoperative neck ultrasound is recommended for patients with malignant findings on FNAB to evaluate the contralateral lobe and lymph node regions. All clinically apparent disease in the central neck should be removed at the time of total thyroidectomy to improve clearance of disease from the central neck. Bilateral prophylactic central node dissection (level VI) may also improve survival compared to historic controls and decrease the risk of central neck recurrence. Other studies, however, show that central neck dissections are associated with a higher risk of hypoparathyroidism and recurrent nerve injury rates without any reduction in recurrence rates. Given the above, recently published ATA guidelines do not recommend routine prophylactic lymph node dissections but indicate that they should be considered in patients with advanced primary tumors (T_3 or T_4), clinically involved lateral neck nodes (N1b) or if the information may be useful in planning additional therapy. Prophylactic central neck clearance should also be considered for Hürthle cell cancers which tend to be less RAI-responsive, provided they can be performed by experienced surgeons without increased rates of hypoparathyroidism and recurrent nerve injury.

Papillary and Hürthle cell cancers can also metastasize to lymph nodes in the lateral and posterior compartments (II, III, IV, and V). In patients with biopsy-proven nodal involvement, either clinically or on preoperative ultrasound examination, an ipsilateral modified radical neck dissection is recommended, particularly if these
FIGURE 26–1   Lymph node regions of the neck. Level I, submandibular; levels II, III, and IV, upper, middle, and lower jugular nodes; level V, posterior triangle nodes; and level VI, central compartment nodes.

patients may fail RAI therapy based on lymph node number, size, or aggressive primary tumor histology. This procedure removes all the fibrofatty and lymph node tissue while preserving the internal jugular vein, the spinal accessory nerve, the cervical sensory nerves, and the sternocleidomastoid muscle and may reduce the risk of recurrence and subsequent mortality. Because thyroid cancers rarely metastasize to compartment I, these nodes are not routinely removed during a modified radical neck dissection.

In case of MTC, prophylactic central neck lymph node clearance is recommended because patients with these tumors have a worse prognosis and do not take up RAI. In patients with involved lateral neck nodes or calcitonin levels more than 400 pg/mL, additional imaging to include a neck and chest CT and a triple phase liver CT or contrast-enhanced MRI should be obtained to assess for metastatic disease. In patients with no distant disease, an ipsilateral or bilateral lateral neck dissection (levels IIA, III, IV, and V) is indicated. Less aggressive neck surgery should be considered to preserve speech and swallowing while maintaining locoregional control in patients with limited metastatic disease. The role of prophylactic lateral neck dissection is controversial. Some groups favor this procedure if central neck lymph nodes are involved or if the primary tumor is larger than 1.5 cm.

6. RECURRENT AND METASTATIC THYROID CANCER

Thyroglobulin levels are generally undetectable in patients following total thyroidectomy and RAI ablation. Patients with suppressed thyroglobulin levels less than 0.2 ng/mL or TSH-stimulated

levels less than 1 ng/mL in the absence of thyroglobulin antibodies are deemed to have had an excellent response to treatment. Patients with suspected recurrence should be imaged with neck ultrasound, CT, or MRI. In general, surgical extirpation is recommended for patients with macronodular disease (>1 cm in diameter), followed by RAI therapy and TSH suppression. Percutaneous ethanol ablation or radiofrequency ablation (RFA) of recurrent nodal disease may also be used in selected cases. Thyroid cancers may metastasize to the lungs, bone, liver, and brain. Microscopic lung metastases in patients with papillary and follicular thyroid cancer are best treated with RAI and macroscopic disease surgically although RAI may be useful if the latter are iodine avid. External beam radiation is useful for unresectable, locally invasive or recurrent disease and to treat bony metastases with minimal to no RAI uptake. Therapy with kinase inhibitors should be considered in RAI-refractory DTC patients with metastatic, rapidly progressive, symptomatic and/or imminently threatening disease which cannot be locally controlled by other means.

CONDUCT OF THYROIDECTOMY

A preoperative laryngeal examination is recommended in all patients who report voice changes, have a history of prior neck or chest surgery and those known to have extensive disease at presentation. A 4- to 5-cm incision is placed in or parallel to a natural skin crease 1 cm below the cricoid cartilage (Figure 26–2A). The subcutaneous tissue and platysma are divided, subplatysmal flaps are raised (Figure 26–2B), and the strap muscles are separated in the midline from the thyroid cartilage to the suprasternal notch. Initial dissection is begun in the midline by identification of delphian nodes and the pyramidal lobe, followed by division of the fascia just cephalad to the isthmus. The trachea is then cleared just caudal to the isthmus. The thyrothymic ligaments and the inferior thyroid veins are ligated and divided. The side with the dominant or suspicious mass is approached first. In case of a proposed lobectomy or the absence of cancer, the isthmus is divided. Tissues are swept lateral to the thyroid by blunt dissection, and the middle thyroid veins are ligated and divided (Figure 26–2C). The superior pole vessels are then individually ligated and divided low on the thyroid gland to decrease the risk of injury to the external branch of the superior laryngeal nerve (Figure 26–2D). The recurrent laryngeal nerve and the superior parathyroid gland are identified at the level of the cricoid cartilage. Once this is accomplished, the ligament of Berry is divided (Figure 26–2E), and the thyroid is sharply dissected off the trachea. Of note, the current ATA guidelines advise routine identification of the recurrent laryngeal nerve in all cases, although routine use of neuromonitoring is not recommended. The same procedure is repeated on the other side for a total thyroidectomy.

Several approaches to minimally invasive thyroidectomy such as mini-incision procedures, video-assisted thyroidectomy and total endoscopic thyroidectomy via supraclavicular, axillary incisions, chest, and breast approaches have been described (Figure 26–3). The endoscopic approaches can also be performed with robotic assistance, including recent reports of transoral robotic-assisted thyroidectomy. These methods are clearly feasible; however, they do require further study to determine whether there are advantages over the more traditional open approach.

Complications of Thyroidectomy

General complications after thyroid surgery include bleeding and wound complications such as infection and keloid formation. Specific complications include injury to the recurrent laryngeal nerve (<1%), or external branch of the superior laryngeal nerve, temporary hypocalcemia (1.6%-15%), permanent hypocalcemia (<2% for total thyroidectomy), and injury to surrounding structures such as the esophagus, major vessels (carotid artery, internal jugular vein), and the cervical sympathetic trunk.

THE PARATHYROID GLAND

EMBRYOLOGY AND ANATOMY

Around the fourth week of gestation, the human embryo forms five pairs of endoderm-lined pharyngeal pouches. The inferior parathyroid glands are derived from the third branchial pouch (with the thymus), whereas the superior glands arise from the fourth branchial pouch. Most individuals have four parathyroid glands that are found as paired structures on the posterior aspect of the thyroid gland. Supernumerary glands occur in up to 22% of people. Fewer than four glands have also been reported in 3% to 5% of individuals. Approximately 85% of parathyroid glands are found within 1 cm of the point of intersection of the recurrent laryngeal nerve and the inferior thyroid artery. The superior parathyroid glands are usually dorsal to the nerve, whereas the inferior glands are usually ventral to it. The glands may also be found in several ectopic locations. Because the inferior glands migrate farther, they are more often situated in ectopic locations such as the thyrothymic ligament, thymus, carotid sheath, and anterior mediastinum. Ectopically located superior glands can be located in the tracheoesophageal groove, carotid sheath, and posterior mediastinum. Intrathyroidal glands have been reported in 0.5% to 3% of individuals and may be superior or inferior. Normal parathyroid glands are generally embedded in fat, appear golden-yellow to light-brown in color, and weigh approximately 40 to 50 mg. The blood supply to the parathyroid glands is primarily via the inferior thyroid arteries, but the superior thyroid arteries may also supply both the upper and the lower glands.

INDICATIONS FOR SURGERY

PRIMARY HYPERPARATHYROIDISM

This disorder occurs in 1:500 women and 1:2000 men. It is the most common cause of hypercalcemia in the outpatient population, and along with malignancy-associated hypercalcemia accounts for the majority (>90%) of cases of hypercalcemia. Although most cases of PHPT are sporadic, the disorder may also be inherited as
FIGURE 26–2 Conduct of thyroidectomy. **A.** Placement of incision. **B.** Raising subplatysmal flaps. **C.** Dissection of the middle thyroid vein. **D.** Dissection of superior pole vessels. **E.** Dissection at the ligament of Berry. a component of MEN 1, MEN 2A, isolated familial hyperparathyroidism, and familial hyperparathyroidism with jaw tumor syndrome. PHPT is the earliest and most common manifestation of MEN 1, and 80% to 100% of patients develop hypercalcemia by age 40. MEN 1 is characterized by germline mutations in the *MENIN* gene located on chromosome 11. In contrast, hyperparathyroidism develops in only 20% of individuals with MEN 2A and is generally less severe. MEN 2A is characterized by inherited mutations in the *RET* proto-oncogene located on chromosome 10. In sporadic cases, hyperparathyroidism results from a single enlarged gland (adenoma) in 85%, multiple enlarged glands (hyperplasia) in 11%, double adenomas in 3%, and parathyroid carcinoma in 1% of patients. Parathyroid carcinoma should be suspected if patients present with a short history, profound hypercalcemia, and a palpable parathyroid gland. In heritable disorders, hyperparathyroidism is more frequently associated with multiple abnormal parathyroid glands and a higher risk of persistent or recurrent disease. Familial hyperparathyroidism with jaw tumor syndrome is associated with an increased risk of parathyroid cancer and results from germline mutations in the *HRPT2* (CDC73 or parafibromin) tumor suppressor gene on chromosome 1.

The classic symptoms of PHPT include painful bones, renal stones, abdominal groans, psychic moans, and fatigue overtones. Other symptoms such as polyuria, nocturia, polydipsia, constipation, and musculoskeletal aches and pains may be present. The disorder may also be associated with hypertension, osteopenia, osteoporosis, nephrolithiasis, gout, pseudogout, peptic ulcer disease, and pancreatitis.

Diagnostic Tests

Other causes of hypercalcemia can generally be excluded by a careful history and physical examination. Laboratory tests that are helpful in making the diagnosis have been discussed in Chapter 8. PHPT is characterized by hypercalcemia (95%), hypophosphatemia (50%), hyperchloremia (30%), elevated 24-hour urinary

calcium, and an increased or inappropriately elevated intact PTH. An elevated alkaline phosphatase level suggests bone disease (osteitis fibrosa cystica). The 24-hour urinary calcium levels may be normal or elevated. Usually, 24-hour urinary studies are obtained unless the patient has previously had documented normocalcemia, to rule out familial hypocaluric hypercalcemia (FHH) type 1, a disorder caused by inherited mutations in the *CASR* gene and characterized by low (often <50 mg) 24-hour urinary calcium excretion. Furthermore, the serum calcium to creatinine clearance ratio is less than 0.01 in patients with FHH type 1 and generally more than 0.02 in patients with PHPT. Two other types of FHH have been described due to mutations in G-alpha 11 (type 2) and adapter protein-2 subunit 1 (AP2S1; type 3) (see Chapter 8).

Parathyroid tumors may be localized using noninvasive studies such as Tc-99m sestamibi (Figure 26–4A) and ultrasound scanning (Figure 26–4B). MRI and CT scans and invasive localizing studies, including highly selective venous catheterization for PTH, and FNAB of suspected parathyroid masses and arteriograms are generally only used in cases of recurrent or persistent hyperparathyroidism. The utility of noninvasive studies prior to initial neck exploration is controversial; however, most surgeons agree that they are indispensable for recurrent or persistent hyperparathyroidism and for using a minimally invasive approach. 99m-Technetium-labeled sestamibi has more than 80% sensitivity for the detection of hypercellular parathyroid glands, and when it is used in conjunction with SPECT, it has particular utility in identifying ectopic tumors. Neck ultrasound is often complementary and has a sensitivity of 75% in experienced centers. More recently, 4-D CT scans have shown tremendous utility in localizing parathyroid tumors with excellent anatomic detail, in addition to providing functional information. It is important to note that most localizing studies are less sensitive in the setting of multiglandular disease. Since the first use of intraoperative PTH in 1993, it has become widely used to assess the adequacy of parathyroid resection. Although preoperative localization studies and a focused surgical approach are being increasingly used,
FIGURE 26–4 Parathyroid localization studies. **A.** Sestamibi scan with early (5-10 minutes) and delayed (60-90 minutes) images showing persistent uptake inferior to the right thyroid lobe (black arrow), suggesting a hypercellular parathyroid gland in this location. **B.** Neck ultrasound (longitudinal view). **C.** Neck ultrasound (transverse view) also showing a probable right inferior parathyroid adenoma (white arrow), which is hypoechoic compared to thyroid tissue.

long-term outcome and cost-effectiveness studies will be necessary before recommending their routine use. However, they should be obtained if a focused parathyroidectomy is planned.

Surgical Management

A. Rationale and guidelines for parathyroidectomy

Patients with classic symptoms and metabolic complications related to PHPT are generally treated by parathyroidectomy. Whether asymptomatic patients should undergo parathyroidectomy is controversial. One aspect of the controversy is the fact that there is no consensus on what constitutes an asymptomatic patient. At the 1990 NIH Consensus Conference, asymptomatic PHPT was defined as, "the absence of common symptoms and signs of PHPT, including no bone, renal, gastrointestinal or neuromuscular disorders." Nonoperative management was recommended in this group of patients with calcium levelsless than or equal to 12 mg/dL, based on several observational studies that suggested stability with respect to serum calcium, kidney stones, bone loss, and renal function with time. Parathyroidectomy was recommended for asymptomatic patients less than 50 years of age and in certain other patients.

A second NIH Conference was held in 2002 to reevaluate the criteria for parathyroidectomy in asymptomatic patients. The guidelines issued were similar to the previous recommendations except for the following changes. Parathyroidectomy was recommended in the following cases: for milder elevations in serum calcium (ie, if the serum calcium was 1 mg/dL above reported normal range) and if the bone mineral density at any site (forearm, spine, or hip) was more than 2.5 standard deviations below that of gender-matched peak bone mineral density (T score, rather than Z score, of –2.5). The panel recommended caution in using neuropsychological abnormalities, cardiovascular disease, menopause, gastrointestinal symptoms, and serum or urine indices of increased bone turnover as sole indications for parathyroidectomy. These

recommendations were revised again in 2008, with elevated urinary calcium excretion (in the absence of nephrolithiasis) no longer being a criterion for surgery. In the most recent 2014 revision of the guidelines, urine calcium has become a consideration again and parathyroidectomy is indicated for urine calcium more than 400 mg/d in the presence of increased stone risk by biochemical stone risk analysis. The significant changes from the previous guidelines pertain to the fact that (a) patients with nephrolithiasis or nephrocalcinosis by X-ray, ultrasound or CT scan and (b) those with vertebral fracture by X-ray, CT, MRI, or vertebral fracture assessment (VFA) are also candidates for parathyroidectomy. Recommendations from all these conferences are summarized in Table 26–6.

However, other investigations suggest that true asymptomatic hyperparathyroidism may be rare. Patients without classic symptoms often present with weakness, fatigue, polydipsia, polyuria, nocturia, bone and joint pain, constipation, and other symptoms. These patients also score lower than healthy controls when assessed by multidimensional health assessment tools such as the SF-36 and other more specific questionnaires. Furthermore, parathyroidectomy not only often improves the classic, but also the nonspecific symptoms described above in most patients. In addition, parathyroidectomy has been associated with improved survival (in both asymptomatic and symptomatic patients), is more cost-effective than lifelong follow-up, and is successful in 95% of patients with a minimal (<1%) complication rate. Although bisphosphonates and calcimimetics show promise in the treatment of patients with PHPT, further studies are needed prior to recommending their routine use in this setting. Therefore, most clinicians recommend parathyroidectomy (by surgeons experienced in the procedure) for patients with PHPT, except in those patients where operative risks are prohibitively high. This thought process is also reflected in the 2008 Workshop guidelines and reiterated in the most recent 2014 guidelines on the management of asymptomatic primary hyperparathyroidism.

TABLE 26–6 NIH Consensus Conference and International Workshop indications for surgery in patients with asymptomatic primary hyperparathyroidism.

Criterion	1990	2002	2008	2014
Serum calcium	>12 mg/dL	>1 mg/dL above upper limit of normal	>1 mg/dL above upper limit of normal	>1 mg/dL above upper limit of normal
Urinary calcium	>400 mg/24 h	>400 mg/24 h	Not indicated	>400 mg/24 h
Creatinine clearance	<30% of normal age-matched controls in the absence of another identifiable cause	Reduced by 30% of normal	Reduced to <60 mL/min	Reduced to <60 mL/min
Bone mineral density	<2 SD below age- and sex-matched normal value (Z-score)	<2.5 SD below peak bone mass (T-score) at any site	T-score <−2.5 at any site and/or previous fracture	T-score <−2.5 at any site and/or previous fracture
Age	<50 y	<50 y	<50 y	<50 y

B. Conduct of parathyroidectomy Issues to consider before deciding on the optimal treatment approach are whether one is dealing with sporadic or familial disease and whether it is the initial operation or reexploration. The presence of concurrent thyroid pathology needing surgical treatment must also be considered. The positioning, incision, and dissection are as described previously for thyroidectomy. A bloodless field is crucial to enable identification of parathyroid glands. The middle thyroid veins are ligated and divided to allow medial retraction of the thyroid lobe. The space between the carotid sheath and thyroid is then opened by sharp and blunt dissection, from the level of the cricoid to the thymus, and the recurrent laryngeal nerve is identified. Most parathyroid glands are found within 1 cm of the junction of the nerve and inferior thyroid artery—the superior glands lie dorsal and the lower glands more ventral or anterior to the nerve. Because parathyroid glands are often embedded in fat, any fat lobule at typical parathyroid locations should be explored.

C. Bilateral versus unilateral approach Traditionally, all four parathyroid glands have been explored without preoperative localizing studies, with a 95% success rate in the hands of an experienced surgeon. Investigators in favor of unilateral exploration have suggested decreased recurrent laryngeal nerve injury, less postoperative hypocalcemia, shorter operative time, and early discharge as advantages of this approach. Potential disadvantages of unilateral exploration include the risk of missing multiple abnormal or ectopic parathyroid glands.

More surgeons today are using a unilateral or focal approach directed by localizing studies with or without intraoperative gamma probe or intraoperative PTH measurements. We have found that when two localizing studies—Tc-99m sestamibi and ultrasound—identify the same solitary parathyroid gland in patients with sporadic PHPT, this was the only abnormal parathyroid gland in 95% of patients. In patients with sporadic PHPT and positive preoperative localization studies, our current approach is to recommend focused parathyroidectomy via a 2.5-cm incision with intraoperative PTH measurement. If the PTH level falls more than 50% within 10 minutes after removal of an abnormal parathyroid gland, the procedure is terminated. If the level does not fall, a PTH measurement is repeated in another 10 minutes,

because it may fall slowly in some patients. A bilateral approach is needed in patients with known familial disease, with negative or equivocal localization tests, with secondary or tertiary HPT, or a history of lithium treatment. If parathyroid cancer is suspected intraoperatively, it is resected with the ipsilateral thyroid lobe and regional lymph nodes.

D. Subtotal parathyroidectomy versus total parathyroidectomy with autotransplantation Either subtotal (generally resection of 3½ glands) or total parathyroidectomy with primary parathyroid autotransplantation may be performed in patients with multiglandular disease. In the latter technique, 12 to 20 small fragments (1 × 1 mm) of parathyroid tissue are placed into multiple pockets in the forearm muscle of the nondominant arm. The site is marked with silk sutures and is easily accessible under local anesthesia should the patient develop recurrent hypercalcemia. The recurrence rates for hyperparathyroidism appear to be similar after subtotal or total parathyroidectomy. However, a 5% failure rate has been reported after autotransplantation of parathyroid tissue. Therefore, subtotal parathyroidectomy is preferred. The most normal gland is biopsied first, leaving a 50-mg remnant (the size of a normal parathyroid gland); if it appears viable, the remaining glands are excised. Patients undergoing either of these procedures should have tissue cryopreserved, if possible. Parathyroid glands should not be routinely biopsied at exploration but rather biopsy should be used to confirm parathyroid tissue or help determine if the gland is normal or abnormal. As with thyroid surgery, video-assisted and endoscopic axillary approaches are feasible, but clear benefits compared with the open approach await long-term multicenter studies. The area where endoscopic approaches has shown most promise are in the resection of ectopic mediastinal tumors where thoracoscopic parathyroidectomy is an alternative to sternotomy.

NORMOCALCEMIC PRIMARY HYPERPARATHYROIDISM

This entity is being increasingly recognized and is characterized by the presence of elevated PTH levels with persistently normal serum calcium levels, including ionized serum calcium levels. The diagnosis is established after excluding causes of secondary PTH

elevation such as vitamin D deficiency, osteomalacia, malabsorption, hypercalciuria (renal leak), and renal insufficiency. Medications such as hydrochlorthiazide and lithium should be discontinued. Patients may present with classical features of PHPT including a history of kidney stones (14%), fragility fractures (11%) and osteoporosis (57%). While some symptomatic patients may benefit from parathyroidectomy, close follow-up is also an option due to the lack of long-term outcome data. If the patient develops hyeprcalcemia, the usual parathyroidectomy guidelines may be applied in management decisions.

PERSISTENT AND RECURRENT PRIMARY HYPERPARATHYROIDISM

Persistent hypercalcemia occurs after about 5% to 10% of explorations. Recurrent hypercalcemia is rare except in patients with familial disease and occurs after an intervening period (>6 months) of normocalcemia. The most common reasons for persistent or recurrent hyperparathyroidism are a missed gland in normal or ectopic location, unrecognized hyperplasia, supernumerary glands, subtotal tumor resection, parathyroid carcinoma, or parathyromatosis (usually due to implantation of cells due to spillage at the initial procedure). The most common sites of ectopic glands in patients with recurrent or persistent PHPT (Figure 26–5) are
FIGURE 26–5 Ectopic locations of parathyroid tumors found at reoperation after an initial failed neck exploration. The numbers indicate the frequency with which missing glands are found in that location with 1 being most common and 8 being least common.

paraesophageal (28%), mediastinal (26%), intrathymic (24%), intrathyroidal (11%), carotid sheath (9%), and undescended (high cervical 2%). The management of these patients involves confirmation of the diagnosis—in particular, exclusion of FHH; review of original operative notes and pathology reports; and localization studies, which are absolutely essential in this group of patients. Preoperative evaluation of the vocal cords is routinely performed. The issue of reexploration in mildly symptomatic patients is controversial. The neck is usually reexplored first, and median sternotomy may be needed in 1% to 2% of patients. Cryopreservation should be performed routinely and autotransplantation selectively. Reexploration by an experienced surgeon is successful in more than 90% of patients, but reoperative parathyroidectomy is generally associated with more complications than an initial operation.

SECONDARY HYPERPARATHYROIDISM

This disorder occurs most often in individuals with end-stage renal failure but may also occur in other conditions resulting in hypocalcemia, such as vitamin D deficiency, idiopathic hypercalciuria, and long-term lithium therapy.

Indications for surgery include serum calcium and phosphate product more than 70, renal osteodystrophy with or without bone pain, severe pruritus, ectopic soft tissue calcifications and tumoral calcinosis, serum calcium more than 11 mg/dL with markedly elevated PTH, and calciphylaxis.

These patients should undergo dialysis the day prior to surgery to correct electrolyte (specifically potassium) abnormalities. Patients with this disorder require bilateral exploration and either subtotal parathyroidectomy, leaving a 50 to 60 mg histologically confirmed, well-vascularized remnant of hyperplastic parathyroid distant from the recurrent laryngeal nerve; or total parathyroidectomy with autotransplantation of a similar amount of tissue. Upper thymectomy is usually performed in these patients, because up to 15% of patients have a fifth hyperplastic gland.

SPECIAL CONSIDERATION: FAMILIAL HYPERPARATHYROIDISM

Patients from MEN 1 families should have PHPT treated before coexisting gastrinoma. All glands should be identified, ectopic glands should be sought in the neck and upper mediastinum, and bilateral cervical thymectomy should be routinely performed due to the occurrence of thymic carcinoids. A subtotal parathyroidectomy (preferred by authors) or total parathyroidectomy, as described above, can be performed. MEN 2A patients should undergo screening for the presence of a pheochromocytoma and *RET* mutation prior to thyroid or parathyroid surgery. Because the parathyroids are at risk during thyroidectomy and central neck node dissection, and hyperparathyroidism is less virulent in these patients, only obviously enlarged glands should be removed. Normal-appearing glands should be marked and removed abnormal parathyroid tissue cryopreserved.

COMPLICATIONS OF PARATHYROID SURGERY

General complications are similar to those associated with thyroidectomy. Specific complications include recurrent laryngeal nerve injury, hypomagnesemia, and hypocalcemia. The latter may arise due to suppressed function of the remaining glands after removal of an adenoma; injury to the parathyroid remnant; or "bone hunger," which is the influx of calcium and phosphorus into previously demineralized bones. Bone hunger can be predicted to occur based on the severity of bone disease present prior to surgery and at times by the elevated preoperative alkaline phosphatase level and is generally more severe in individuals with uremic secondary hyperparathyroidism. Hypocalcemia can be treated with oral calcium and vitamin D supplementation (calcitriol, 0.25-0.5 μg twice daily). Intravenous calcium is seldom required but may be necessary in severely symptomatic patients.

THE ADRENAL (SUPRARENAL) GLAND

EMBRYOLOGY AND ANATOMY

The adrenals are paired structures located superior to the kidneys. The adrenal is divided into an outer cortex and an inner medulla. The cortex originates from mesodermal tissue near the gonads on the adrenogenital ridge at approximately the fifth week of gestation. Adrenocortical tissue can thus be found in the ovaries, spermatic cord, and testes. The adrenal medulla originates from the neural crest, which is ectodermal in origin.

Each adrenal is supplied by three sets of arteries: the superior adrenal (from the inferior phrenic artery), the middle adrenal (from the aorta), and the inferior adrenal (from the renal artery). These vessels branch into as many as 50 arterioles. The left adrenal vein empties into the ipsilateral renal vein, whereas the right adrenal vein drains into the inferior vena cava (see Chapter 9).

INDICATIONS FOR SURGERY

PRIMARY HYPERALDOSTERONISM

This disorder accounts for 1% of hypertensive patients and results from an adrenal adenoma (Conn syndrome, 75%), adrenal hyperplasia (24%), or adrenocortical cancer (1%). Glucocorticoid-suppressible hyperaldosteronism is another rare cause of hyperaldosteronism. Patients with primary hyperaldosteronism typically present with hypertension (longstanding and difficult to control despite multiple medications), muscle weakness, polydipsia, polyuria, headaches, and fatigue.

Diagnostic Tests

The diagnosis must be suspected in any hypertensive patient with spontaneous hypokalemia or hypokalemia while on diuretic therapy (despite potassium supplementation), although hypokalemia is not required for the diagnosis. Other abnormalities include hypernatremia, alkalosis, and hypochloremia. Elevated plasma and urine aldosterone levels with suppressed plasma renin activity levels confirm the diagnosis. Plasma aldosterone concentration to plasma renin activity ratios of more than 1:25 to 30 are highly suggestive of the diagnosis. The diagnosis can be confirmed by documenting failure to suppress plasma aldosterone with oral or intravenous salt loading. Once the biochemical diagnosis is confirmed, it is important to distinguish between patients with a unilateral adenoma from those with hyperplasia because unilateral adrenalectomy is virtually always curative for the former (see Chapter 10 for details). Tumors can be localized with CT scans, MRI, iodocholesterol scans, or selective venous catheterization for aldosterone and cortisol. A unilateral 0.5- to 2-cm adrenal tumor with a normal-appearing contralateral gland essentially confirms an aldosteronoma if the biochemical and clinical profiles are appropriate.

Surgical Management

Patients are prepared for surgery with potassium repletion, sodium restriction, and treatment with spironolactone or eplerenone (aldosterone antagonists). Amiloride or triamterene (potassium-sparing diuretics) as well as other effective antihypertensive medications, including calcium channel blockers and angiotensin-converting enzyme inhibitors, can also be used. Patients with a unilateral hyperfunctioning tumor are best managed with a laparoscopic adrenalectomy. Postoperatively, patients may require saline infusions, fludrocortisone (50-100 μg/d), or, rarely, glucocorticoids if they develop Addison disease. Adrenalectomy improves blood pressure in approximately 80% of patients and leads to resolution of hypokalemia in most. Only 20% to 30% of patients with bilateral hyperplasia benefit from adrenalectomy. Surgical candidates can be selected based on bilateral adrenal vein sampling for aldosterone and cortisol. A unilateral gradient suggests a potential benefit from surgical intervention. The remaining patients are best managed by medical therapy with spironolactone or eplerenone, triamterene, or amiloride.

HYPERCORTISOLISM

Cushing syndrome refers to a complex of symptoms and physical signs resulting from cortisol hypersecretion, independent of etiology. Causes of Cushing syndrome include ACTH–secreting pituitary tumor leading to bilateral adrenal hyperplasia (Cushing disease 70%); primary adrenal adenoma, hyperplasia, or carcinoma (20%); ectopic ACTH-secreting tumors (small cell lung, pancreatic, thyroid, thymic, and other cancers—10%); or the exogenous administration of steroids. Patients present with weight gain, muscular weakness, polyuria, emotional lability, moon facies, acne, hirsutism, central obesity, hypertension, diabetes mellitus, and virilization (see Chapters 4 and 9).

Diagnostic Tests

Diagnostic tests in patients with Cushing syndrome are directed toward confirming the diagnosis and determining the etiology of

the disorder. A low-dose (1-mg) overnight dexamethasone suppression test is usually performed. Patients with Cushing syndrome do not generally suppress cortisol levels to less than 3 ug/dL, although this threshold is controversial. In patients with a negative test but high clinical suspicion, the classic dexamethasone suppression test (2 mg over 48 hours) or a 24-hour urinary free cortisol measurement is performed. Salivary cortisol measurements are increasingly being used. Once hypercortisolism is confirmed, the plasma ACTH level, if suppressed, indicates a primary adrenal etiology for the disorder. High-dose (8-mg) dexamethasone suppression tests may be performed to delineate the source of increased cortisol secretion (see Chapter 9 for details). Adrenal tumors are localized using CT, MRI, or iodocholesterol scans and pituitary tumors by MRI scanning and selective venous catheterization of petrosal veins after corticotropin-releasing factor stimulation.

Surgical Management

Cushing disease is treated with transsphenoidal hypophysectomy and microsurgical excision of the pituitary adenoma. Irradiation may also be used, but the response is delayed, and the treatment often results in panhypopituitarism. Unilateral laparoscopic adrenalectomy is the treatment of choice in patients with adrenal adenomas, whereas open adrenalectomy is recommended for carcinomas. Bilateral laparoscopic adrenalectomy is used to treat patients with Cushing disease who fail to respond to radiation or hypophysectomy and selected patients with Cushing syndrome secondary to ectopic ACTH production. Symptoms of Cushing syndrome can be treated with medications that inhibit steroid production (ketoconazole, metyrapone, aminoglutethimide).

Preoperatively, electrolyte abnormalities are corrected, and all patients are given exogenous steroids (hydrocortisone, 100 mg intravenously every 8 hours). After unilateral adrenalectomy, steroids are tapered off over months. After bilateral surgery, lifelong treatment with hydrocortisone is necessary. Fludrocortisone is sometimes needed, and steroid supplementation must be increased in situations of stress. The prognosis after adrenalectomy for adenoma is excellent. After bilateral adrenalectomy, approximately 20% of patients develop Nelson syndrome (hyperpigmentation, headaches, exophthalmos, and blindness) from continuing growth of the pituitary tumor.

ADRENAL CORTICAL CARCINOMA

This rare neoplasm is slightly more common in women than in men and has a bimodal age distribution, occurring more frequently in children under 5 years of age and in adults in their forties and fifties. Approximately 50% of these tumors are nonfunctioning. The remaining secrete cortisol (30%), androgens (20%), estrogens (10%), aldosterone (2%), or multiple hormones (35%). Most adrenocortical cancers are sporadic, but they can also occur in the setting of the Li-Fraumeni syndrome (*p53*) and MEN 1 (*MENIN*). Adrenocortical cancers are often characterized by the rapid onset of Cushing syndrome with virilizing features. Nonfunctioning

tumors usually present with an enlarging abdominal mass and abdominal pain or, less commonly, with weight loss, hematuria, varicocele, and dyspnea.

Diagnosis

The biochemical workup of a unilateral adrenal mass is outlined in the section on adrenal incidentaloma (see Chapter 9). CT or MRI scans are commonly employed to evaluate the size and invasiveness of the mass. FDG-PET scans may have some utility in predicting malignancy. The size of the mass remains the single most reliable indicator of malignancy. Carcinomas are more likely to be present in lesions over 6 cm in diameter. Studies based on SEER registry data show that the sensitivity, specificity, and likelihood ratio of tumor size in predicting malignancy as 96%, 51%, and 2, respectively, for tumors larger than or equal to 4 cm; and 90%, 78%, and 4.1, respectively, for tumors larger than or equal to 6 cm. Other features suggesting malignancy on CT include irregular shape and margins, heterogeneity, and hemorrhage. On MRI, carcinomas have amoderate signal intensity on T2-weighted image (adrenal tumor to liver ratio 1.2-2.8). FNAB is usually recommended for patients with an isolated adrenal mass and a history of carcinoma of the lung, breast, stomach, kidney, colon, melanoma, or lymphoma and in those with symptoms and signs of underlying malignancy. FNAB is generally not recommended when a primary adrenal carcinoma is suspected as the diagnosis cannot be reliably made via this test and has the potential to seed the biopsy tract. Care must be taken to exclude pheochromocytoma prior to any biopsy to avoid precipitating a hypertensive crisis (see Chapters 9 and 11).

Surgical Treatment

Complete surgical excision offers the only chance of prolonged survival or cure. Transabdominal adrenalectomy with en bloc excision of contiguously involved structures (liver, kidney, spleen, or pancreas) is usually recommended. A thoracoabdominal approach may also be used for large (>10 cm) right-sided tumors. Laparoscopic adrenalectomy is not usually recommended for suspected adrenal cancers. The adrenolytic agent mitotane and other antitumor drugs such as etoposide, cisplatin, and doxorubicin have also been used with partial success for metastatic tumors. Mitotane has also been associated with an improved recurrence-free survival in the adjuvant setting. Five-year actuarial survival rates of 32% to 48% have been reported in patients who underwent complete resection. Features predicting poor survival include tumor size over 12 cm, six or more mitoses per high-power field, intratumoral hemorrhage, local invasion, and distant metastases.

SEX STEROID EXCESS

Virilization and feminization can be caused by many disorders, including congenital adrenal hyperplasia, adrenal adenomas or carcinomas, ovarian or testicular tumors, hypothalamic or pituitary disease, placental disorders, and exogenous sex steroid administration. Several different variants of congenital adrenal hyperplasia occur, each caused by a specific enzyme defect. Adrenal virilization

occurring postnatally usually results from an adenoma or carcinoma. Virilization presents in females with hirsutism, clitoromegaly, alopecia, breast atrophy, and oligomenorrhea. In males, feminizing tumors lead to gynecomastia and testicular atrophy.

Diagnostic Tests

Karyotype analysis to rule out sex chromosome anomalies such as Klinefelter syndrome and determinations of either plasma and or urinary steroid metabolites are needed to establish the diagnosis of a particular enzyme deficiency as discussed in Chapters 9, 12, and 14. The dexamethasone suppression test (2-4 mg/d in divided doses 4 times daily for 7 days) can be used to distinguish congenital adrenal hyperplasia from neoplasia. CT, MRI, and iodocholesterol scans are used to localize the tumors.

Surgical Management

Congenital adrenal hyperplasia is managed medically not surgically. Adrenalectomy is reserved for treatment of adrenal steroid excess caused by an adenoma or carcinoma. The perioperative management is similar to that for patients with Cushing syndrome. Patients with adrenal carcinomas have a poor prognosis.

PHEOCHROMOCYTOMA

This catecholamine-secreting tumor of the adrenal medulla and extra-adrenal chromaffin tissue accounts for 0.1% to 0.2% of all patients with hypertension. It is often called the "10% tumor" because 10% are bilateral, 10% are malignant, 10% occur in children, 10% are extra-adrenal, and 10% are familial (occurring in association with MEN 2A, MEN 2B, von Hippel-Lindau syndrome, neurofibromatosis, other neurocutaneous syndromes, and the familial paraganglioma and pheochromocytoma syndromes caused by mutations in the succinyl dehydrogenase family of genes [*SDHB, SDHC and SDHD*]). Mutations in SDHA and SDH5 have also been identified. The mTORC1 signaling pathway and MAX (myc-associated factor X) also appear to be involved (see Chapter 11).

Headache, palpitations, and diaphoresis constitute the classic triad of pheochromocytoma. Nonspecific symptoms include anxiety, tremulousness, severe headaches, paresthesias, flushing, chest pain, shortness of breath, abdominal pain, nausea, and vomiting as well as others. The most common clinical sign is hypertension, which may be sustained or episodic.

Diagnostic Tests

These are performed in a nonstressed patient. Twenty-four-hour urine collections are tested for catecholamines (epinephrine, norepinephrine, dopamine) and their metabolites (metanephrines and normetanephrines). Plasma metanephrines, catecholamines, and chromogranin A levels are also used to make the diagnosis. Provocative tests such as glucagon infusion and clonidine suppression are rarely necessary. Radiologic investigations such as CT or

MRI scans, and metaiodobenzylguanidine scans are used to localize the tumors and assess for possible extra-adrenal tumors (see Chapter 11). Of note, extra-adrenal sites lack phenylethanolamine-*N*-methyltransferase, and hence, secrete primarily norepinephrine rather than epinephrine.

Surgical Treatment

Adrenalectomy is the treatment of choice and can safely be performed laparoscopically. Preoperative preparation typically consists of treatment with an alpha-adrenergic blocker such as phenoxybenzamine (10-40 mg 4 times daily; maximum: 300 mg/d) for at least 7 days preoperatively. Beta-blockers such as propranolol (5-40 mg 4 times daily) are added in patients who have persistent tachycardia and arrhythmias but only after adequate alpha blockade has been established in order to avoid the effects of unopposed alpha stimulation (ie, hypertensive crisis and congestive heart failure). Calcium channel blockers such as nicardipine appear to be as effective as alpha and beta blockade preoperatively. Patients should also be volume repleted to avoid intraoperative or postoperative hypotension, which ensues with the loss of vasoconstriction after tumor removal. Nitroprusside is the drug of choice for intraoperative hypertension. After surgery, 95% of patients with paroxysmal hypertension and 65% with sustained hypertension become normotensive. Patients with malignant pheochromocytoma, defined by invasion into surrounding structures or presence of distant metastases, have a poor prognosis. Although risk of malignancy increases with size for all pheochromocytomas, size does not seem to reliably predict malignancy in pheochromocytomas. The risk of malignant tumors is also increased in patients with germline *SDHB* mutations.

ADRENAL INCIDENTALOMA

The term **incidentaloma** is used to denote an adrenal mass discovered during imaging done for other reasons. Adrenal masses have been identified in up to 8% of individuals in autopsy series and in 4.4% of those undergoing abdominal CT scans. The widespread use of ultrasound, CT, and MRI scans over the past two decades has led to an appreciable increase in the number of these lesions identified. Most of these lesions are benign nonfunctioning adenomas. The differential diagnosis of these lesions is summarized in Table 26–7.

Diagnosis

The workup is used to discern which lesions are functional or malignant and thus, warrant adrenalectomy. Asymptomatic patients with obvious cysts, hemorrhage, myelolipomas, or diffuse metastatic disease do not mandate further testing. All other patients should undergo biochemical testing for hormonally active tumors. At a minimum, this includes serum electrolytes; low-dose (1-mg) dexamethasone suppression testing; and a 24-hour urine collection for catecholamines, metanephrines, and 17-ketosteroids; however, the issue of which tests to order is controversial. Confirmatory tests can be performed based on the results of these screening tests. It is

TABLE 26–7 Differential diagnosis of an adrenal incidentaloma.

extremely important to identify patients with subclinical Cushing syndrome. Functional tumors and nonfunctional masses over 4 cm (in patients who have an acceptable operative risk) are treated by laparoscopic adrenalectomy, whereas heterogeneous, irregular, or enlarging tumors are treated by open or laparoscopic adrenalectomy. FNAB should be performed only in patients with a history of carcinoma and a suspected isolated adrenal metastasis, or if there is a question as to whether the tumor is of adrenal origin (see Chapter 9 for details). Care must be taken to exclude pheochromocytoma prior to biopsy to avoid precipitating a hypertensive crisis.

Treatment

Laparoscopic adrenalectomy has become the procedure of choice for most of the lesions described above except when malignancy is likely or suspected. Patients with nonfunctioning homogeneous lesions less than 4 cm in diameter should be followed with serial examinations and CT or MRI scans at 3 to 12 months. Adrenalectomy is indicated for any lesion that grows during the observation period.

TECHNIQUE OF ADRENALECTOMY

There are no randomized controlled trials comparing laparoscopic and open adrenalectomies. However, several retrospective studies have shown that the laparoscopic technique is safe and associated with less postoperative pain, shorter mean hospital stay, lower morbidity, and more rapid complete recovery. Laparoscopic adrenalectomy has become the procedure of choice for most adrenal lesions, and the indications are similar to those for open procedures.

Laparoscopic adrenalectomy is contraindicated in patients with a known adrenocortical cancer or coagulopathy. Two approaches have been described: transperitoneal (lateral and anterior) and posterior retroperitoneal. The former provides a conventional view of the anatomy, and the anterior approach allows for bilateral procedures without repositioning the patient. The posterior approach may be preferable in reoperative cases and obese patients but provides a limited working space. The lateral transperitoneal approach is described in the next paragraph.

The patient is placed in the lateral decubitus position, with the table flexed to open the space between the lower rib cage and the iliac crest. Pneumoperitoneum is created by insufflating carbon

dioxide gas and four 10-mm trocars are placed between the midclavicular line medially and the anterior axillary line laterally (Figure 26–6A), approximately two finger-breadths below the costal margin. A 30-degree laparoscope inserted via the midclavicular port is used to aid the dissection, which is carried out via atraumatic instruments inserted via the two most lateral ports. In general, the dissection of the adrenal usually begins superomedially and then proceeds inferiorly in a clockwise fashion (Figures 26–6B and 26–6C). The adrenal gland is dissected from
FIGURE 26–6 Technique of laparoscopic adrenalectomy. **A.** Positioning and placement of trocars. **B.** Exposure of the right adrenal is facilitated by division of the triangular ligament. **C.** Dissection and reflection of the spleen and tail of the pancreas aids in identifying the left adrenal. (Reproduced with permission from Brunicardi F, Andersen D, Billiar T, et al. *Schwartz's Principles of Surgery*, 8th ed. New York: McGraw-Hill; 2004.)

surrounding tissue using an electrocautery or an ultrasonic scalpel (Harmonic Ultrasonic Scalpel). These instruments are also useful for control of the small adrenal arteries, but the larger adrenal arteries and adrenal veins need to be clipped or stapled. The adrenal is placed in a specimen (EndoCatch) bag and can be morcellated prior to extraction.

Adrenalectomy can also be performed via the posterior retroperitoneal approach, especially in patients who have had prior abdominal surgery. Another advantage is that bilateral adrenalectomy can be performed without repositioning the patient. However, the working space is limited making vascular control difficult. This technique is being increasingly used for small adenomas but is less suitable for tumors larger than 5 cm.

Open adrenalectomy may be performed by the anterior, posterior, retroperitoneal, or thoracoabdominal approaches. The latter is very useful, particularly for large adrenal cancers.

Complications of Laparoscopic Adrenalectomy

Specific procedure-related complications include trocar site-associated hematoma and subcutaneous emphysema, injury to surrounding organs such as the spleen, pancreas, liver and colon, and bleeding from venous injuries.

THE ENDOCRINE PANCREAS

EMBRYOLOGY AND ANATOMY

The pancreas is a retroperitoneal organ located at the level of L2. It weighs 75 to 100 g, is approximately 15 to 20 cm in length, and is divided into the head and uncinate process, the neck, the body, and the tail. The uncinate process forms part of the head and surrounds the superior mesenteric vessels. The main pancreatic duct (duct of Wirsung) is 2 to 3.5 mm wide, runs in the center of the pancreas, and drains the body, tail, and uncinate process. The lesser duct (duct of Santorini) usually drains the head, communicates with the duct of Wirsung, and drains separately via a minor papilla located 2 cm proximal to the ampulla of Vater. The common bile duct is found posteriorly in the pancreatic head and joins the main pancreatic duct before draining into the ampulla.

The pancreas originates as dorsal and ventral pancreatic buds from the primitive endoderm at about the fifth week of gestation. The former gives rise to the superior head, neck, body, and tail, whereas the later forms the inferior head and the uncinate process. The ventral duct fuses with the dorsal bud to form the duct of Wirsung, and the proximal portion of the dorsal duct forms the duct of Santorini. In 10% of individuals, the ducts fail to communicate, resulting in pancreas divisum, where the entire pancreas is drained by the lesser duct.

INDICATIONS FOR SURGERY

Endocrine pancreatic tumors arise from the islet cells, which are derived from the neural crest. Common functioning tumors are described next.

INSULINOMA

This β-cell–derived neoplasm is the most common pancreatic endocrine tumor. Insulinomas are evenly distributed throughout the pancreas (one-third each in the head, body, and tail). Most patients (90%) have a benign, solitary lesion. Approximately 10% of patients have malignant insulinomas with metastatic disease to the liver and peripancreatic lymph nodes. The insulinoma syndrome is characterized by the Whipple triad, which includes symptoms of hypoglycemia during fasting, serum glucose less than 50 mg/dL, and relief of hypoglycemic symptoms by exogenous glucose administration. Hypoglycemic symptoms may result from neuroglycopenia (confusion, seizures, personality change, coma) or due to a catecholamine surge (tachycardia, diaphoresis, trembling). Other causes of hypoglycemia such as reactive hypoglycemia, adrenal insufficiency, end-stage liver disease, nonpancreatic tumors (mesothelioma, sarcoma, adrenal carcinoma, carcinoid), and surreptitious administration of oral hypoglycemics or insulin should be excluded.

Diagnostic Tests

The diagnosis is made during a 72-hour monitored fast if glucose levels fall to less than 50 mg/dL, while insulin levels are more than 20 uU/mL and the insulin to glucose ratio is more than 0.4 (normal: <0.3). This is considered the gold-standard test. Increased levels of C peptide and proinsulin are also diagnostic, whereas low levels suggest factitious hyperinsulinemia.

Once the diagnosis is confirmed biochemically, noninvasive tests such as double-contrast, fine-cut (5 mm) CT or MRI scans can identify large tumors or liver metastases. Transgastric endoscopic ultrasound is the most successful preoperative localization test (sensitivity 83%-93%). Some pancreatic neuroendocrine tumors also express somatostatin receptors and can be imaged using radiolabeled octreotide. Unfortunately, this is only effective in about 30% of patients with insulinomas (see Chapter 18 for details). PET/CT scan with ^{68}Ga-somatostatin analogs may be helpful. Selective arteriography with calcium stimulation of insulin secretion, monitored through a catheter positioned in the right hepatic vein (Imamura-Doppmann test, sensitivity 88%) is an invasive test that is used selectively when other localization studies fail to identify the tumor or in patients following unsuccessful prior surgery. Glucagon-like peptide-1 (GLP-1) receptor expression is high in most insulinomas and may be promising in localizing small tumors.

Treatment

A. Surgical treatment   Operation is the only curative treatment. Prior to surgery, patients are instructed to take several small frequent meals, and diazoxide administration can be helpful in avoiding hypoglycemic attacks. Other medications commonly used include verapamil, diphenylhydantoin, and glucocorticoids. Somatostatin analogues can also be used if the tumors are positive for somatostatin receptors. Glucose levels are monitored perioperatively. The combination of inspection, palpation, and

intraoperative ultrasound allows detection of nearly all tumors and their relationship to the pancreatic duct. Small (<2 cm) benign tumors in any part of the pancreas that are not intimately associated with the main pancreatic duct are best treated by enucleation. Larger tumors (up to 5 cm) can be enucleated if located in the pancreatic head but are removed by spleen-preserving distal pancreatectomy if located in the tail. Large tumors in the head that appear malignant are usually resected by a Whipple procedure. When a tumor cannot be identified, blind distal resections should generally not be performed. However, a small distal pancreatic resection may be sufficient to rule out nesidioblastosis (β-cell hyperplasia). Resection of peripancreatic and duodenal nodes is advised in patients with probable malignant tumors. Hepatic resection should be considered for cure or palliation in patients with metastatic tumors. In cases of nonresectable disease, debulking may be reasonable to achieve symptomatic control and may also prolong survival. Other modalities such as RFA, cryotherapy, and transarterial chemoembolization (TACE) may also be considered in this setting. Patients with insulinomas in the setting of MEN 1, in contrast to those with sporadic tumors, require distal pancreatectomy and enucleation of tumors from the head of the pancreas. Surgical resection is curative in about 95% of cases.

B. Medical treatment   Diazoxide and verapamil are often used to decrease insulin secretion from insulinoma. Combination chemotherapy (streptozocin, 5-fluorouracil (FU), and doxorubicin) has also been used for unresectable insulinomas.

GASTRINOMA (ZOLLINGER-ELLISON SYNDROME)

This neoplasm leads to abdominal pain, peptic ulceration of the proximal gastrointestinal tract (90%) and diarrhea (50%). The diagnosis should be suspected in patients with recurrent postoperative and postbulbar ulcers, ulcers associated with diarrhea, a family history of ulcer diathesis or MEN 1, and failure to respond to adequate medical therapy. Up to 75% of gastrinomas occur sporadically. In contrast to insulinomas, 60% of gastrinomas are malignant and present with local invasion and metastases. Also, virtually all insulinomas are situated within the pancreas, but up to 70% of gastrinomas are found within the duodenum.

Diagnostic Tests

Fasting serum gastrin levels are generally over 200 pg/mL, and values over 1000 pg/mL are diagnostic of gastrinomas except in hypochlorhydric patients. Elevated gastrin levels may also be found in several other disease states (Table 26–8), and other tests are therefore necessary. Basal gastric acid output over 15 mEq/h (>5 mEq/h in patients with previous vagotomy) or a ratio of basal to maximal acid output more than 0.6 suggests a gastrinoma. An increase of gastrin over 200 pg/mL above the basal level on stimulation with secretin (2 U/kg) confirms the diagnosis. In patients with Zollinger-Ellison syndrome (ZES), serum PTH, calcium, and prolactin levels should be measured to rule out MEN 1.

TABLE 26–8 Causes of hypergastrinemia.

A. Hypergastrinemia associated with increased gastric acid
  1. Gastrinoma, sporadic, or familial (MEN 1)
  2. Antral G cell hyperfunction (rare)
  3. Retained gastric antrum
  4. Short bowel syndrome
  5. Gastric outlet obstruction
  6. Renal failure (acid can be normal)
  7. *Helicobacter pylori* gastritis (acid can be low)
B. Hypergastrinemia associated with little or no gastric acid
  1. Pernicious anemia (achlorhydria)
  2. Chronic atrophic gastritis
  3. Vagotomy
  4. Gastric ulcer associated with hypochlorhydria

Imaging studies used to localize gastrinomas are similar to those used for investigation of insulinomas. However, endoscopic ultrasound and visceral angiograms are less sensitive for gastrinomas, because many are small and not within the pancreas. Most pancreatic gastrinomas are situated to the right of the superior mesenteric vessels. Octreotide scans or positron emission tomography (PET) with Ga-DOTATOC may be useful. Selective pancreatic angiograms utilizing secretin stimulation and hepatic venous sampling for gastrin levels may also be used.

Treatment

A. Surgical treatment   Patients are treated with proton pump inhibitors preoperatively. Most gastrinomas are located in the gastrinoma triangle, which is surrounded by the cystic duct superiorly, the second and third portions of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially. The Whipple procedure is recommended for large (>6 cm) or clinically malignant tumors in the head of the pancreas. Intraoperative ultrasound, endoscopy with duodenal transillumination, and a longitudinal duodenotomy are necessary to identify many tumors. All peripancreatic and periduodenal lymph nodes should be removed, as primary lymph node gastrinomas have been reported. Single hepatic metastases may be resected. Total gastrectomy is rarely indicated today except in noncompliant patients or those refractory to medical therapy when the gastrinoma cannot be identified or completely removed. Patients with MEN 1 often have multiple gastrinomas. The extent and role of surgery in patients with MEN 1/ZES remains controversial. Some groups advise early and aggressive surgeries to prevent liver disease, whereas others advise resection of MEN 1 gastrinomas larger than 2 cm as small tumors are characterized by a good prognosis. In advanced, surgically incurable tumors, cytoreductive measures including resection or RFA/TACE are reasonable if more than 90% of the tumor mass can be removed, although this does not appear to prolong survival. Liver transplantation may be a consideration in young patients with diffuse, unresectable pancreatic metastases. In contrast to patients with MEN 1 who have nearly 100% recurrence rates, about 34% of patients with sporadic gastrinomas remain disease-free at 10 years after surgical treatment. Overall survival rates after surgical treatment are reported to be 94% at 10 years.

B. Medical treatment   Octreotide may be used to decrease gastrin secretion. The combination of doxorubicin, streptozotocin, and 5-FU can be used as systemic chemotherapy. Somatostatin analogues and interferons have not shown much efficacy.

VIPOMA (VERNER-MORRISON) SYNDROME

This disorder is also known as the WDHA (watery diarrhea, hypokalemia, achlorhydria) or pancreatic cholera syndrome. Patients typically present with high-volume diarrhea (>5 L/d), muscular weakness (due to hypokalemia) and lethargy, hyperglycemia, hypercalcemia, and, rarely, cutaneous flushing.

Diagnostic Tests

Because secretion of vasoactive intestinal polypeptide (VIP) can be episodic, multiple fasting levels should be measured. Localizing studies are performed as described earlier for insulinomas and gastrinomas.

Treatment

A. Surgical treatment   Fluid and electrolytes should be aggressively repleted prior to surgery. The diarrhea often responds to octreotide. Most of these tumors are located in the body and tail and hence are best managed by a distal pancreatectomy. Small tumors may be enucleated. If the tumor is not localized, the autonomic chain and adrenals should be examined for extrapancreatic tumors. If no tumor is identified, distal pancreatectomy may be considered. Palliative debulking may be performed for metastatic disease to control symptoms if more than 90% of the tumor mass can be resected. Other ablative therapies such as RFA/TACE or cryotherapy may also be used as cytoreductive measures and liver transplantation may be an option in selected cases.

B. Medical treatment   Somatostatin analogues may provide palliation of symptoms particularly if the tumors are octreotide scan positive. They may also have an effect on tumor growth. Interferon-α may be indicated in tumors not responding to somatostatin analogues. Systemic therapy as described for other tumors may also be used.

GLUCAGONOMA

Patients with this tumor have mild diabetes, stomatitis, anemia, malnutrition, hypoproteinemia, and a characteristic severe dermatitis (necrolytic migratory erythema). The latter is thought to be secondary to the hypoaminoacidemia.

Diagnostic Tests

The clinical presentation and biopsy of the rash are sufficient for the diagnosis. Hyperglycemia, hypoproteinemia, and an elevated fasting glucagon level (>150 pg/mL) confirm the diagnosis.

Localizing and staging tests are performed, as described above for the more common tumors. Most of these tumors are malignant.

Treatment

A. Surgical treatment   Patients need preoperative octreotide, hyperalimentation, and routine deep venous thrombosis prophylaxis. Up to 70% of these tumors present with metastases, and surgery is the only potentially curable treatment. Most tumors are solitary and located in the tail, where they are amenable to distal pancreatectomy. Palliative debulking with distal pancreatectomy and splenectomy (if needed) in the setting of metastatic disease may help refractory symptoms. If splenectomy is planned, appropriate vaccination to reduce the risk of overwhelming post-splenectomy sepsis is recommended preoperatively.

B. Medical treatment   As with other neuroendocrine tumors, octreotide and embolization of hepatic metastases may help control symptoms.

SOMATOSTATINOMA

The somatostatinoma syndrome is characterized by steatorrhea, diabetes, hypochlorhydria, and gallstone disease. Most somatostatinomas are malignant (75% have metastases at presentation) and are located in the pancreatic head. The diagnosis is established by fasting somatostatin levels of 100 pg/mL or more. Somatostatinomas are usually treated with the Whipple procedure (ie, pancreaticoduodenectomy). Fluid and electrolyte abnormalities should be corrected preoperatively.

NONFUNCTIONING PANCREATIC TUMORS

Approximately 33% of patients with pancreatic endocrine neoplasms have no evidence of a defined clinical syndrome and are deemed to have nonfunctioning tumors. However, some of these tumors produce pancreatic polypeptide and chromogranin A, particularly in the setting of MEN 1. These patients usually present with abdominal pain, weight loss, and jaundice—similar to ductal adenocarcinoma of the pancreas. The tumors are most commonly present in the head, neck, and uncinate process. The tumors are localized and staged similar to functional tumors. Octreotide scans are recommended to assess receptor expression status and assess extent of disease. Endoscopic retrograde cholangiopancreatography and percutaneous transhepatic cholangiography are used for the evaluation of jaundice.

Surgical Treatment

Approximately 75% of these tumors are malignant. Surgical resection (pancreaticoduodenectomy or distal pancreatectomy) is the treatment of choice for sporadic tumors, because these tumors are not amenable to enucleation. In the presence of MEN 1, the indications for surgery are controversial. More aggressive groups recommend

tumor enucleation in the head and prophylactic subtotal pancreatectomy, whereas more conservative groups recommend close follow-up and enucleation of lesions larger than 2 cm. Biliary and gastric bypasses may be necessary for palliation. These tumors often grow slowly. Five-year survival rates after resection are 50%. Resectable liver disease should be treated with surgery and or RFA. In patients with unresectable disease, combination chemotherapy (streptozocin and doxorubicin) with RFA/TACE may provide palliation. Poorly differentiated tumors are characterized by aggressive tumor biology, absence of somatostatin receptors, and poor prognosis. Surgical resection is recommended only for resectable primary tumors. Cytoreductive procedures are generally not recommended in these patients.

Novel Therapies

Patients with advanced pancreatic neuroendocrine tumors not amenable to resection may be treated with everolimus (a serine-threonine kinase mTOR inhibitor) and sunitinib (a tyrosine-kinase inhibitor). Both targeted therapies have been associated with improved progression-free survival. Isotope therapy with labeled somatostatin analogs (peptide receptor radionuclide therapy) is also being increasingly used as palliative therapy. Pneumococcal vaccine should be given at least 2 weeks preoperatively in all patients having a splenectomy. Additionally, vaccines against Hemophilus influenza B, meningococcus, and Influenza are also recommended.

Technique of Pancreatic Exploration for Neuroendocrine Tumors

Patients are explored through a midline or bilateral subcostal incision. A detailed description of the Whipple procedure and a distal pancreatectomy is beyond the scope of this chapter, and the reader is referred to surgical atlases. A general description of the necessary maneuvers is presented here. The gastrocolic ligament and the inferior retroperitoneal attachments of the pancreas are divided to permit examination of the body and tail. A Kocher maneuver is performed to facilitate bimanual examination of the head and uncinate process. The duodenum, splenic hilum, small bowel mesentery, gonads (in women), and lymph nodes are assessed for extrapancreatic disease. The liver is examined for metastatic disease. Intraoperative ultrasound facilitates identification of tumors. A laparoscopic approach is also feasible in these tumors, particularly sporadic insulinomas, when the lesion is identified with preoperative localization studies and/or intraoperative ultrasound. Minimally invasive procedures also appear to be safe in the treatment of benign and malignant pancreatic nueoendocrine tumors without compromising oncologic outcomes. However, larger, multicenter studies are needed to evaluate them in relation to traditional open approaches. Liver transplantation may be considered in selected patients with difficult to control hormone oversecretion-related symptoms and low-risk tumors without distant metastases.

Complications of Pancreatic Surgery

The most important complications of pancreatic surgery (tumor enucleation, distal pancreatectomy, or Whipple resection) are pancreatic fistula, pseudocyst, or abscess formation, which may lead to necrotizing retroperitoneal infection, and hemorrhage. Other complications include upper gastrointestinal tract bleeding, marginal ulceration, and biliary fistula formation. The mortality of a Whipple procedure is less than 5% and that of other pancreatic surgical procedures is less than 1%.

Appendix

Normal Hormone Reference Ranges[a,b]

Test	Source	Ages, Conditions, etc	Conventional Units	Conversion Factor	SI Units	Comments
Adrenocorticotropic hormone (ACTH) stimulation test (cosyntropin test): 0.25 mg of synthetic ACTH$_{1-24}$ (cosyntropin) is administered IV or IM, and serum cortisol is measured at 0, 30, and 60 min. Normal response: peak cortisol >20 µg/dL (>540 nmol/L). A dose of 1 µg of ACTH will give a similar response in the normal individual (see Chapter 9).						
ACTH	Plasma			0.222		Collect in silicone-coated EDTA-containing tubes. Keep iced. Avoid contact with glass during collection and separation. Process immediately. Separate and freeze plasma in plastic tube at −20°C.
		<3 y	Not established		–	
		3-17 y	9-57 ng/L		2-12.7 pmol/L	
		>18 y	6-50 ng/L		1.3-11 pmol/L	
Aldosterone	Serum (fasting)			27.7		Levels in pregnant patients are three to four times higher.
		>18 y				
		Upright 8:00-10:00 AM	<28 ng/dL		<776 pmol/L	
		Upright 4:00-6:00 PM	<21 ng/dL		<582 pmol/L	
		Supine 8:00-10:00 AM	3-16 ng/dL		83.1-443 pmol/L	
		Pediatric				
		1-12 mo	2-70 ng/dL		55.4-1939 pmol/L	
		1-4 y	2-37 ng/dL		55.4-1025 pmol/L	
		5-9 y	<9 ng/dL		<243 pmol/L	
		10-13 y	<21 ng/dL		582 pmol/L	
		14-17 y	<35 mgdL		970 pmol/L	
		Premature Infants (31-35 wk)	<144 ng/dL		3989 pmol/L	
		Term Infants	<217 ng/dL		6011 pmol/L	
	Urine	Sodium diet (100-300 mmol/d)	–		–	Collect 24-h specimen in 10 g boric acid to maintain pH ≤7.5. Refrigerate during collection.
		Children:				
		2-7 y	≤5.7 µg/d			
		8-11 y	≤10.2 µg/d			
		12-16 y	≤15.6 µg/d			
		Adult	≤2.3-21 µg/d			
		Post-fludrocortisone or intravenous saline infusion	≤5.0 µg/d			
Alkaline phosphatase, bone specific	Serum	2-24 mo	25.4-124.0 µg/L	–	–	IRMA; collect following an overnight fast; useful in Paget disease and osteoporosis; assay also known as Ostase; increased levels seen in states of high bone turnover (Paget disease, hyperthyroidism, osteoporosis).
		6-9 y	41-134.6 µg/L			
		10-13 y				
		Males	43.8-177.4 µg/L			
		Females	24.2-154.2 µg/L			
		14-17 y				
		Males	13.7-128 µg/L			
		Females	10.5-75.2 µg/L			
		Adult males				
		18-29 y	8.4-29.3 µg/L			
		30-39 y	7.7-21.3 µg/L			
		40-49 y	7.0-18.3 µg/L			
		60-68 y	7.6-14.9 µg/L			

(Continued)

		>17 y	1.45-15.27 ng/mL		–	
Angiotensin II	Plasma	Adults	10-50 ng/L	–	–	Collect in EDTA. Centrifuge refrigerated. Store frozen at −70°C.

(*Continued*)

Test	Source	Ages, Conditions, etc	Conventional Units	Conversion Factor	SI Units	Comments
C peptide of insulin	Serum	Fasting	0.8-3.1 ng/mL	0.331	0.26-1.03 nmol/L	Freeze serum at −20°C; stable for 1 d at room temperature and 1 wk at −20°C.
Calcitonin	Serum	Male Female Child ≤6 mo 6 mo-3 y 3-17 y	≤10 pg/mL ≤5 pg/mL ≤41 pg/mL ≤14 pg/mL ≤6 ng/mL	0.293	≤2.93 pmol/L ≤1.46 pmol/L ≤12 pmol/L ≤4.1 pmol/L ≤1.76 pmol/L	Fasting, non-lipemic specimen. Refrigerate, spin down immediately. Store at −20°C.
Calcitonin stimulation test utilizing calcium infusion: 2 mg/kg of calcium in the form of calcium gluconate is administered IV over 1 min. Blood samples for calcitonin are obtained at 1, 2, 5, and 10 min after the infusion. Normal peak values for calcitonin 2 min after calcium infusion: female; <70 ng/L (≤20.5 pmol/L); male: ≤491 ng/L (≤144 pmol/L).							
Calcium, 24-h urinary	Urine		100-300 mg/ 24 h			Collect in 25 mL of 6N HCl. Refrigerate during collection; elevated in primary hyperparathyroidism, Paget disease, multiple myeloma, vitamin D toxicity; reduced in rickets, osteomalacia, familial hypocalciuric hypercalcemia.
Calcium, ionized	Serum	0-1 mo 1-6 mo >6 mo	1-1.5 mmol/L 0.95-1.5 mmol/L 1.16-1.36 mmol/L	–	–	Refrigerated serum must be collected anaerobically in gel barrier tube; elevated in primary hyperparathyroidism, vitamin D toxicity, cancer; reduced in pseudohypoparathyroidism, hypoparathyroidism, and severe vitamin D deficiency.
Calcium, total	Serum	<1 y >1 y	9.0-10.9 mg/dL 8.8-10.3 mg/dL	–	–	Overnight fasting preferred; used to diagnose parathyroid and vitamin D disorders; elevated in primary hyperparathyroidism, vitamin D toxicity; reduced in hypoparathyroidism and vitamin D deficiency.
Catecholamines (fractionated by HPLC)	Plasma	Adults: Norepinephrine Supine Ambulatory Epinephrine Supine Ambulatory Dopamine Supine Ambulatory Total (N+E) Supine Upright	– 112-658 pg/mL 217-1109 pg/mL – ≤50 pg/mL ≤95 pg/mL – ≤10 ng/mL ≤20 ng/mL 123-671 pg/mL 242-1125 pg/mL	0.00591 0.00546 0.00654 0.00591	– 0.66-3.89 nmol/L 1.18-6.55 nmol/L – ≤0.27 nmol/L ≤0.52 nmol/L – ≤0.065 nmol/L ≤0.13 nmol/L 0.73-3.97 nmol/L 1.43-6.64 nmol/L	Collect by intravenous catheter after patient has rested 30 min. Collect and centrifuge under refrigeration; freeze in plastic tube at −20°C.

		24-h urine >18 y old Premenopausal	5-79 nmol BCE/mmol creatinine			

Corticotropin-releasing hormone (CRH) test: Ovine CRH in a dose of 1 μg/kg is administered IV. Blood samples for ACTH and cortisol determinations are taken at 15, 30, and 60 min. The peak ACTH response of >10 pg/mL (>2.2 pmol/L) occurs at 15 min. The peak cortisol response of >10 μg/dL (>280 nmol/L) occurs at 30-60 min (see Chapter 4).

Test	Source	Ages, Conditions, etc	Conventional Units	Conversion Factor	SI Units	Comments
Corticotropin-releasing hormone	Plasma	Men and nonpregnant women	≤34 pg/mL	2.0	≤68 pmol/L	Markedly elevated at term pregnancy.
		Pregnant women				
		1st trimester	≤40 pg/mL		≤80 pmol/L	
		2nd trimester	≤153 pg/mL		≤306 pmol/L	
		3rd trimester	≤847 pg/mL		≤1694 pmol/L	
		Cord blood	≤338 pg/mL		≤676 pmol/L	
Cortisol	Serum	Adult		27.59		Collect and process under refrigeration. Spin down immediately. Salivary cortisol is in equilibrium with free cortisol and may be used as an index to free cortisol. Reference range may vary with method and laboratory.
		Total				
		7-9 AM	4-22 μg/dL		193-607 nmol/L	
		3-5 PM	3-17 μg/dL		83-469 nmol/L	
		Peak post-ACTH	>20 μg/dL		551.8 nmol/L	
		Children				
		Premature (31-35 wk)	≤15 μg/dL		≤414 nmol/L	
		Term Infants (3 d)	≤14 μg/dL		≤386 nmol/L	
		1-17 y	2-17 μg/dL		55-469 nmol/L	
		Free				
		Adult				
		8-10 AM	0.07-0.93 μg/dL		2-25.6 nmol/L	
		4-6 PM	0.04-0.45 μg/dL		1.1-12.4 nmol/L	
		10-11 PM	0.04-0.35 μg/dL		1.1-9.7 nmol/L	
	Saliva	Adult				
		8-10 AM	0.04-0.56 μg/dL		1.1-15.6 nmol/L	
		4-6 PM	<0.15 μg/dL		<4.2 nmol/L	
		10-11 PM	<0.09 μg/dL		<2.5 nmol/L

Dexamethasone suppression test (low dose) for the diagnosis of Cushing syndrome (see Chapter 9): Obtain a baseline serum cortisol at 0700-0800 h. Administer 1 mg dexamethasone orally at 2300 h that evening and obtain another serum cortisol at 0700-0800 h the following morning. **Interpretation:** A normal response (normal suppressibility) is a reduction of the post-dexamethasone serum cortisol to ≤1.8 μg/dL (≤50 nmol/L).

Dexamethasone suppression test (high dose) for the differential diagnosis of Cushing syndrome (see Chapter 9): Obtain a baseline serum cortisol at 0700-0800 h. Administer 8 mg dexamethasone orally at 2300 h that evening and obtain another serum cortisol at 0700-0800 h the following morning. **Interpretation:** A reduction of the post-dexamethasone serum cortisol to ≤50% of the baseline cortisol indicates suppressibility.

Dexamethasone-CRH test: Administer dexamethasone, 0.5 mg every 6 h orally for eight doses, followed by CRH, 1 μg/kg IV 2 h after the last dose of dexamethasone. Plasma cortisol is obtained 15 min after CRH. Normal: ≤1.4 μg/dL (≤38.6 nmol/L). (See Chapter 9.)

Insulin-like growth factor-II (IGF-II)	Serum	Pre-puberty Puberty >18 y old	334-642 µg/L 245-737 µg/L 288-736 µg/L	1.0		Store serum at −20 C. Elevated in mesenchymal tumors with hypoglycemia; overnight fasting preferred.
Insulin-like growth factor–binding protein-III (IGFBP III)	Serum	Premature	Range	1.0	Mean	Separate serum within 1 h. Free serum in plastic vial at −20°C. Major carrier of IGFs, transporting ~95% of IGF-I and IGF-II. IGF-BP3 is GH-responsive and reflects GH actions: elevated in acromegaly and low in hypopituitarism and GH deficiency. Can be used to discriminate among causes of short stature.

Islet cell antibody (ICA)	Serum	Adults and children	Negative (≤1.25 JDF units)	1.0	Negative (≤1.25 JDF units)	Room temperature (2 d) or refrigerated serum sample (2 wk). ICA includes antibodies directed against GAD (glutamic acid decarboxylase), IA-2, insulin, GM2-1, and other cell surface proteins. ICA is present during the prediabetic phase and predicts the development of type 1 diabetes. Titers are compared to a single international reference standard reported in JDF (Juvenile Diabetes Foundation) units.

Metanephrines, plasma, free fractionated	Plasma	Metanephrine Normetanephrine Total metanephrines	≤57 pg/mL ≤148 pg/mL ≤205 pg/mL		≤0.29 nmol/L ≤0.75 nmol/L ≤1.04 nmol/L	Maintain on ice until centrifuged. Separate plasma within 2 h of venipuncture. Freeze plasma and store frozen until assay at −20°C. Assay by liquid chromatography, tandem mass spectrometry (LC/MS/MS). Requires minimum of 1.5 mL refrigerated EDTA plasma. Patient should refrain from alcohol, coffee, tea, tobacco, and strenuous exercise. Patient should be seated and relaxed before the sample is collected. Overnight fasting is recommended. Increased in pheochromocytoma, neuroblastoma, and stress.

Metyrapone stimulation test: Metyrapone in a dose of 30 mg/kg is administered orally at midnight. The 8 AM plasma 11-deoxycortisol is >7 μg/dL (>0.2 nmol/L) and plasma ACTH is >100 pg/mL (22 pmol/L). (See Chapter 4.)

Test	Source	Ages, Conditions, etc	Conventional Units	Conversion Factor	SI Units	Comments
Renin	Plasma	Normal sodium diet (75-150 mmol/d) Recumbent	0.25-5.82 ng/ mL/h			Discontinue diuretics, estrogens and oral contraceptives for at least 2 wk and non-diuretic anti-hypertensive Rx several days before study. Dietary sodium content should be main-tained for at least 3 d prior to testing. Collection instruc-tions: Supine speci-mens should be drawn in the morning, prefer-ably after over-night recumbency, but in any case, after a minimum of 30 min supine prior to drawing the specimen. Collect in lavender tube and transport to the laboratory at room temperature for prompt separa-tion and freezing of plasma. Do not place on ice or refrigerate sample.
Sex hormone–binding globulin	Serum	1 mo-2 y	60-252 nmol/L	1.0	60-252 nmol/L	Store refrigerated, collect room temperature and process serum sample immedi-ately and store frozen at –20°C. Two-site immuno-radiometric assay.

Test	Source	Ages, Conditions, etc	Conventional Units	Conversion Factor	SI Units	Comments
Thyroglobulin	Serum	Adult Males Females	1.4-29.2 ug/L 1.5-38.5 ug/L	1.00		Freeze at −20°C. Presence of thyroglobulin autoantibodies in the patient's serum may falsely lower the result. Ultrasensitive assay. Immuno-enzymatic assay for thyroglogulin and antibodies.
		Thyroglobulin antibodies	<2.00 IU/L			
Thyroid antibodies	Serum	Thyroperoxidase antibodies	≤100 IU/mL (negative) >100 IU/mL (positive)			Serum collected and refrigerated. ELISA for thyroperoxidase antibodies. Chemiluminescent microparticle immunoassay for anti-thyroglobulin antibodies.
		Thyroglobulin antibodies	≤2 IU/mL (negative)			
Thyroid-stimulating hormone (TSH) ultrasensitive	Serum or heparinized plasma	Adult Males and nonpregnant females	0.45-4.12 mU/L		0.45-4.12 mU/L	Chemiluminescent microparticle immunoassay. Sensitivity: 0.01 mU/mL. TSH levels decline in first several weeks of life, although they remain elevated in some infants. Free T_4 is helpful in the interpretation of TSH.
		Children Term infants <2 mo 2 mo to <6 mo 6 mo to <14 y 14 y to <18 y	1.12-6.31 mU/L 0.73-4.77 mU/L 0.70-4.17 mU/L 0.47-3.41 mU/L		1.12-6.31 mU/L 0.73-4.77 mU/L 0.70-4.17 mU/L 0.47-3.41 mU/L	
Thyroid-stimulating hormone receptor antibody (TSH-R Ab [stim])	Serum		≤140% of basal activity		–	Assay based on cyclic AMP generation in CHO cells transfected with human TSH receptor gene. Also known as TSI.
Thyroid uptake of radioactive iodine (RAIU)	Activity over thyroid gland	Fractional uptake 2 h 6 h 24 h	4-12% 6-15% 8-30%			Ingestion or administration of iodide will decrease thyroid uptake of RAI.
Thyrotropin-binding inhibitory immunoglobulin (TB-II)	Serum	Adults and children Graves disease	≤16% inhibition 16-100% inhibition	–	–	Sensitivity: 2% inhibition. May be useful in Graves disease, neonatal hypothyroidism, and postpartum thyroid dysfunction.
Thyroxine-binding globulin (TBG)	Serum	Men (>18 y) Women (>18 y) Children 4-6 y 7-8 y 9-10 y 11 y 12 y 13 y 14 y 15 y 16 y 17 y	12.7-25.1 µg/mL 13.5-30.9 µg/mL 14.8-32.9 µg/mL 16.3-30.7 µg/mL 15.8-27.4 µg/mL 15.5-27.4 µg/mL 14.8-26.2 µg/mL 13.8-25.2 µg/mL 12.2-25.2 µg/mL 10.8-23.8 µg/mL 10.0-23.8 µg/mL 8.5-23.1 µg/mL	18.5	235-464.5 nmol/L 249.8-571.7 nmol/L 273.8-608.7 nmol/L 301.6-568 nmol/L 292.3-506.9 nmol/L 286.8-506.9 nmol/L 273.8-484.7 nmol/L 255.3-466.2 nmol/L 225.7-466.2 nmol/L 199.8-440.3 nmol/L 185-440.3 nmol/L 157.2-427.4 nmol/L	Chemiluminescent assay. Quantifies TBG to differentiate TBG abnormalities from thyroid dysfunction.

Free T$_3$ (FT$_3$)	Serum	Adults Children ≤1 y 1-9 y 10-13 y 14-18 y	169-370 pg/dL Not established 337-506 pg/dL 335-480 pg/dL 287-455 pg/dL	15.4	2.6-5.7 pmol/L Not established 5.19-7.79 pmol/L 5.16-7.79 pmol/L 4.42-7.01 pmol/L	Nondialysis; two-step chemilumi-nescent microparticle immunoassay on refrigerated serum.
Reverse T$_3$ (RT$_3$)	Serum	Males Females	0.09-0.28 ng/mL 0.07-0.24 ng/mL	0.0154	0.14-0.431 nmol/L 0.108-0.370 nmol/L	LC/MS/MS Assay may be used to establish the cause of abnormal thyroid function tests as due to nonthyroidal illness.
Vanillylmandelic acid (VMA)	24-h urine	1-12 mo 1-2 y 2-5 y 5-10 y >10 y	<36 mg/g Cr <31 mg/g Cr <17 mg/g Cr <15 mg/g Cr <11 mg/g Cr	0.573	<20.63 mmol VMA/mol Cr <17.76 mmol VMA/mol Cr <9.74 mmol VMA/mol Cr <8.59 mmol VMA/mol Cr <6.30 mmol VMA/mol Cr	10 mL aliquot of urine, HPLC detec-tion; 24-h urine is collected with 25 mL of 6N HCl added. Patients should avoid alco-hol, coffee, tea, tobacco, nicotine, bananas, citrus fruit, and heavy exercise prior to the collection.
Vasoactive intestinal peptide	Plasma		22-42 pg/mL	0.30	6.6-12.6 pmol/L	Frozen EDTA plasma. Pre-chill tube and transport to lab on wet ice after collection. Extrac-tion, RIA.
Vitamin D (25-hydroxy)	Serum		20-50 ng/mL	2.50	50-125 nmol/L	Measures both D$_2$ and D$_3$. Freeze serum in plastic tube at −20°C. Chemiluminescent immunoassay.
Vitamin D (1,25 dihydroxy)	Serum	Adults Children 3-7 y	15-60 pg/mL 27-71 pg/mL	2.50	32.5-167 pmol/L 22.5-135 pmol/L	Liquid chromatogra-phy, tandem mass spectrometry. Freeze serum in plastic tube at −20°C.

[a]Adapted from the *Clinical Laboratories Manual* of the University of California Hospital and Clinics, San Francisco, California, September 7, 2015; and, with permission, from Mayo Clinic Rochester 2016 Interpretive Handbook (June 1 2016) normal values for endocrine tests. The factors used in converting conventional units to SI units were derived in part from the *CRC Handbook of Chemistry and Physics* and conversion tables from other online resources. It is important to emphasize that normal ranges vary among different labo-ratories, and the clinician must know the normal range for the test of interest in the laboratory performing the test.

[b]Semen analysis is discussed in Chapter 12.

BCE, bone collagen equivalent.
